Firstly, the charging process were computed in COMSOL with different inflow rate proportion. Considering the melting and solidification temperatures, the initial temperature in this model was set as 24 °C, which is the end temperature of discharging process. Different meshing methods with mesh elements of 2244, 4134, 6747 were compared and the difference in the calculation results can be ignored. The curves of accumulated thermal energy during charging process with inflow rate proportion of 0.2, 0.3 and 0.5 are exhibited in Figure 7. In this study, the inflow rate was selected as 30% of radiator return water and the complete melting time was 4.4 hours.

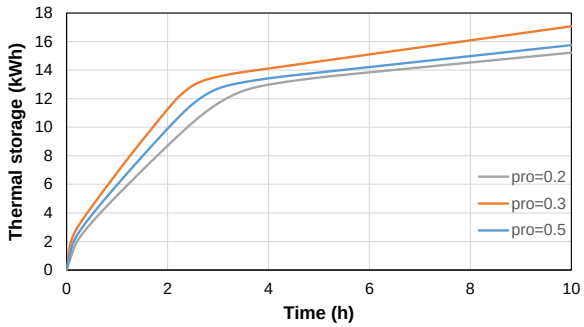

Figure 7. Accumulated thermal storage with different inflow rate.

The mass flow rate of discharging process was set as the same with charging process. The discharging process is related to the outside heat exchanger, which is explained in Section 2.4. With the cooling effect of the heat exchanger, the inlet temperature is variable during the charging process.

2.4. Heat exchanger

The shell-and-tube heat exchanger with one-pass shell was designed, totally 14 tubes with diameter of 0.04 m and height of 1 m. Water flows in the tubes, and air flows counter-currently between the shell and tubes. The material and thickness of shell and tubes are Aluminum and 3 mm, respectively. The heat transfer coefficient (U_{hex}) of the shell-and-tube heat exchanger was set as 500 W/(m^2·K) [52].

The heat capacity of heat exchanger is calculated with Eq. (14). According to ε-NTU method (effectiveness-number of transfer units) [53], the maximum heat transfer rate between water and air is given in Eq. (15), where $C_{\min}$ is the minimum of C_{disch} and C_{air}. The value of C_{air} was determined by comparison of commercial pumps. The thermal capacity ratio (Cr) and NTU is calculated with Eq. (16) and Eq. (17). For counter-current flow, the effectiveness is obtained with Eq. (18).

$$q_{hex} = C_{disch}(T_{disch,out} - T_{disch,in}) = C_{air}(T_{air,out} - T_{amb}) \quad (14)$$

$$q_{\max} = C_{\min}(T_{disch,out} - T_{amb}) \quad (15)$$

$$Cr = C_{\min} / C_{\max} \quad (16)$$

$$NTU = U_{hex} A / C_{\min} \quad (17)$$

$$\varepsilon = q_{actual} / q_{\max} = \left\lfloor 1 - e^{-NTU(1-Cr)} \right\rfloor / \left\lfloor 1 - Cr \cdot e^{-NTU(1-Cr)} \right\rfloor \quad (18)$$

Through the Eq. (14)-Eq. (18), $T_{disch,in}$ and $T_{air,out}$ can be obtained by overall analysis of the heat exchanger. It is assumed that the inlet temperature of LHTES is cooled down under the influence of average actual heat transfer rate.

2.5. Performance evaluation

The rated heat capacity of heat pump was designed to cover 60% of the required heat demand at DOT, which covers around 90% of the annual heating demand [41]. The COP of heat pump is the ratio of heat pump capacity to the compressor power input, as shown in Eq. (19). In this study, COP was assessed with the ambient temperature based on commercial heat pump data.

$$COP = q_{hp} / P_{comp} \quad (19)$$

The electrical appliances in this system includes a compressor, two pumps, a fan and a supplementary electrical heater. The extra power of electrical appliances is shown in Eq. (20).

$$\Delta P_{tot} = \Delta P_{comp} + \Delta P_{pump} + \Delta P_{fan} + \Delta P_{elect} \quad (20)$$

The levelized cost of energy is calculated with Eq. (18) [54].

$$LCOE = \left\{ \sum_{t=1}^{N} \left[(CAPEX_t + OPEX_t) / (1+i)^t \right] \right\} / \left\{ \sum_{t=1}^{N} \left[E_t / (1+i)^t \right] \right\} \quad (21)$$

The compressor, fan and pump 6 in Figure 4 are assumed to be the same in the typical system and in the integrated system due to their abilities to be adjusted within a certain operating range. The extra capital cost (CAPEX) in integrated system is LHTES component (PCM and tank), heat exchanger and pump 10, as exhibited in Table 5.

Table 5. Extra capital costs of integrated system.

Components	PCM	Tank of LHTES	Heat exchanger	Pump 10	Total
Price (€)	509	467	187	334	1498

3. Results and discussions

3.1. Techno-analysis

The total heat pump capacity of integrated LHTES and HP system and typical system is displayed in Figure 8 for November 2022. The heat pump capacity is fluctuating in the integrated system. The capacity above the typical system curve is due to the charging of the LHTES component during off-peak periods. More energy is required from heat pump side. The capacity below the typical system curve is the process by which LHTES releases heat to preheat inlet air as heat source of the heat pump. The warmer air into the evaporator with higher temperature contributes to COP increase, which leads to the decrease of heat pump electric power demand, reducing thus the electricity cost and allowing peak/load shifts alleviating thus the electricity grid supply.

During the on-peak periods in the integrated system, the warmer air temperature rises to 5.9 °C~8.9 °C, leading to the increase in COP between 3.74 and 3.91 compared to 3.56 for the typical system. The amount of the shifted electricity from on-peak to off-peak periods is 25.6 kWh.

3.2. Economic-analysis

The heating costs including electricity trading price, tax, transmission fee and value-added tax [20] are presented in Figure 9. As it can be seen in Figure 9 (b), the hourly heating costs of integrated system are lower than the typical system during on-peak periods, while the heating costs increase during the off-peak periods with higher heat pump electricity input for charging. The peak/load shifting scheme can potentially compensate for the increased heating costs. From the view of whole November, the monthly accumulated heating costs in the integrated system are 0.8% higher than in the typical system.

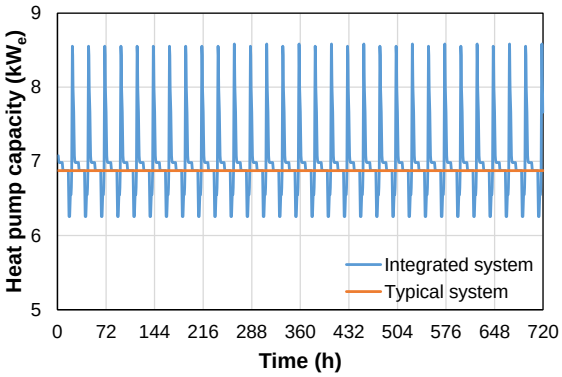

Figure 8. Total heat pump capacity.

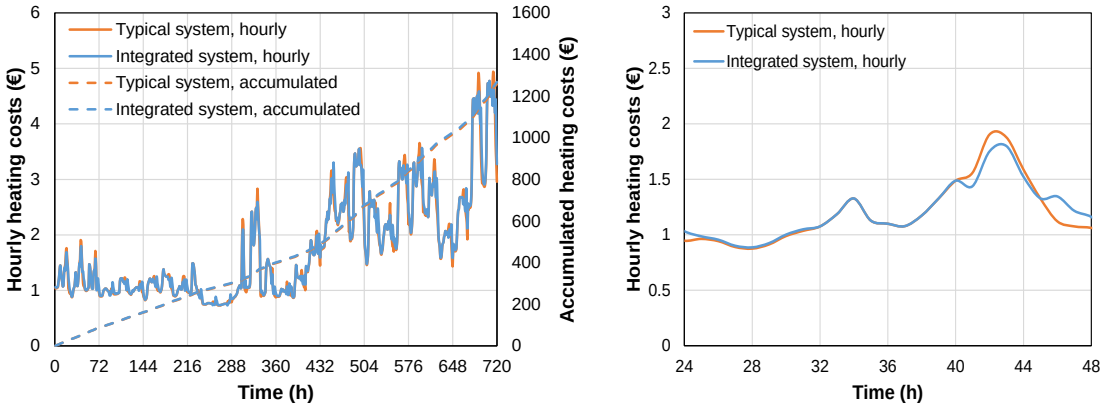

(a) *(b)*

Figure 9. Heating costs: (a) in November 2022; (b) on Nov 2, 2022.

In case the relationship between average electricity trading prices during on-peak and off-peak periods is $\overline{RP}_{onpeak} > 2.35 * \overline{PR}_{offpeak} + 85$ €/MWh in November 2022, the reduced heating cost will overweight the increased cost in integrated system and will breakeven the investment. In addition, the alleviated peak/load shifting allows the reduction of the power plants and electricity grid expansion costs.

Assuming the life periods of the integrated system is 15 years and the discount rate at 10%, with heating months from September to April in Stockholm, the LCOE leads to 0.072 €/kWh.

4. Conclusions

This paper proposed a novel layout of LHTES component integrated to the return line of radiator in a heat pump heating system. The heating demand of a typical multi-family building was calculated. A packed bed cylindrical LHTES component was simulated in an axisymmetric 2D model with spherical encapsulated PCM. The LHTES component was connected to a shell-and-tube heat exchanger as a heat source for the evaporator. The results show that the LHTES needs higher thermal power input in charging, while the heat pump capacity is intrinsically lower during on-peak periods. This study needs further studies including the other months of the year with detailed LHTES and heat exchanger design. The LCOE can be further reduced from optimal tank sizing, heat storage materials selection and enhanced heat exchanger design.

Appendix A

Nomenclature

A	area, m^2
c	specific heat capacity, J/(kg·K)

C	heat capacity rate, J/(K·s)
Cr	heat capacity ratio
$CAPEX$	capital expense, SEK
$OPEX$	operating expense, SEK
COP	coefficient of performance
E	annual generated energy
d	diameter of PCM encapsulation, m
DOT	designed outdoor temperature, K
h	heat convective coefficient, W/(m^2·K)
H / D	height to diameter ratio
k	thermal conductivity, W/(m·K)
$LMTD$	logarithmic mean temperature difference, K
$\dot{m}$	volume flow rate, kg/s
n	radiator exponent
N	year N
Nu	Nusselt number
P	power, W
$\overline{PR}_{onpeak}$	average electricity trading price during on-peak periods, €/MWh
$\overline{PR}_{offpeak}$	average electricity trading price during off-peak periods, €/MWh
pro	proportion of water from radiator return water into LHTES
q	thermal power, W
Q	thermal heat, J
r	discount rate
t	time/year
T	temperature, K
$\mathbf{u}$	velocity field
U	overall heat transfer coefficient, W/(m^2·K)
UA_{bd}	UA-value of building, W/K
UA_{rad}	UA-value of radiator, W/K^n
$\dot{V}$	volume flow rate, m^3/s
Δ	Difference between typical heat pump heating system and novel integrated system

Greek symbols

ε	porosity of packed bed
ε	effectiveness
κ	permeability of packed bed, m^2
μ	viscosity, Pa·s
ρ	density, kg/m^3

Subscripts and superscripts

$actual$	actual value
air	air
amb	ambient
bd	multi-family building
ch	charging process
$comp$	compressor
$elect$	supplementary electrical heater
$disch$	discharging process

fan	fan
hex	heat exchanger
hs	heating system
in	inlet
ind	indoor
$loss$	heat loss
$\min$	minmum
out	outlet
p	pressure
pe	encapsulation of phase change material
$pump$	pump
rad	radiator
re	radiator return side
s	solid matrix (phase change material)
$shell$	shell of the LHTES component
f	fluid (water)
su	radiator supply side
w	water

Abbreviations

HP	heat pump
HTF	heat transfer fluid
LHTES	latent heat thermal energy storage
LCOE	levelized cost of energy
NTU	number of transfer units
PCM	phase change material

Abstract:

This work proposes a thermochemical storage system for Iron, aluminium, and nickel oxidation/reduction reactions. The chemical looping process based on the analysed reaction pairs will involve high energy efficiencies, given their high energy density (40-80 MJ/l) and the contribution of reducing agents such as hydrogen and carbon monoxide. The mix of these reductor agents is considered according to the Baur-Glassner diagram. In the charging process, it will make use of renewable energy sources (CSP+PV) to carry out the decomposition process (570°C or lower, depending on the number of stages in the reduction in the iron case). In the discharge phase (800°C depending on the metal and the particle radius), the reduced metal passes through a combustion chamber where it is oxidised, generating thermal energy useful for other processes, and obtaining metal oxides that will serve to close the proposed cycle. The temperatures required in the charge/discharge processes by the different metals have been studied, including an analysis of the energy integration of the different equipment and heat for processes. The simulations were carried out in the commercial software EES to evaluate the more suitable metals to obtain the reductant. a Round Trip Efficiency study has been carried out to evaluate the different TCES configurations.

Keywords:

Thermochemical storage, Chemical looping, Hydrogen, Energy integration, Round Trip Efficiency.

1. Introduction

Reducing dependence on carbon sources meeting the growing energy demand of society [1], is together with climate change one of the main challenges facing the world today [2]. One of the current lines of greatest development is energy storage. Have systems that take advantage of the surplus energy production offered by other facilities to be used later.Developing low-carbon energy carriers has become crucial for reducing dependence on fossil fuels in energy production and distribution. This, together with other fundamental aspects of decarbonization and the use of renewables, leads to the search for cost-efficient energy storage systems. Energy storage is crucial for a market with a high presence of renewable generation. To increase the availability of renewable generation and increase the inertia of the grid. One of the main advantages of energy storage is the possibility of designing renewable facilities of greater capacity, improving their inertia in the electricity grid [3]. Parameters for the competitiveness of renewable energies.

Different types of energy can be stored depending on the systems to which they are linked [4] and the form in which the energy is stored/released: chemical, electrical, magnetic, electrochemical, mechanical, and thermal storage systems [5]. The use of these systems supports installations to produce electricity.Metal oxides can be integrated as energy storage systems [6]. These materials have been studied from the electrical point of view, to be used directly in batteries. Recently, they have been studied as regenerative fuel sources [7], in reactors with metals as a fuel source, taking advantage of the thermal energy generated in the oxidation process [8]. It arises because of the high energy density of these materials, which require a lower fuel volume, availability, and regenerative capacity. The iron powder has been tested in the MP100 reactor developed by the University of Eindhoven [9]. There are possibilities for considering the use of a series of metals for this application. Based on the development of these reactors, it is feasible to create a thermochemical storage system based on metals, obtaining thermal energy from their oxidation. Regeneration of the reduced metal from different metal oxides can be obtained in elements such as nickel [10] or iron [9] from reducing agents such as Hydrogen or Carbon Monoxide [11]. Having identified the possibility of integration of these systems,

this work analyses different configurations of thermochemical storage systems, analysing their potential as energy storage systems [11] and their potential to advance in this line.

2. State of the art

2.1. Energy storage based on metals

Metals have high energy densities when compared to other types of fuels. The graph below shows the gravimetric energy density [MJ/kg] versus the volumetric energy density [MJ/L] of a wide range of fuels used today.

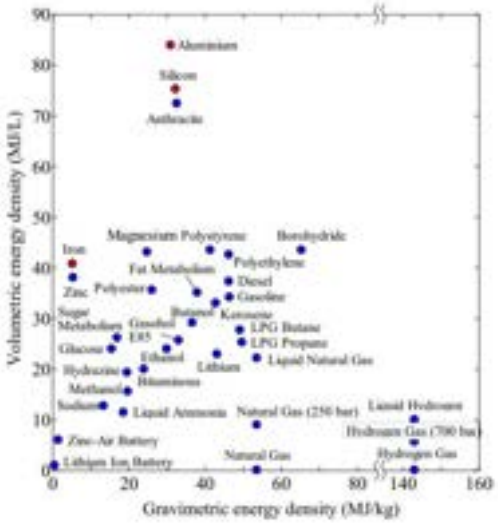

Figure. 1. Gravimetric energy density versus volumetric energy density of different fuels.[8]

Figure 1 shows a number of metals with high volumetric energy densities, like Iron, providing the opportunity of reducing the required volume for an energy design and smaller equipment if used in oxidation/combustion processes. Figure 1 shows the main metals studied. This study also will address the use of Nickel, that is not included in Figure 1 [8]. Their use in an energy storage system considers a closed chemical looping system, operating sequentially on loading and discharging stages, where the metal is oxidised and regenerated. The metals subjected to the oxidation/combustion process will form the discharge system. The metal oxides formed in the process will be stored in the loading system, from which the initial fuel will be regenerated from a reduction process [13]. Figure 2 shows a general operating scheme that has been proposed that will be used for assessing the use of different metals:

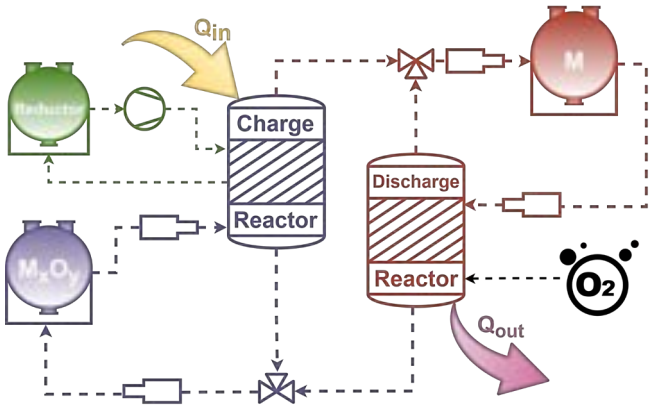

Figure. 2. General diagram of the storage system.

The cycle is divided into two main blocks/reactors:

- Charging system: Consists of two subsystems. The storage and management of metal oxide and the management of the reducer to reconvert the product of the discharge into fuel.
- Discharging system: Management of the storage and oxidation of the original fuel in the discharge reactor.

For the operation of the loading system, two possible reducers will be considered: carbon monoxide as a reductant as a product of synthesis gasification and hydrogen. This hydrogen can be produced within the gasification or by electrolysis powered by photovoltaic or wind energy. The selected metals to analyse the concept were Fe, Al, and Ni.

2.3. State diagrams

2.3. 1 Charging process

Departing with the charging process, integrating a metal oxide and a reducer generates a reduced metal. The reaction requires appropriate temperature and reaction conditions. In this work, Fe and Ni have been considered. To identify their behaviour and evolution under different conditions, their state diagrams graphs were modelled in the FactSage program for the following combinations of metals and reducers:

Table 1. Generated status diagrams.

Chart No.	Process	Elements evaluated
1	Reduction	$Fe – H_2 – H_2O$ $Fe – CO – CO_2$
2	Reduction	$Al – H_2 – H_2O$ $Al – CO – CO_2$
3	Reduction	$Ni – H_2 – H_2O$ $Ni – CO – CO_2$
4	Oxidation	$Fe – O_2$
5	Oxidation	$Al – O_2$
6	Oxidation	$Ni – O_2$

The elements were included using the FactPs and FToxid databases [12] These state diagrams provide guidelines about phase equilibria temperatures depending on the amount of oxidiser or reductant in the reactors. In this environment, metals, their oxides, oxygen, reducers, and their products are considered. These graphs provide the temperatures for reducing metal oxides as a function of the minimum metal fraction and the operating atmospheres of CO / CO_2 and H_2 / H_2O [13]. Different reduction processes of iron oxide are considered for the generation of DRI (Direct Reduced Iron) [14]. The Bauer-Glaessner diagram can be used to [10] compare the reducer's concentrations and process temperatures using Carbon Monoxide and Hydrogen [11]. The curves for the case of Aluminum and Nickel used in this study obtained using FactSage, are presented in Figure 3.

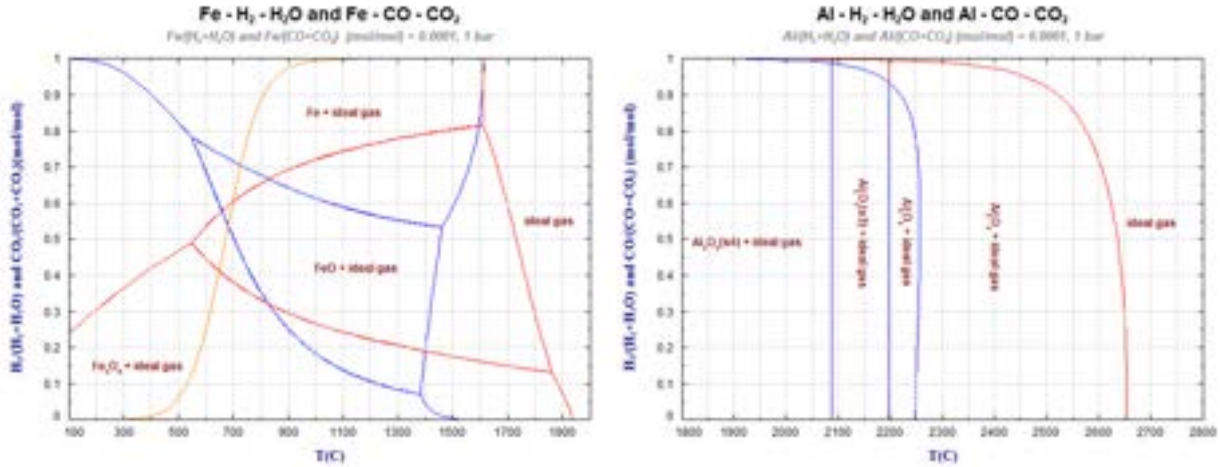

Figure. 3. Comparison of temperatures in the reduction of oxides of Iron and Aluminum.

2.2.3 Discharging process

The oxidation process is studied for the selected metals. The Figure 4 represents the equilibrium curves and metal concentration in all cases.

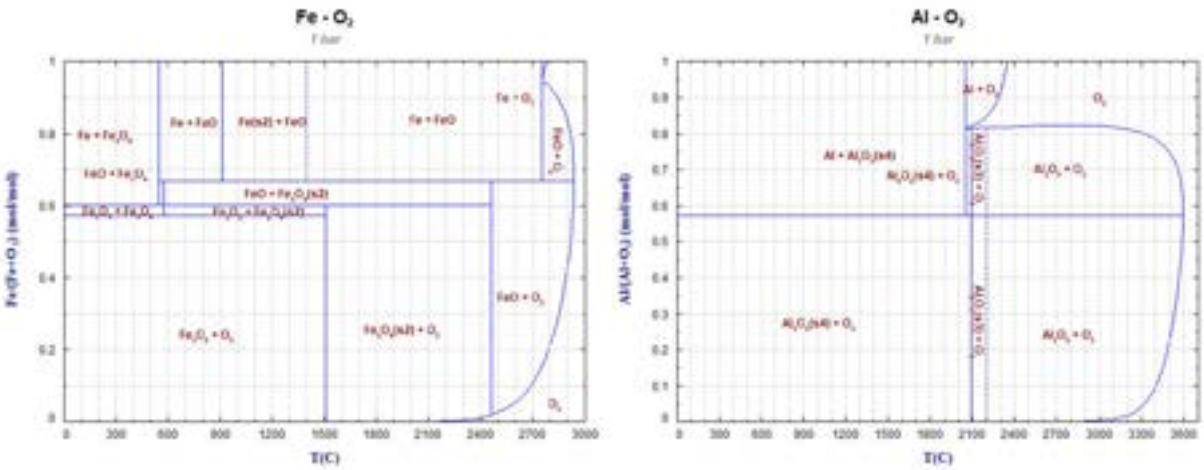

Figure. 4. Comparison of temperatures in the oxidation of Iron, Aluminum and Nickel.

The analysis of gigures 3 and 4 shows seen how in the case of Iron and Aluminum, different metal oxides can be obtained depending on the reaction temperature and the proportion of metal and oxidiser. On the other hand, it is also observed that in the reduction processes, depending on the metal chosen, a different amount of reducer is required if Hydrogen or Monoxide is chosen as a reducing agent.

2.3.4 Reducer mixtures

As can be seen in the case of Iron, reducer concentrations mark different equilibrium curves. For mixtures of CO and H_2, as in the case of syngases, the resulting equilibrium curve will be between the two represented in the diagram, in a phase diagram with intermediate states that depend on the concentration of the reducer mixture, Figure 5.

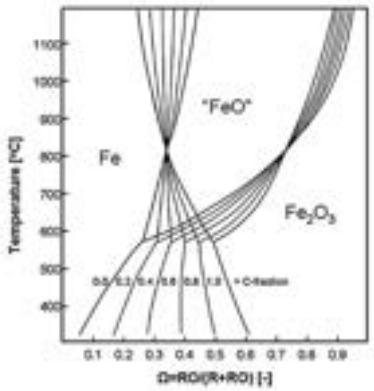

Figure. 5. Baur-Glaessner diagram for CO-H2 mixtures as reducing agent.[14]

It is observed how the equilibrium curves are distributed between the two extreme cases depending on the concentration of reducers in the mixture and the amount of monoxide present. Therefore, regarding the proposed charging system, cases have been studied in which only Hydrogen or Carbon Monoxide is available as a reducer agent. The reducer management schemes in both cases could be as presented in Figure 6:

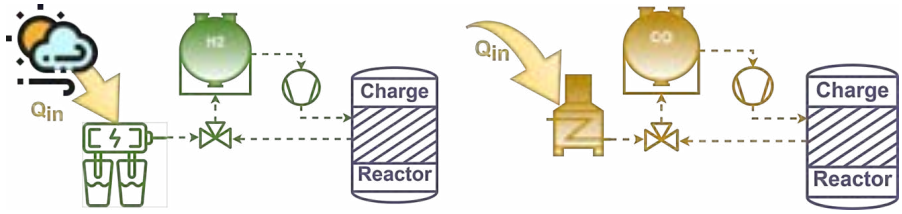

Figure. 6. Possible operating schemes for the reducing agent.

2.3.2 Activation energies

A relevant aspect is the activation energy of the reactions. It will penalise the available energy, both in the case of the charge and the discharge. The energy needed to activate the process will depend, among other factors, on the kinetics of each reaction. The dependencies of variables depend on each reaction. Accurate information can be obtained by measuring the concentrations through thermogravimetric analyses. Based on the experimental results of the specific results, methods such as Kissinger's are used [15] to determine the kinetic characteristics of the reaction. The activation energies of the following reactions are identified in the literature:

Table 2. Activation energies.

Reaction	Mechanism	Minimum [kJ/mol]	Maximum [kJ/mol]
$NiO(s) + H_2(g) \rightleftarrows Ni\,(s) + H_2O\,(g)$	Reduction	85 [16]	126 [16]
$Ni(s) + \frac{1}{2}\,O_2(g) \rightleftarrows NiO$	Oxidation	172,38 [17]	209,2 [17]
$3Fe(s) + 2O_2(g) \rightleftarrows Fe_3O_4(s)$ below 570°C	Oxidation	130 [18]	170 [18]
$3Fe_2O_3(s) + 4H_2(g) \rightleftarrows 2Fe_3O_4(s) + 4H_2O_{(g)}$	Reduction	89,1 [19]	282 [20]
$Fe_3O_4(s) + 4H_2(g) \rightleftarrows 3Fe(s) + 4H_2O_{(g)}$	Reduction	54,0 [19]	167 [21]
$2Fe(s) + \frac{3}{2}O_2(g) \rightleftarrows Fe_2O_3(s)$	Oxidation	110 [22]	
$Fe_3O_4(s) + H_2(g) \rightleftarrows 3FeO(s) + H_2O_{(g)}$	Reduction	47 [23]	
$FeO\,(s) + H_2(g) \rightleftarrows Fe\,(s) + H_2O_{(g)}$	Reduction	30 [23]	

To determine the power of the use of the metals selected for the described application, a theoretical Round-Trip Efficiency (RTE) [24] is defined [25]. It determines the energy recovery potential of the system at different operating temperatures, equation 1.

$$\eta_{RTE} = \frac{Q_{Av}}{Q_N} = \frac{\left|Q_{disc} + E_A^{Disch}\right|}{\left|Q_{ch} + E_A^{ch}\right|} \tag{1}$$

Where Q_{Av} refers to the energy per mole of fuel available in the discharge process. This is determined from the discharge energy per mole of fuel obtained, Q_{disc} minus the activation energy term needed to start the process E_A^{Disch}. The same reasoning is applied to the charging process, Q_N where Q_{ch} is the energy per mole of fuel necessary for the reduction of the metal oxides studied and refers to the term of activation energy necessary to start the charging process E_A^{ch}, Figure 7.

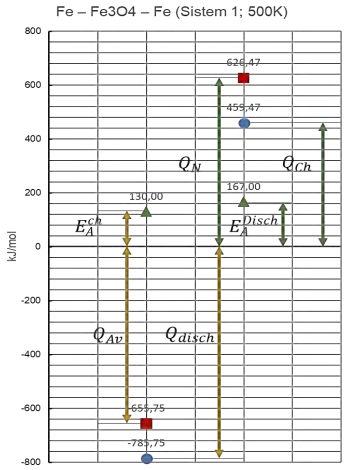

Figure. 7. Theoretical Round Trip Efficiency of Iron.

3. Results and discussion

3.1. Description of the system

Considering the layout in Figure 2, two sources have been taken to obtain the reducer. First, there is the possibility of using hydrogen from electrolysis. This process will be powered by a photovoltaic solar installation. On the other hand, the production of carbon monoxide through gasification from synthesis is proposed.

3.2. Calculation of properties

For the analysis of the different configurations, metals and potential metal oxides, a series of models have been implemented in OpenModelica [26], [27]. An OpenModelica library for the calculation of thermodynamic properties has been implemented based on Glenn coefficients[28], equations 2 to 4.

$$\frac{c_p^{\circ}(T)}{R} = a_1T^{-2} + a_2T^{-1} + a_3 + a_4T + a_5T^2 + a_6T^3 + a_7T^4 \tag{2}$$

$$\frac{h°(T)}{RT} = -a_1T^{-2} + a_2\frac{lnT}{T} + a_3 + a_4\frac{T}{2} + a_5\frac{T^2}{3} + a_6\frac{T^3}{4} + a_7\frac{T^4}{5} + b_1T^{-1} \tag{3}$$

$$\frac{s°(T)}{R} = -a_1\frac{T^{-2}}{2} - a_2T^{-1} + a_3 lnT + a_4T + a_5\frac{T^2}{2} + a_6\frac{T^3}{3} + a_7\frac{T^4}{2} + b_2 \quad (4)$$

Using the coefficients by intervals for each element/substance, the demands and energy released in the loading and unloading processes can be calculated [29]. The "Equilibrium" module included in FactSage has been used, as well as the [30] Chemical Equilibrium Applications (CEA), for the verification of the calculation of the properties[31], [28]. A second library was generated aimed at performing energy analysis of the charge/discharge processes where the enthalpies of the reaction and Gibbs free energy of all processes were calculated.

$$h_{reac} = \sum n_P \cdot \Delta h(T)_{,P} - \sum n_R \cdot \Delta h(T)_{,R} \quad (5)$$

$$g = \Delta h - T\Delta s \quad (6)$$

The reaction enthalpies were calculated based on the moles of metal in the reactors. In this way, the molar mass, the energy demand of the charging process, and the amount of energy of the discharge process produced per kilogram of metal can be calculated.

3.3. Discharging process

The processes modelled for the discharge of the thermochemical system are presented in Table 3

Table 3.- Discharge reactions considered.

$$2Fe(s) + O_2(g) \rightleftarrows 2FeO(s) \quad (6)$$

$$2Fe(s) + \frac{3}{2}O_2(g) \rightleftarrows Fe_2O_3(s) \quad (7)$$

$$3Fe(s) + 2O_2(g) \rightleftarrows Fe_3O_4(s) \quad (8)$$

$$2Al(s) + \frac{3}{2}O_2(g) \rightleftarrows Al_2O_3(s) \quad (9)$$

$$Ni(s) + \frac{1}{2}O_2(g) \rightleftarrows NiO \quad (10)$$

The models performed simultaneous calculations within a temperature range from 300K to 3600K. This range was selected based on the analysis of phase diagrams.

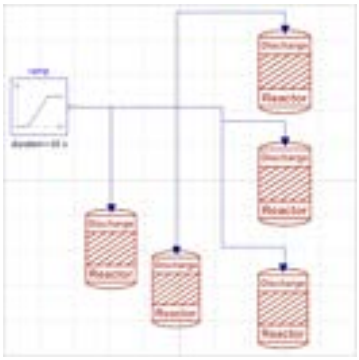

Figure 8.- OpenModelica graphical representation of reactor models.

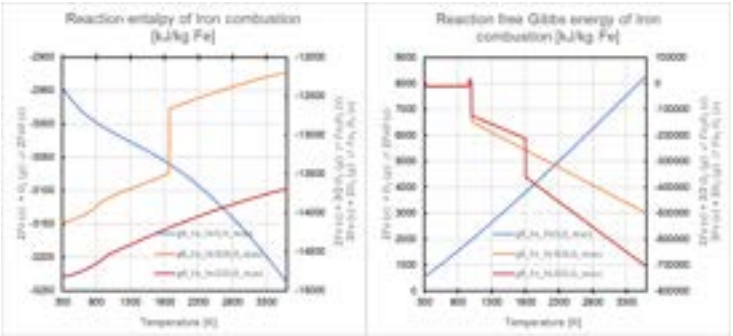
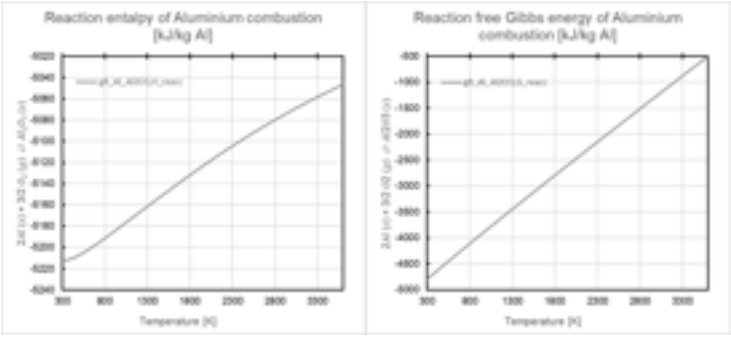
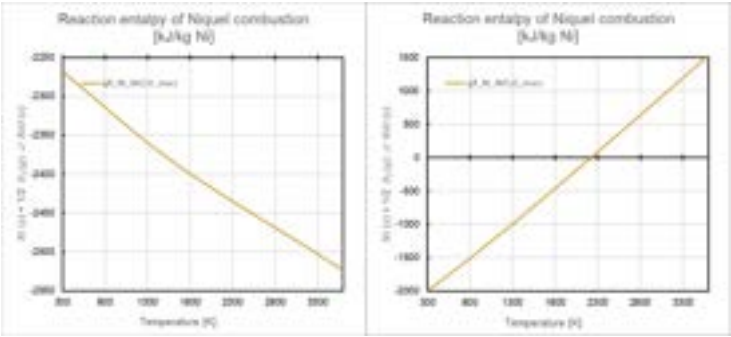
Graph 4, 5 and 6 shows the enthalpy and Gibbs free energy curves for the different reactions resulting from the simulations.



Graph1.- Enthalpy of reaction and Gibbs free energy for possible oxidation reactions of Iron.



Graph2.- Enthalpy of reaction and Gibbs free energy for the oxidation of Aluminum.



Graph3.- Enthalpy of reaction and Gibbs free energy for the oxidation of Nickel.

The variation of the power obtained per kilogram of fuel is observed in temperatures ranging from 300K to 3600K. They show the high energy potential of these metals as fuels in oxidising processes. On the other hand, within the oxidation reactions studied for the case of Iron, it is known according to literature that the majority product generated in the oxidation process can be Hematite or Magnetite depending on the conditions.

3.4. Charging processes

In the charging process the reactions evaluated are presented in Table 4:

Table 4.- Charge reactions considered.

$$3Fe_2O_3(s) + 4H_2(g) \rightleftarrows 2Fe_3O_4(s) + 4H_2O_{(g)}$$
$$Fe_3O_4(s) + H_2(g) \rightleftarrows 3FeO(s) + H_2O_{(g)} \quad (11)$$
$$FeO\ (s) + H_2(g) \rightleftarrows Fe\ (s) + H_2O_{(g)}$$

$$3Fe_2O_3(s) + CO(g) \rightleftarrows 2Fe_3O_4(s) + CO_2(g)$$
$$Fe_3O_4(s) + CO\ (g) \rightleftarrows 3FeO\ (s) + CO_2(g) \quad (12)$$
$$FeO\ (s) + CO\ (g) \rightleftarrows Fe\ (s) + CO_2(g)$$

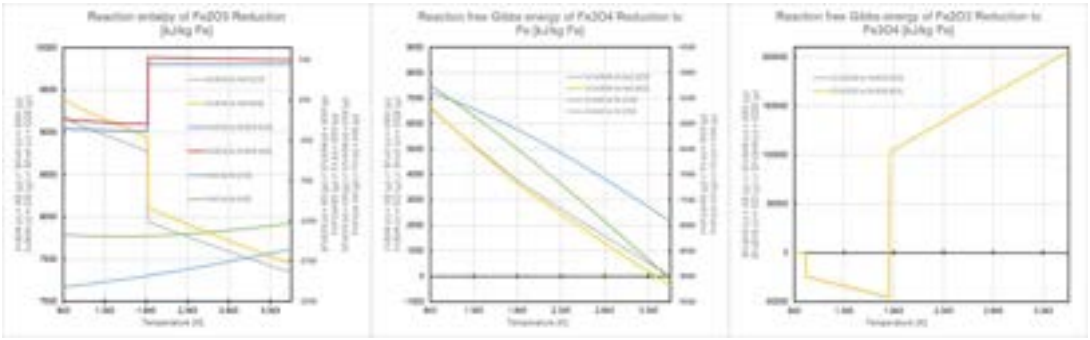
$$Fe_3O_4(s) + 4H_2(g) \rightleftarrows 3Fe\ (s) + 4H_2O(g) \quad (13)$$
$$Fe_3O_4(s) + 4CO(g) \rightleftarrows 3Fe(s) + 4CO_2(g) \quad (14)$$
$$NiO(s) + H_2(g) \rightleftarrows Ni\ (s) + H_2O\ (g) \quad (15)$$
$$NiO(s) + CO(g) \rightleftarrows Ni\ (s) + CO_2\ (g) \quad (16)$$
$$Al_2O_3(s) + 3H_2(g) \rightleftarrows 2Al\ (s) + 3H_2O\ (g) \quad (17)$$
$$Al_2O_3(s) + 3CO(g) \rightleftarrows 2Al\ (s) + 3CO_2\ (g) \quad (18)$$

Two different paths have been identified for the reduction of Magnetite (Fe_3O_4),since if it is reduced to a temperature lower than 843K, the reduction occurs directly without passing through the state of Wüstite (FeO), as observed in Figure 3, It should also be noted within the initial scope of this study, Hydrogen, and Carbon Monoxide have been chosen as reductants, but the use of combinations of metals in the reduction process that requires a lower amount of energy in the process can be studied.

3.4.1. Reduction of F2O3 to Fe at temperatures above 843K

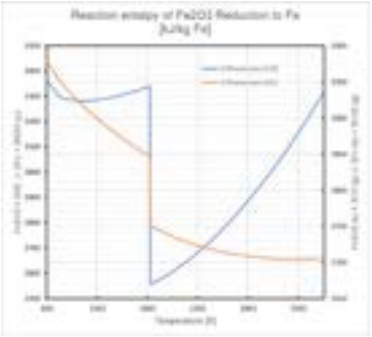
For temperatures above 570K the reduction of Hematite is done in three steps. First, it is reduced to Magnetite (Fe3O4). Subsequently, increasing the concentration of the reducer is passed from Magnetite to Wüstite (FeO). Finally, it is reduced to Iron. This 3-phase process has some interesting characteristics when compared

to the loading processes of systems with Nickel or Aluminum since, depending on the operating conditions, up to two exothermic phases can be achieved, corresponding to the reduction of Hematite and Wüstite.



Graph4.- Enthalpy and Gibbs free energy for the reduction of Hematite to Iron at temperatures greater than 843K.

It is observed that, in the first step of the process, the reduction of Hematite to Magnetite is spontaneous between 843K and 1800K. From that temperature, the equilibrium between phases is not given[12]. On the other hand, in the overall balance of the reduction, having the same temperature for all phases, the following process demand is obtained depending on the operating temperature:



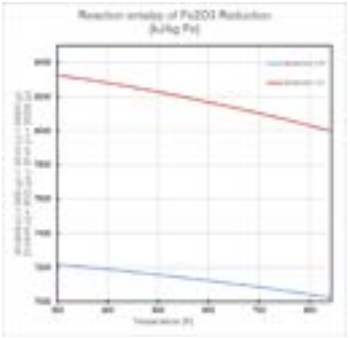
Graph5.- Total loading process in the reduction of Hematite at temperatures above 843K.

It is observed how this configuration offers a variety of configurations where lower demands can be obtained than those shown if adequate temperatures of reduction of Hematite and Wüstite are chosen. In the same way, this demand can be reduced according to the reducer chosen in each phase.

3.4.2. Reduction of F2O3 to Fe at temperatures below 843K

In this case, the reduction occurs directly from the Magnetite phase to Iron. Therefore, the charging system would have two phases. An initial phase in which the Hematite is reduced obtaining Magnetite, and a final phase in which the Magnetite is reduced directly to Iron. This system, as in the previous one, can be operated at different temperatures depending on the phase being studied, so the system can operate as follows:

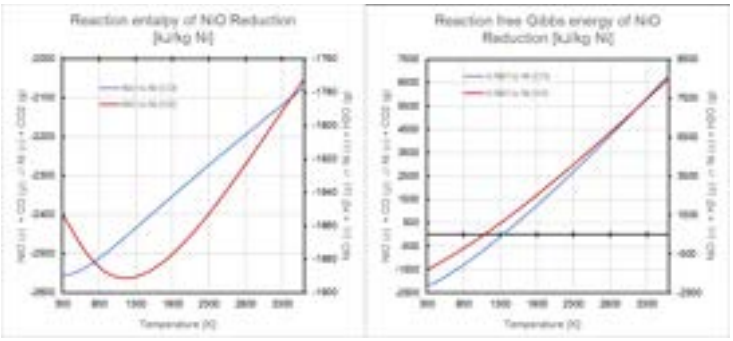
- The first phase can occur at any temperature, provided that the product obtained is Magnetite.
- Once Magnetite is obtained as a product, it is passed to a temperature within the study range. Process heat will be obtained from the temperature reduction.
- When the temperature of the Magnetite is lower than the 843K that has been marked as a limit, the reduction to Iron is made.



Graph 9.-6 Total loading process in the reduction of Hematite at temperatures below 843K.

3.4.2. Reduction from NiO to Ni

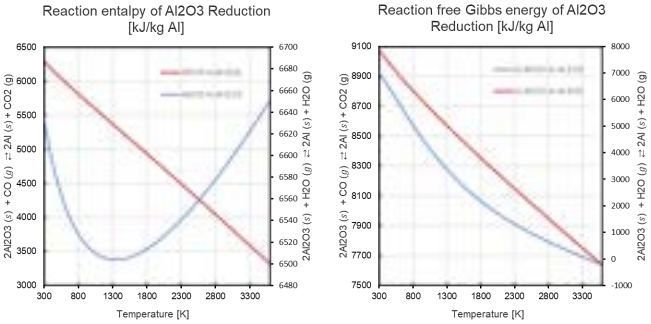
For this system of cages, the demand for the reduction process per kilogram of Nickel has been studied. In this case, as in the previous ones, the reduction has been compared using Hydrogen and Carbon Monoxide as reducers.



Graph7.- Enthalpy and Gibbs free energy in the reduction of NiO to Ni.

3.4.2. Reduction of Al2O3 to Al

In the charging system corresponding to obtaining reduced Aluminum, the same approach has been followed as in the case of nickel, making a temperature analysis with the two reducers chosen. Taking this into account, the demand for the reduction of 1kg of Aluminum would be as follows:



Graph8.- Enthalpy and Gibbs free energy in the reduction of Al2O3 to Al.

3.4. Energy Storage Layouts

The energy storage layouts and processes are presented following the layout presented in ***Figure 2,*** *with* different configurations depending on the metal used, and in the case of Iron, depending on the temperature of reduction of Magnetite Three different systems are proposed:

- System 1: In the case of working with Nickel or Aluminum.
- System 2: In the case of working with Iron and carrying out the reduction of Magnetite to a temperature below 873K. It will have two charge stages.
- System 3: For the case in which you work with Iron, the magnetite reduction process is carried out in 2 stages, forming Wüstite in phase 2.

The general operating schemes of the different configurations presented would be as follows:

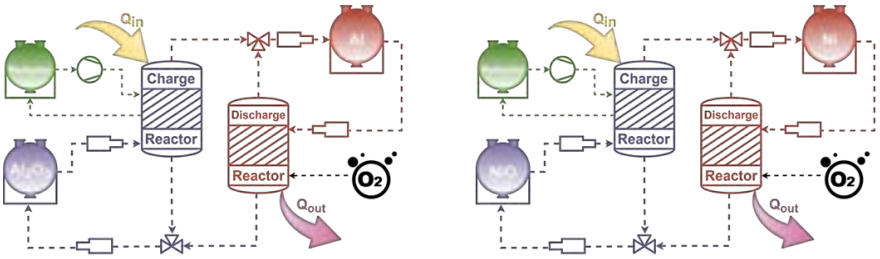


Figure 9.- Operating scheme type 1 charge / 1 discharge.

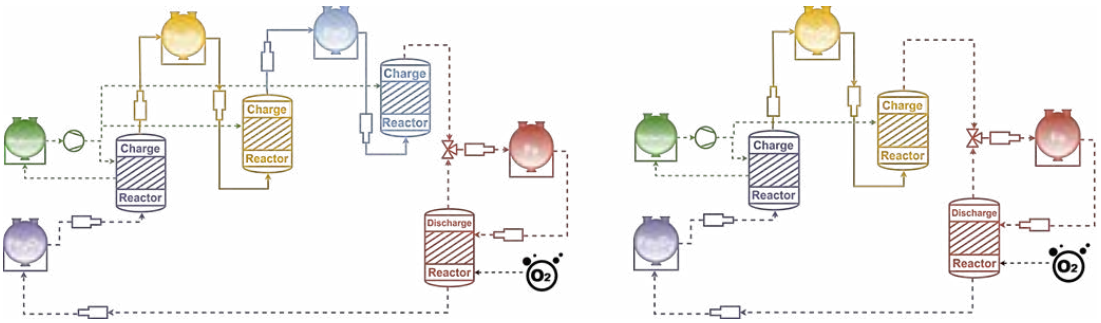

Figure 10.- Operating scheme type 1 charge / 2 discharges, and operating scheme (2 charges/ 1 discharge).

For the operating schemes in the case of Iron, the tanks defined as charge, in the case of the reduction of hematite will demand or offer energy to the system depending on the operating conditions that define the process.

3.5. Performance

This section makes ana preliminary study of the performance of the systems based on their Round-Trip Efficiencies. The same temperature has been considered for the charging and discharge processes, although any other could have been selected. The viability of the process and the RTE have a strong dependence on the reaction's evolution.

Table 5.-5 Results of RTE at different temperatures.

Temperature [K]	Metal	System	RTE	Notes
500	Fe	2	78,83%	Oxidation to Fe2O3, reduction by H2
800	Fe	3	78,92%	Oxidation to Fe2O3, reduction by H2
1100	Fe	3	87,89%	Oxidation to Fe2O3, reduction by H2

The description of the type of system in the table can be found in section 3.4.

Once the graphs relating to the selected metals have been presented, and an RTE has been proposed for iron-based systems (due to having a wider and more reliable amount of information in these reactions), it can be observed how for ranges between 500K and 1800K, the oxidation processes of the three metals studied have an energy potential that can range since 2.4 MJ/kg in the case of Nickel to 5 MJ/Kg in the case of Aluminum. These results have been obtained under the assumption of complete conversion. As presented in [7], it is also verified that the work of the discharge system in the range of the proposed temperatures is possible. On the charging process side, the amount of energy required and the possibility of performing the reduction depending on the mechanism employed. It is verified that there are cases in which the most favorable reducing agent (energetically) is carbon monoxide, where differences of up to 1MJ / Kg of reduced metal can be found compared to using hydrogen as a reducing agent. On the other hand, taking into account the state diagrams presented in Figure 3, it is observed that the reduction process is more favorable energetically at certain temperatures, being usually more favorable when increasing the temperature of the process. The energy required in the reduction processes as a function of temperature is different for the three metals due to the stability of the phases. In terms of activation energies necessary for the processes, several sources in the literature have been evaluated, and those for which more information was available under the conditions that have been studied have been chosen for the initial estimation of the RTE. It is observed how the importance of determining the conditions in which the charging process will take place is vital to minimize the activation energies. It was considered that taking into account the conditions under which the activation energies were determined, those used for the determination of the RTE would be the ones of greater value, even considering that, for the reactions studied, these values may be higher. Finally, it is observed that the values of RTE vary between 78% and 88%.

4. Conclusions

This work presents a preliminary analysis of metal-based energy storage systems. The energy potential of these types of reactions raises the modality of the proposed thermochemical storage system. The analysis in a wide range of temperatures shows how there are conditions for charge and discharge reactions, which make using metals as a thermochemical storage base possible. The systems were modelled in an OpenModelica library. It has been assembled where the entire modelling process has been carried out, from the properties of the materials to the study of the reactions. This library is designed to be able to make comparisons with laboratory tests and will serve as support for the study of this storage system.

The analyses show the feasibility and potential of the proposed energy storage layouts. Taking into account the range of working temperatures, it opens the possibility of integrating these facilities in processes with high thermal production, increasing the energy integration of existing facilities with the possibility of energy recovery. The analyses show how activation energies for the specific working conditions affect the round-trip efficiency values.

For this proposal of thermochemical energy storage based on the combustion of metals, the interest that the use of this type of materials as fuel can offer is observed. Among the points raised in this article, different lines of study are opened that will have this concept as a starting point. They include the study of the integration of green hydrogen production facilities from photovoltaic solar energy in this system, as well as carbon monoxide production plants and energy integration of the system depending on the chosen configuration.

Acknowledgments

This work has been partially developed within the project, New modular high-temperature thermo-chemical energy storage concept based on innovative processes (TED2021-131839B-C21) funded by the Recovery and Resilience Funds of the European Union and Spanish Ministry of Science and Innovation.

Abstract

Tube in tube phase change material (PCM) heat exchangers have great potential as latent thermal energy storage (LTES) systems. However, sizing and designing these systems is still a challenge. Standard heat exchanger models cannot be applied due to the non-linear and transient heat transfer behavior of the PCM. Several alternative methods are suggested but these models are unable to predict the complete outlet state as a function of time. To fill this gap, an analytical model is derived to estimate the phase change front position as a function of time. It is proposed that the time the front needs to reach a certain vertical position is a linear function of the position. To validate the proposed analytical model, experiments are performed on a vertical tube in tube heat exchanger with varying inlet conditions. In the inner tube, water flows as heat transfer fluid (HTF). A paraffin is used as PCM in the outer tube. The phase change front position is evaluated at the outside of the tube. The movement of the phase change front is represented by plotting the vertical position of the front as a function of time. The position of the front is determined based on visual measurements using a camera placed next to the tube. By predicting the front position as a function of time, the performance of the heat exchanger can be determined. Different designs can be compared more easily, without needing to experimentally test or simulate, leading to a shorter and less expensive design phase for LTES systems, enhancing their large-scale roll-out.

Keywords:

Latent thermal energy storage; Phase change material; Tube in tube; Phase change front.

1. Introduction

Latent thermal energy storage (LTES) systems are regarded as an effective means of storing thermal energy, utilizing phase change materials (PCMs) that absorb or release energy during the phase change. The European Union (EU) has set ambitious goals concerning energy efficiency and reducing carbon emissions [1, 2]. To reach these goals, the EU has made energy storage systems one of its research goals [2]. Especially thermal energy storage systems are of paramount importance, as 50% of our energy use is thermal [3]. LTES systems offer an effective way to store thermal energy, which is beneficial in reducing energy consumption during peak demand periods and can help in the reduction of reliance on fossil fuels.

Different types of LTES systems exist. A distinction can be made between systems that use or do not use heat transfer fluids (HTFs) to exchange heat or cold [4]. In this paper, the focus is on LTES systems that use HTFs: LTES heat exchangers. Different geometries are possible but the shell and tube configuration is the most commonly used [5].

However, designing an effective LTES heat exchanger can be challenging. The key design problem requires determining the heat transfer rate from HTF to PCM (or from PCM to HTF) as a function of time and the outlet HTF temperature as a function of time, based on the system's geometrical and operational conditions [6]. When designing conventional heat exchangers, the effectiveness-number of transfer units (NTU) and logarithmic mean temperature difference (LMTD) methods can be used. The methods are developed for heat exchangers which reach a steady state, implying that the local state of the heat transfer fluid is no longer a function of time. However, LTES systems are transient in nature [4], consequently, these methods are not applicable to such systems.

Previous attempts have been made to develop analytical methods that are suitable for LTES heat exchanger design. Some of the methods that have been proposed are the average effectiveness method, which was

introduced by Tay et al. [6, 7], and the phase change time method proposed by Raud et al. [8]. However, these methods only allow an estimation of a specific aspect of the outlet state of an LTES heat exchanger. Another approach is the charging time energy fraction method (CTEFM) method developed by Beyne et al. [9], which allows the outlet HTF temperature to be estimated as a function of time. However, this method cannot be used as a design method, as fitting to experimental data is required. Alternatives such as purely experimental methods and Computational Fluid Dynamics (CFD) based design are often too expensive and time-consuming.

Despite the above-mentioned efforts, there is still a gap in LTES heat exchanger design methodology. Therefore, there is a need for further research to develop more accurate and cost-effective analytical methods that can be used to design LTES heat exchanger systems with high efficiency and performance, for specific applications.

Recently, Beyne et al. [10] developed an analytical solution to predict the performance of LTES heat exchangers based on the heat transfer model of a cross section. A model is used for the local heat transfer under constant boundary conditions, based on the solution to the Stefan problem. In the Stefan problem, sensible heat is neglected compared to the latent heat of the PCM and the phase change is assumed to occur isothermally. The phase change problem is considered purely conductive and the PCM properties are assumed independent of the temperature. Computation of the phase change front location as a function of time allows determining the phase change fraction as a function of time. This relates to the PCM internal energy per unit of heat transfer surface. Next, this solution is integrated to determine the overall phase change fraction of the complete LTES heat exchanger. In [10] this analytical solution is verified for a planar geometry by comparing it to a numerical simulation. The results had small average deviations for the phase change fraction and effectiveness. The total phase change time was very well predicted.

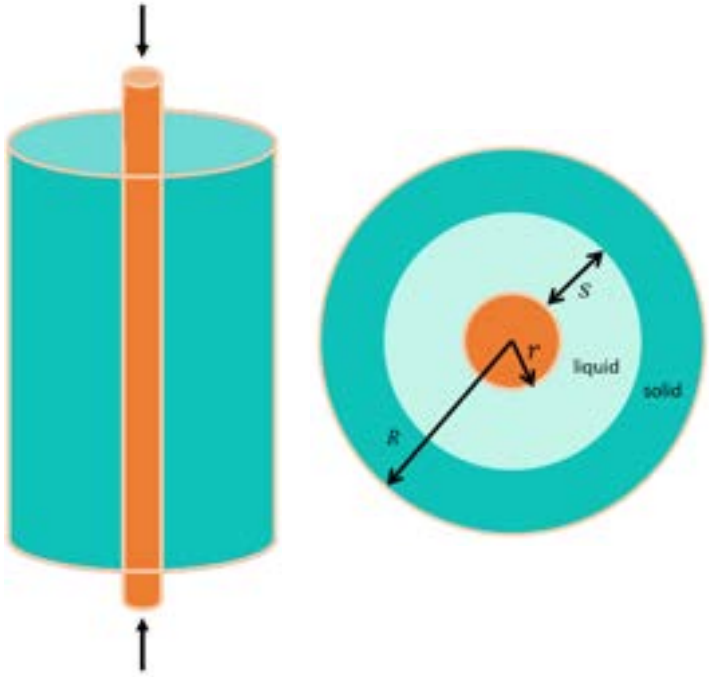

Figure 1. Schematic of tube in tube system during phase change.

In this paper, the proposed analytical method will be evaluated based on experimental data of a tube in tube LTES heat exchanger. The geometry is schematically shown in Figure 1. Similar to the planar geometry, analytical equations can be derived to predict the phase change front behavior as a function of time, now for a cylindrical geometry. The overall phase change fraction of a tube in tube heat exchanger can be determined based on the position of the phase change front in a cylindrical cross-section with constant boundaries, which relates to the PCM internal energy per unit of heat transfer surface. When this solution is integrated over the heat exchanger, the overall phase change fraction of the complete LTES system can be determined.

Beyne et al. [10] states that the phase change front moves linearly in time over the length of the tube. The time for the front to reach a certain vertical position $x = x_1$ is then given by Equation 1. The x-axis indicates the position of the phase change front at the outer diameter of the tube, as indicated in Figure 2.

$$t(x_1) = t_0 + \sigma . x_1 \qquad 1$$

t_0 is the time that is needed for the phase change front to reach the outer diameter of the PCM tube for the first time, thus at height $x = 0$. The slope σ can be estimated as in Equation 2. U_a is the latent heat of phase change of the PCM per length unit. $\dot{m}$ and c_p are respectively the mass flow rate and specific heat capacity of

the HTF, and ΔT_0 is the temperature difference between the HTF temperature at the inlet and the PCM phase change temperature.

$$\sigma = \frac{U_a}{\dot{m} c_p \Delta T_0} \quad (2)$$

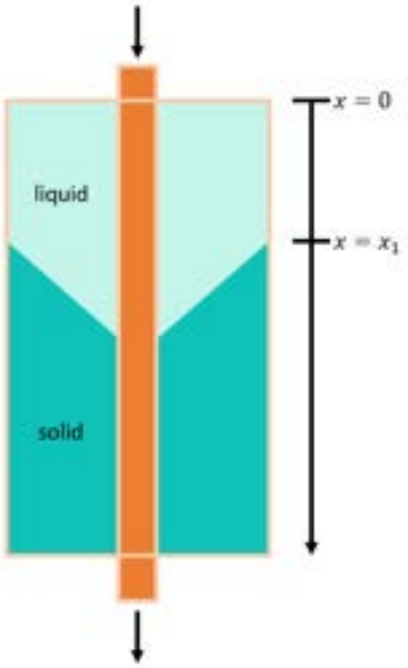

Figure 2. Section of tube in tube heat exchanger with phase change front schematically shown.

Mehling and Cabeza [11] provide a correlation for the radial movement of the phase change front in a one-dimensional cylindrical geometry. This correlation is based on the solution to the Stefan problem. Equation 3 denotes the time t that is needed for the phase change front to move a distance s away from the HTF tube with radius r. Equation 3 can be split up into two factors. The first factor relates the front position s to the phase change fraction, defined based on the latent heat of phase change the PCM h_{lat}, the density of the PCM ρ_{PCM}, the thermal conductivity k of the PCM and the temperature difference ΔT_0 between HTF temperature at the inlet and the phase change temperature of the PCM. The second factor f is a function of the ratio of the thermal conductivity k of the PCM to the convective heat transfer coefficient h of the HTF and the radial front position s. This factor describes the deviation of the solution compared to the solution of the Stefan problem, due to the boundary effects of the HTF. For the considered tube in tube heat exchanger, the second factor can be calculated as in Equation 4. It is assumed that the thickness of the HTF tube wall is much smaller than the outer HTF tube radius r and that the conductivity of the HTF wall is much larger than the conductivity of the PCM. These assumptions apply to the considered experimental setup (see Section 2). Equation 3 can be used to calculate t_0 in Equation 1, by defining $s = R - r$.

$$t(s) = \frac{h_{lat} \cdot \rho_{PCM} \cdot s^2}{2 \cdot k \cdot \Delta T_0} \cdot f\left(s, \frac{k}{h}\right) \quad (3)$$

$$f\left(s, \frac{k}{h}\right) = \left(1 + \frac{r}{s}\right)^2 \ln\left(1 + \frac{s}{r}\right) - \left(1 + \frac{2r}{s}\right)\left(\frac{1}{2} - \frac{k}{hr}\right) \quad (4)$$

A series of experiments on a tube in tube heat exchanger are conducted while the position of the phase change front is tracked over time. The observed results regarding the phase change front position are compared to the expected front position, based on the correlations from Beyne et al. [10] and Mehling and Cabeza [11], mentioned above. The accuracy of the proposed analytical model is investigated.

2. Setup description

The heat exchanger tested, is a tube in tube configuration with a length of one meter, which is oriented vertically to take advantage of the axisymmetry [12]. In this configuration, the heat transfer fluid (HTF) flows through the inner tube, while the PCM is located in the shell region. The direction of flow of the HTF can be changed using two three-way valves. During the melting process, the HTF flows from the top of the heat exchanger to the bottom. During the solidification process, it flows in the opposite direction to limit thermal stresses imposed by the PCM volume change.

The HTF flows through a copper tube with an outer diameter of 15 mm and a wall thickness of 2 mm. The copper tube is positioned concentrically within a transparent polycarbonate tube, which houses the PCM. The

shell has an outer diameter of 60 mm and a wall thickness of 3 mm. In the experiments, the paraffin RT35HC provided by Rubitherm [13] is used. This nontoxic PCM has a high thermal storage capacity and stable performance during the phase change cycles. An overview of the properties of RT35HC can be found in Table 1. A total of 1.497 kg of PCM is used during the experiments, which corresponds to a total latent heat capacity of about 380 kJ. Water is used as HTF.

Table 1: RT35HC properties [13].

Melting area	34-36	°C
Congealing area	36-34	°C
Specific heat capacity	2	kJ/kgK
Density solid (at 25°C)	0.88	kg/l
Density liquid (at 60°C)	0.77	kg/l
Heat conductivity	0.2	W/mK
Max. operating temperature	70	°C

Figure 3. Picture of the setup: insulation box.

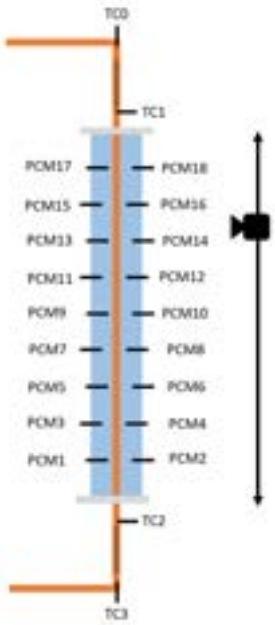

Figure 4. Schematic of the heat exchanger with camera slider, placed inside the insulation box.

A picture of the setup and a schematic of the heat exchanger be seen in respectively Figure 3 and Figure 4. Next to the tube, a camera on a linear slider is placed to allow observation of the location of the phase change front over the complete tube length. The whole of the heat exchanger and camera slider are placed in a big box filled with insulation granulates [14]. This way, thermal losses are limited in a uniform way. On the schematic, the thermocouples which are used to measure the temperature of the PCM and the HTF are indicated. The temperatures inside the PCM are measured with 18 1 mm K-type thermocouples, placed every 10 cm in the axial direction. At each height, a temperature measurement at both 0.5 and 1 cm from the outside shell wall is performed. These thermocouples are calibrated to an uncertainty of ± 0.15 °C and are acquired by a Keithley 2700 multiplexer with a sampling rate of 2.5 s. The temperatures at the HTF inlet and outlet of the heat exchanger are also measured. Mixers are inserted into the HTF tubes, ensuring the thermocouples measure the bulk HTF temperature. Before and after each mixer, a 1.5 mm K-type thermocouple was added. This way, both melting and solidification experiments can benefit from the effect of the mixers. These thermocouples are again calibrated with an uncertainty of ± 0.15 °C and are sampled with a sampling rate of 0.5 s, as the transient behavior needs to be captured. During melting, TC1 and TC3 will be used as respectively inlet and outlet of the HTF in the heat exchanger. While during solidification, this will be TC2 and TC0, as now the HTF flows from bottom to top.

In Figure 5 a picture taken during a melting experiment is shown. The figure includes a tape measure and a part of the transparent container, where the PCM can be seen. The transparent PCM is liquid, the white is solid.

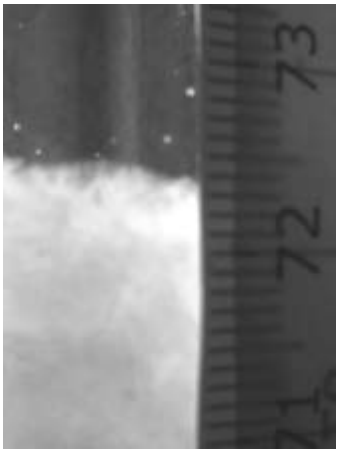

Figure 5. Picture of the phase change front during melting, taken with the camera installed next to the tube in tube heat exchanger (x = 72.4 cm).

In Table 2 an overview is given of the operational conditions of the considered melting experiments performed on the above-described setup. For each experiment, the HTF mass flow rate and two temperature differences are given. ΔT_0 quantifies the difference between the HTF inlet temperature and the phase change temperature (here assumed equal to 35 °C). ΔT_{init} is the difference between the phase change temperature and the initial temperature of the PCM. To define the initial PCM temperature, the mean of all PCM temperature measurements is used. The last column of the table gives the Reynolds number linked to the HTF.

Table 2. Overview of performed experiments.

experiment	$\dot{m}\ [kg/h]$	$\Delta T_0\ [°C]$	$\Delta T_{init}\ [°C]$	$Re\ [-]$
M1	68	26.5	8.0	4762
M2	80	25.6	14.5	5482
M3	20	22.5	17.0	1300
M4	156	19.5	10.0	9824

Only melting experiments are performed and no solidification data is taken into consideration in the context of this paper. The focus of this work is on melting experiments because during solidification tests, difficulties arise when visually observing the front. During solidification, conduction is the dominant heat transfer mode [15]. Therefore, the solidification front moves very radially from the inner shell diameter to the outside shell diameter. Because of this, it is very difficult to visually determine the moment when the front reaches the outside diameter. Similar difficulties were observed by Longeon et al. [12]. Lipnicki et al. [16] observed during their experiments that the solidification front almost has a constant radial thickness along the length of the heat exchanger, explaining the difficulties concerning determining the vertical front position at the outside of a PCM tube.

3. Results

3.1 Experimental results

As explained before, during each melting experiment, the location of the phase change front at the outer diameter of the heat exchanger is tracked over time. The position of the phase change front is normalized to the total height of the PCM ($L_{PCM} = 0.93m$), as in Equation 5. L_{PCM} is a bit smaller than 1m, as the tube is not completely filled with storage material to allow volume expansion during melting.

$$\xi = \frac{x}{L_{PCM}} \qquad 5$$

In Figure 6, the evolution of the position of the phase change front at the outer diameter of the PCM tube can be seen as a function of time, during melting experiment M1. The different melting regimes, as also observed in previous studies, can be recognised in the shape of the front-curve. In the initial phase, conduction is the

main heat transfer mode and the PCM closest to the tube will melt. As melting continues, heat transfer by convection will gain dominance and will fasten the heat transfer in the PCM. This can be seen by the steeper slope of the front-curve, meaning an increasing melting rate of the PCM when a significant part of the PCM has molten. Next, the heat transfer reaches a quasi-steady state regime with a constant heat transfer rate. The phase change front now moves linearly through the tube. Finally, when most of the PCM has molten, the shrinking solid phase starts while the heat transfer, and thus the speed with which the phase change front moves, decreases. These different melting regimes lead to the S-shape that can be recognised in the front-curve in Figure 6.

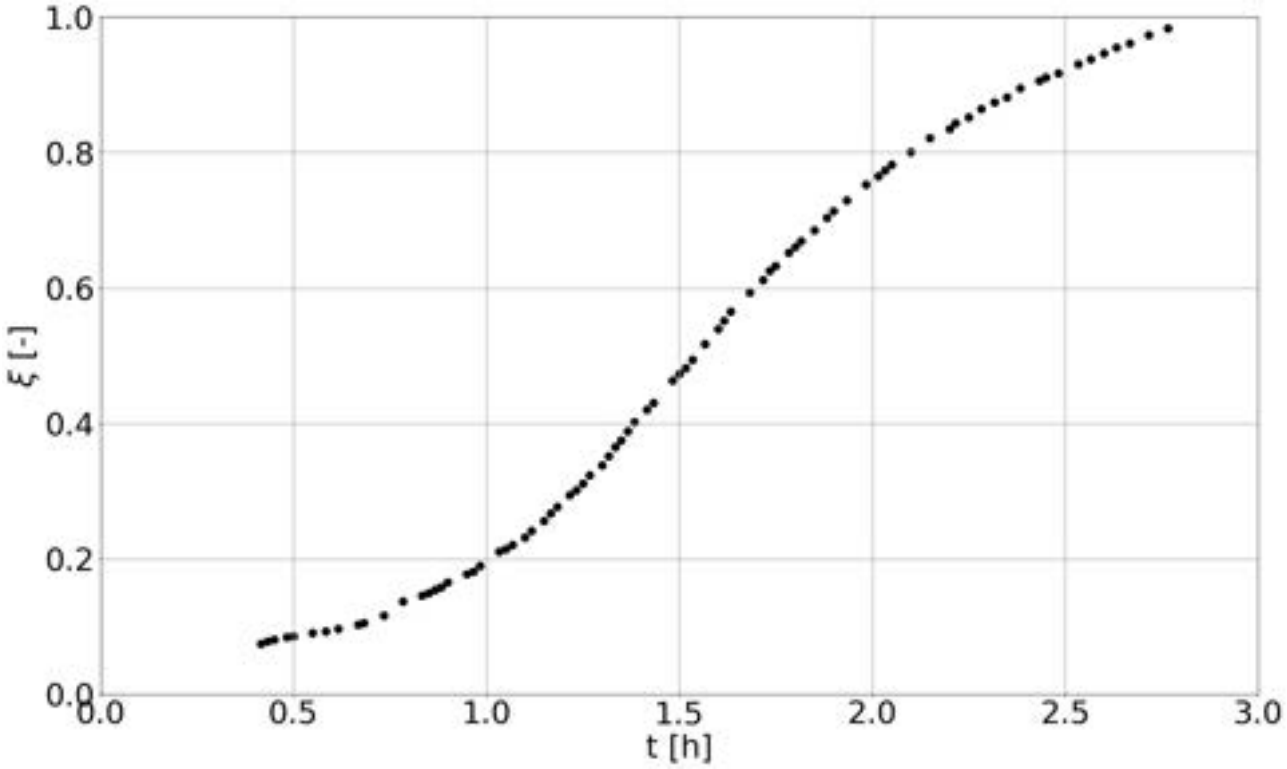

Figure 6. The evolution of the position of the phase change front at the outer radius of the PCM tube, as a function of time (melting test M1), based on the visual tracking of the phase change front position.

As mentioned above, a quasi steady-state melting regime is present during the melting process. During this phase, the melting front at the outside of the PCM tube moves linearly over time. The slope of this part of the front-curve is denoted by β for the remainder of this paper. β is only based on experimental data where ξ ranges from 0.25 to 0.65. In Figure 7 the visual, experimental data for all melting experiments is shown, and the linear approximation of the front movement during the quasi-steady melting regime is shown by the dotted black line. The linear approximation is of the shape as given in Equation 6. Some of the visual measurement points are omitted in Figure 7, to clarify the figure. The shape of the front-curve is however still obviously visible.

$$t(\xi) = \alpha + \beta \, . \, \xi \qquad 6$$

When comparing the different experimental results in Figure 7, the influence of the operational conditions can be seen. Especially increasing the temperature difference between HTF inlet temperature and the phase change temperature of the PCM, decreases the total melting time. These observations are in line with literature [17-20]. In literature is also seen that increasing the mass flow rate of the HTF, shortens the total melting time. However, when comparing experiments M1 and M2, a small increase in melting time is seen for the larger mass flow rate. Khan et al. [21] observed that for higher HTF inlet temperatures, the influence of varying the mass flow rate decreases. The shortened melting time for a larger mass flow rate can probably be explained by experimental uncertainties. The studies found in literature agreed with the observation that the heat transfer characteristics are more sensitive to a change in inlet temperature than a change in mass flow rate [22].

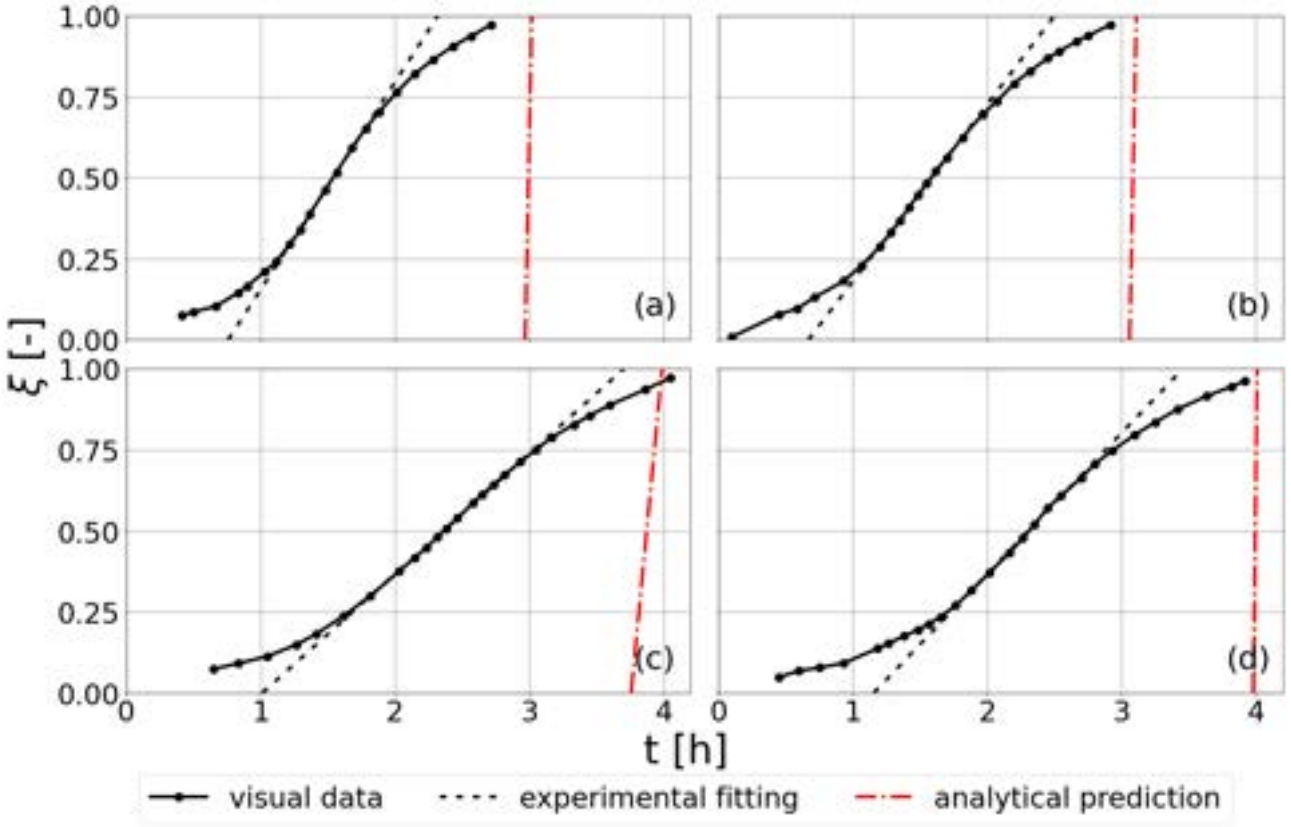

Figure 7. Experimental front data with fitted linear correlations based on β and σ for melting experiments (a) M1, (b) M2, (c) M3 and (d) M4.

3.2 Analytical correlations

As explained in Section 1, various studies propose that the phase change front moves linearly in time during melting experiments. In this Section, the analytical obtained intercept t_0 (Equation 3) is compared to the experimental α, and the analytical obtained slope σ (Equation 2) is compared to the experimental slope β, seen during the quasi-steady melting phase. Table 3 gives an overview of both intercepts and slopes for the considered operational conditions of the melting experiments of Table 2. The comparison between experimental and analytical results is visualized in Figure 7 where the black and red lines respectively represent the experimental and the analytical linear fit.

Table 3. Comparison of experimental and analytical slope.

experiment	$\boldsymbol{\alpha}$ $[\boldsymbol{h}]$	$\boldsymbol{t_0}[\boldsymbol{h}]$	$\boldsymbol{\beta}$ ***[h]***	$\boldsymbol{\sigma}$ ***[h]***
M1	1.560	2.97	0.760	0.05
M2	1.831	3.06	0.669	0.05
M3	2.689	3.76	1.015	0.23
M4	2.299	3.98	1.157	0.03

From Table 3 and Figure 4 it is clear that the proposed analytical correlations are not able to accurately predict the movement of the phase change front as a function of time of a tube in tube heat exchanger. The prediction for the total melting time is a quite an acceptable prediction. However, more experimental data is required to make any conclusions on this statement. Below some considerations are listed, explaining the deviations between experimental and analytical results.

First of all, measurement uncertainties on the measured experimental quantities must be taken into account. To calculate t_0 and σ the mean HTF inlet temperature and mean HTF mass flow rate are used. During the complete melting test, small deviations on these mean values are possible, however, these will not have a significant influence on the obtained results. The error on the visual measurements is difficult to determine but is limited to 2-3 mm. As the front position is measured every 3 minutes, this visual error will not influence the general trend of the front.

Thermal losses during the experiments could also influence the phase change front propagation. Due to the undertaken actions by installing the insulation box around the PCM heat exchanger, heat losses are limited as much as possible. Heat losses will decrease the melting rate and consequently, a faster front movement could be expected using the theoretical correlations, compared to the experimental data. However, it is improbable that the influence of the limited heat losses could be of the proportion that is seen when comparing β and σ.

Furthermore, in the derivation of the analytical correlations, only the latent heat of the PCM is considered. The sensible heat of the PCM also needs to be taken into account, as well as the heat transferred from the HTF to the container during the experiments. However, the latent heat is dominant as it is significantly larger than the other contributors to the internal energy of the system. For example for experiment M1, the latent heat of the PCM corresponds with 380 kJ, whereas the sum of the sensible PCM energy and the energy stored in the container is about 80 kJ. Including all the energy contributions would thus only have a limited influence on the value of σ.

The above-mentioned considerations concerning uncertainties in the experimental results or assumptions in determining the analytical correlations can explain a deviation between experimental and analytical results. However, the observed discrepancies cannot be explained. Therefore, a more fundamental look is taken into the analytical model, and the applicability of the model to the considered melting experiments is evaluated.

In the analytical derivation, pure conduction is assumed and the influence of natural convection is neglected, but during melting, natural convection is the dominant heat transfer mode [15]. It can thus be expected that the analytical solution will overestimate the duration of the melting process, due to the increased heat transfer during melting because of the influence of natural convection. However, the analytical prediction is a large underestimation of the experimental melting duration. A large deviation is seen between the theoretical and experimental obtained intercepts and slopes. From Table 3 and Figure 7, it is clear that the analytical slope σ is a large underestimation of the experimentally obtained β. It is predicted that the phase change front moves faster over the length of the tube, than what is visually observed.

The analytical model is based upon the assumption that the tube in tube heat exchanger can be modelled as distinct infinitesimal slices, stacked upon each other. The heat transfer behavior of the slices is assumed uncoupled. In reality, the phenomena in the different slices will be coupled, especially during melting due to vertical convection bubbles formed in the PCM. The experimental intercept α is expected to be smaller than the predicted t_0 based on purely, uncoupled conduction, due to the enhanced heat transfer because of the natural convection. This is as observed in Table 3 and Figure 7.

The analytical solution is obtained for a tube in tube heat exchanger with a temperature difference between the inlet and outlet of the heat transfer fluid. In the experiments, however, this temperature difference is rather limited. For example, for mass flow rates above $\pm 50 kg/h$ the temperature difference over the heat transfer is not measurable anymore. To validate the analytical solution, meaningful experimental data is required. To achieve this, the temperature over the heat transfer tube must be increased, by increasing the heat transfer rate between HTF and PCM. This can be done by for example adding fins to the HTF tube. However, preferably the analytical method is verified on a basic geometry. Another option to increase the heat transfer rate would be adding metal foam into the PCM to increase the effective conductivity of the storage material. Another approach could be to test a heat exchanger with an increased length. However, the height of the setup is limited due to practical limitations of the lab. In future studies, numerical simulations can be performed, eliminating the height limitations of the heat exchanger. Available experimental results can be used to fit the numerical method.

When analyzing the above-discussed results, the hypothesis arises that the analytical model can have better applicability for solidification experiments. During solidification, conduction is the dominant heat transfer mode, eliminating the deviation between experiments and model due to the influence of natural convection. Furthermore, when tracking the solidification front as a function of time, difficulties arise in determining the exact front position, because the phase change interface moves almost radially from the HTF wall to the outer PCM tube wall. The analytical model predicts such a front behavior: the predicted front moves in a couple of minutes over the complete length of the heat exchanger. In future work, solutions can be developed enabling tracking of the solidification front during experiments, or numerical simulations can be performed to validate this hypothesis.

4. Conclusions

Melting experiments are performed on a tube in tube LTES heat exchanger, with varying operational conditions. During these experiments, the location of the phase change front at the outer diameter of the PCM tube is tracked over time based on photographs. The distinct melting regimes described in literature can be seen in the obtained front movement-curve. The experimental results are compared to a predicted phase change front behavior, based on an analytical model developed by Beyne et al. [10]. It is seen that the analytical model overestimates the movement speed of the phase change front. However, a realistic estimation of the total melting time can be obtained with this model. In future work, numerical simulations are

recommended. Furthermore, tracking the phase change front during solidification experiments is required to validate the applicability of the analytical model for solidification.

Acknowledgment

The authors would like to express their gratitude and appreciation to the technical staff of Ghent University, especially Frederik Martens, Bart Van Daele, and Thomas Blancke for building and maintaining the setup used to obtain the discussed experimental data.

Nomenclature

c_p	specific heat capacity, J/kgK
h	convection coefficient, W/m²K
h_{lat}	latent heat of the PCM, J/kg
k	thermal conductivity, W/mK
L	length, m
m	mass, kg
$\dot{m}$	mass flow rate of HTF, kg/h
r	outer radius of HTF tube, m
R	inner radius of PCM tube, m
Re	Reynolds number, -
s	radial distance the phase change front has traveled, m
t	time, h
t_0	time the phase change front needs to reach the outer diameter of the PCM tube for the first time, h
U_a	latent heat of phase change of the PCM, per length unit, J/m
x	front position, m

Greek symbols

α	experimental intercept, h
β	experimental slope, h
ΔT_0	difference between HTF inlet temperature and PCM phase change temperature, °C
ΔT_{init}	difference between mean initial PCM temperature and PCM phase change temperature, °C
σ	analytical slope, h
ξ	dimensionless front position, -

Subscripts and superscripts

PCM	phase change material
HTF	heat transfer fluid

Abstract:

Policies reasoned by global climate change and increasing commodity prices due to the international energy crisis force district heating providers to transform their assets. Pit thermal energy storage combined with solar energy can improve this transformation process. Optimal energy planning of district heating systems is often achieved by applying a linear programming model due to its fast computing. Unfortunately, depicting those systems in linear programming requires complexity reduction. We introduce a method capable of designing and operating the system with the complexity increase of considering the top and bottom temperatures of the pit thermal energy storage in linear programming.
Firstly, we extract and clean data from existing sites and simulations of seasonal storages. Secondly, we develop a polynomial regression model based on the extracted data to predict the top and bottom temperatures. Lastly, we develop a mixed-integer linear programming model using the predictions and compare it to existing sites. The model uses solar thermal energy, a pit thermal energy storage, and other units to meet the demand of a district heating system.
The polynomial regression results show an accuracy of up to 92 % with only a few features to base the prediction. The optimization model can design the storage and depict the correlation between decreasing specific costs and thermal losses due to an increasing volume. The control strategy of the heat pump requires further improvement.

Keywords:

MILP; Seasonal Storage; Optimization; District Heating; Design.

1. Introduction

The energy transition to a carbon-free system is one of the key challenges in the 21st century. Therefore, district heating systems (DHS) need renewable options and flexibility to reduce the impact of global warming. [1] predicts an expansion of DHS and emphasizes the importance of seasonal storages. Seasonal storages could enhance the integration of renewables like solar thermal energy and increase the system's flexibility. [2] identifies pit thermal energy storages (PTES) as economically feasible compared to other technologies. Combining different renewable technologies and seasonal storages supplying a DHS and the connected consumers is a tested concept in Denmark [3]. However, the planning process of a DHS with different technologies and different locations can be complex and overwhelming. In order to support decision-making processes for planers, we analyze historical and simulation data from seasonal storages. We develop a method to design a DHS with a PTES and other technologies inside a discretized thermal grid.

Figure 1 illustrates the concept of storing solar thermal energy in a PTES and unloading it through a heat pump into a district heating network. The goal is to design and operate energy converters and storages connected to the grid by modeling pipes, consumers, and production units. This approach tries to model a district heating network with all components and allows the integration of PTES in this system. The main research question is how a PTES integration into a DHS with different components can be optimized.

1.1. State-of-the-art

In recent years, several different strategies to model PTES and DHS, design and operate them, have been introduced (see Table 1). Most studies focus on a detailed depiction of the storage to calculate the operation and thermal losses due to charging, discharging, and environmental temperatures. A more in-depth review of those studies is given in the following paragraphs.

Appropriate simulation tools are helpful for the project's economic viability. TRNSYS is found to be the most widely used simulation tool for PTES simulations due to its component sets. [2] used TRNSYS to optimize the efficiency by using the data from a pilot solar heating system combining PTES. Results show that control strategies significantly improve heat collection performance and exergy efficiency, and stratification of seasonal storage impacts collection efficiency, especially at the end of the non-heating season [4]. EnergyPlus has some advantages in modeling heating systems on the demand side to satisfy various loads and is focused on building simulations [5]. FLUENT and COSMOL specialize in the PTES device temperature and velocity field analysis rather than system integration. SDH calculation tools is a bundle of tools developed by EU project SDHp2m [6]. It specializes in calculating solar district heating systems [7].

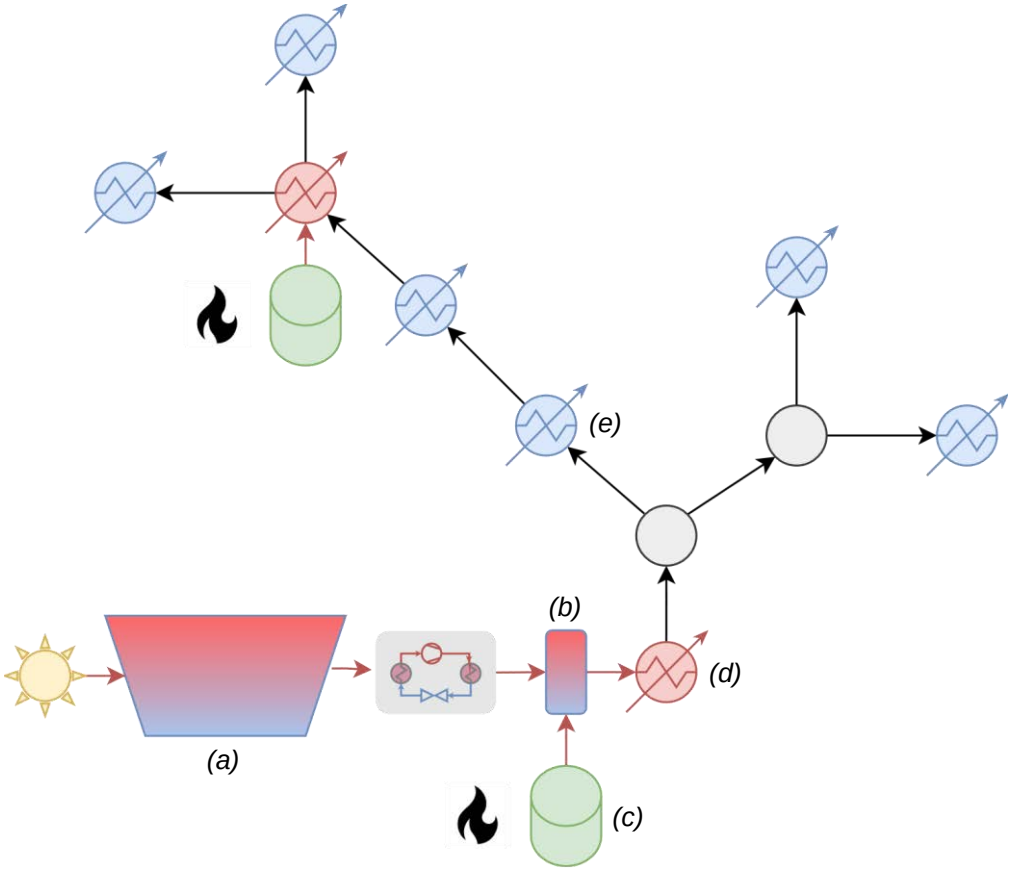

Figure 1: Fictional grid for this research with: a) PTES, solar thermal field, and heat pump as central units, b) buffer storage, and c) biomass boiler as a decentral unit; d) is referred to as a production unit; e) is referred to as consumer.

[8] considers using a biomass trigeneration system and an absorption heat pump to supplement the temperature gap and stabilize the water temperature in PTES at 85 to 90 °C. The model considers the overall efficiency of a power plant and maximizes the net present value to meet the district heating demand [8]. [9] uses TRNSYS to model the combined heating supply system to determine the performance of each plant and the ideal size. [10] studies the Dronninglund water pit thermal energy storage focusing on the balance model of energy and mass flow and providing the charging and discharging data for further research. In winter, the district heating supply temperature in Dronninglund is 75 °C; when the top temperature of the PTES is below the supply temperature, the heat pump works as a compensator. In Marstal, when the PTES top temperature drops below 70 °C, the PTES serves as the heat source for the heat pump to provide the gap between the district heating water temperature and the storage unit [11]. We apply the concept of Marstal using the PTES as a heat source for the heat pump.

The space for the PTES and solar panels affects the economics of the system. [12] compares the parameters of PV panels with thermal solar collectors. Using TRNSYS, three locations across Poland are examined, and the results show solar thermal collectors' advantages in area occupation and economics [12]. [12] uses an

electrode boiler to feed into the PTES. [13] calculates an energy system with additional units and suggests a ratio of the seasonal storage volume to the solar field area of 2 to 3 m. [14] compares distributed and centralized thermal solar collectors in Finland with 1231 MWh yearly heating demand and concludes that the centralized units have a significant advantage in the heat generation costs. The lower costs for central units are caused by decreasing specific investments with increasing dimensions [2].

Table 1. Typical energy system model comparison [15]

Energy system model	Min. Time step	Space range	Related function	Ref.

The mentioned research gives and models the storage geometry and volume inside the simulation. We set the geometry as a variable and contribute to this extensive research with an approach in mixed-integer linear programming (MILP), including

- dynamic network behavior by depicting temperatures inside the grid,
- designing and controlling PTES in combination with other energy converters and storages located at different positions in the grid,
- introducing realistic PTES temperatures from simulations and measured data to obtain more realistic, dynamic coefficients of performance (COPs) (see Marstal concept),
- modeling and calculating the geometry of the PTES inside the optimization to account for thermal losses, space requirements, and specific investments.

The major problem of designing seasonal storage systems in energy system models based on MILP is the temperature modeling inside the storage – which would introduce nonlinearity – and the lack of information concerning the geometry. Our approach is based on the fact that already-designed systems have been operated for several years. [30] gathers data concerning the ratio between volume and surface, while the storages in Marstal and Dronninglund provide operational data. This information provides a generic approach supporting planners in the design phase of a carbon-neutral DHS.

The paper is structured in the method section, result section, discussion, and conclusion. In the method, we explain how we utilize the data from existing sites to model temperatures of PTES supplied by solar thermal energy. Additionally, we explain how we model the geometry of the PTES leading to specific investments, thermal losses, and space requirements. In the result section, we validate our approach by simulating the temperatures in the PTES and comparing the geometry and other parameters to existing sites. We continue by discussing our results and conclude with the most important findings.

2. Method

To find the optimal design for our energy system, we utilize MILP. MILP is a mathematical optimization technique for solving problems where some variables are constrained to be integers. It is used to model real-world problems where decisions are made based on discrete choices [31]. Our approach uses historical data from existing, and simulated PTES projects supplied by solar thermal fields and predicts temperature profiles for the location where the energy system model is applied. Figure 2 gives an overview of the methodology. We train a regression model based on the extracted data to predict the top and bottom temperature. With that temperature information, the MILP model optimizes the heat pump operation, and we also obtain the temperature losses at the surfaces. To create a dynamic PTES surface model, we used existing sites to build a piecewise function in the MILP model that takes the variable volume as an input and delivers the areas of the bottom, top, and sides as an output. The specific investments are modeled analogously. The MILP model includes energy balances around pipes, consumers, energy converters, and storages. The mass flow inside the pipes is estimated a priori, preventing nonlinearity.

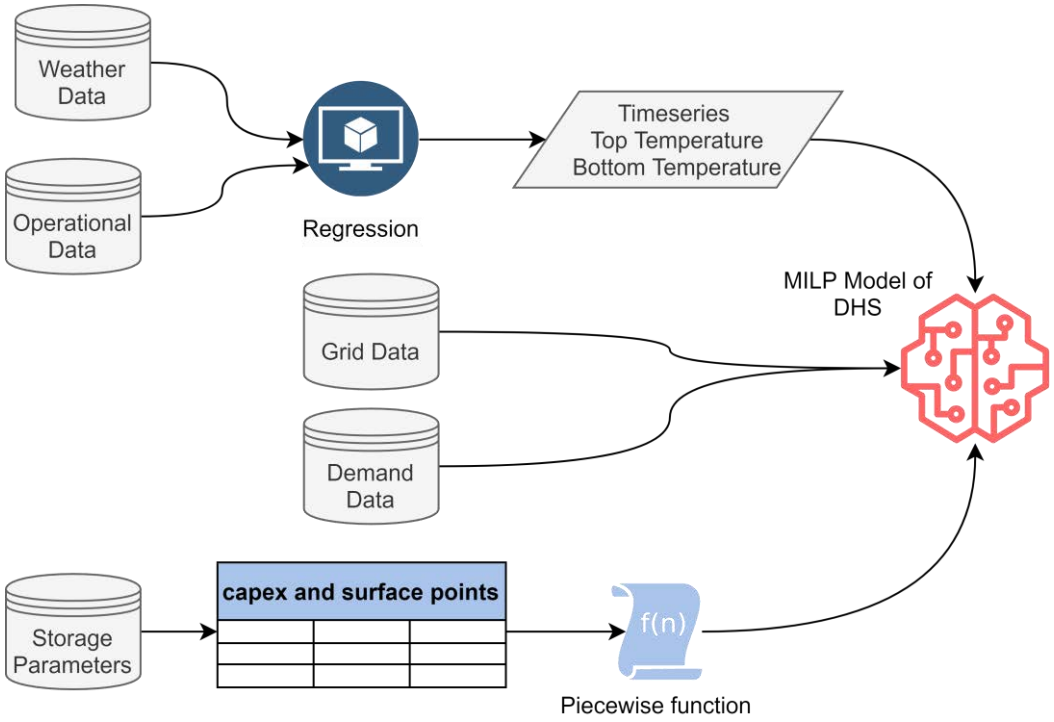

Figure 2: Illustrating the method dividing into the prediction of the temperatures, the piecewise functions for the capex and the surface areas of the storage depending on the volume, and the MILP model for the DHS.

2.1. Regression Model predicting PTES Top and Bottom Temperature

For our approach, we assume that the temperatures in the PTES behave similarly independent of the system due to the seasonal storing of solar thermal energy. To examine this assumption, four datasets were used in this research to predict the internal temperature of the PTES. We use the existing sites in Marstal and Dronninglund [3] and the simulation data from Wadelheim [32] and Florence [33]. The temperatures are extracted using the tool WebPlotDigitizer [34].

Many features can affect the temperature in the PTES. First of all, the environmental factors should be considered. The database of photovoltaic geographical information [35] provides the ambient temperature – two meters above the surface – and irradiance. [30] analyzes the slope and azimuth of solar thermal collectors' installation. Based on this work, the slope is set at 35 degrees, and the azimuth is chosen at 180 degrees. The soil temperature is relatively constant according to the monitoring results in [3]. So, the effect of the deep soil temperature on the tank's bottom temperature is neglected in our model. Additionally, the geometry – volume and surface area – of the PTES could affect the top temperature. However, this effect cannot be considered because the volume is a decision variable in the MILP model; therefore, the storage's geometry is unknown when we apply the regression model (see Figure 2). In conclusion, we use the features time, solar irradiance, and ambient temperature at the given location.

Before applying a polynimal regression [36], we resturcture the data input to improve the accuarcy. The feature time is separated into hour $t^{\text{hour}} \in [1,\ldots,24]$ and day $t^{\text{day}} \in [1,\ldots,365]$. The time is then split into sine and cosine such as $\sin/\cos\left(2\pi\frac{t^{\text{hour}}}{24}\right)$ and $\sin/\cos\left(2\pi\frac{t^{\text{day}}}{365}\right)$. The time is now categorized into four features.

Afterward, we apply the StandardScaler from scikit-learn [37] to all features. Then we use three data sets to train the model and one to test it. To evaluate the performance of the regression, mean squared error, root mean squared error (RMSE), mean average error (MAE), R-squared, explained variation, and accuracy are set as measurements.

2.2. The Energy System Model

A description of all used nomenclature can be found in the Nomenclature section after the conclusion. The energy system model is a MILP model minimizing the costs of the system represented by an objective function

$$\min\left(f^{\text{opex,var}}, g^{\text{opex,fix}}, h^{\text{capex}}\right). \quad (1)$$

$f^{\text{opex,var}}$ is the variable operational cost for energy converters combining costs for energy carriers, maintenance, and repair. $g^{\text{opex,fix}}$ are the fixed costs for storages or energy converters for the operation, maintenance, and repair, and h^{capex} are the investments. The economic calculation is based on [38]. The calculation is performed for one year in 3-hour timesteps. The model was solved with Gurobi [39].

The mass flow in the network is calculated a priori per day based on a fixed temperature delta of 30 K, meeting the demand of the highest peak in the grid of that day. Additionally, the velocity in the pipes is limited by a minimum pressure loss of 80 Pa/m and a maximum pressure loss of 300 Pa/m [40]. The energy balance for the pipes is formulated as

$$c_{\text{p}} m_a \frac{T_{a,t-1}^{\text{out}} - T_{a,t}^{\text{out}}}{\Delta t} + \dot{m}_{a,t} c_{\text{p}} \left(T_{a,t}^{\text{in}} - T_{a,t}^{\text{out}}\right) - U_a A_a^{\text{m}} \left(T_{a,t}^{\text{out}} - T_t^{\text{soil}}\right) = 0 \;\; for\; a \in Z^{\text{ff}}, Z^{\text{bf}}, t \in \tau, \quad (2)$$

where the first term represents the storage capacity of the pipe, the second term is the enthalpy rate entering and exing the pipe, and the last term is the loss of the pipe. The energy balance of the consumers is given by

$$\frac{\dot{Q}_{a,t}^{\text{con}}}{\mu^{\text{con}}} = \dot{m}_{a,t} c_{\text{p}} \left(T_{a,t}^{\text{in}} - T_{a,t}^{\text{out}}\right) \quad for\; t \in \tau, a \in Z^{\text{con}}, \quad (3)$$

and the energy balance of the production units is formulated analogously with

$$\dot{Q}_{a,t}^{\text{pro}} \mu_a^{\text{pro}} = \dot{m}_{a,t} c_{\text{p}} \left(T_{a,t}^{\text{out}} - T_{a,t}^{\text{in}}\right) \quad for\; t \in \tau, a \in Z^{\text{pro}}. \quad (4)$$

The temperatures in the grid are limited by the consumers, with $T_{a \in Z^{\text{con}},t}^{\text{in}} \geq T_{a \in Z^{\text{con}},t}^{\text{min}}$ and a technical limitation between 0 °C and 130 °C.

The heat flow at a production unit is the summation of all heat flows by storages and energy converters at that location a. Therefore, $\dot{Q}_{a,t}^{\text{pro}}$ is given by

$$\dot{Q}_{a,t}^{\text{pro}} = \sum_{k \in Z^{\text{conv}}(a)} \dot{Q}_{k,t}^{\text{conv}} + \sum_{k \in Z^{\text{stor}}(a)} \left(\dot{Q}_{k,t}^{\text{out,stor}} - \dot{Q}_{k,t}^{\text{in,stor}}\right) \quad for\; t \in \tau, a \in Z^{\text{pro}}, \quad (5)$$

$Z^{\text{conv/stor}}(a)$ is the set of energy converters and storages at that location. The solar thermal field is modeled with

$$\dot{Q}_{k=\text{solar},t}^{\text{conv}} = \mu_{k=\text{solar}} \gamma_t^{\text{rad}} A^{\text{collector}} \quad for\; t \in \tau, \quad (6)$$

where $A^{\text{collector}}$ is the variable dimensioned by the optimizer to calculate the area of the collectors. $\mu_{k=\text{solar}}$ is the efficiency of the solar field here assumed to be 0.5 [41]. The solar field charges the PTES, and a heat pump lifts the temperature of the PTES, if necessary, before injecting the heat into the grid. The energy balance of the PTES can be described as

$$E_{k=\text{PTES},t} = E_{k=\text{PTES},t} + \Delta t \left(\mu_{k=\text{PTES}} \dot{Q}_{k=\text{PTES},t}^{\text{in}} - \frac{\dot{Q}_{k=\text{PTES},t}^{\text{out}}}{\mu_{k=\text{PTES}}} - \dot{Q}_{k=\text{PTES},t}^{\text{loss}}\right) \quad for\; t \in \tau. \quad (7)$$

The energy balances for the buffer storages are modeled analogously. The PTES has a cyclic condition where $E_{k=\text{PTES},t=\text{start}} = E_{k=\text{PTES},t=\text{finish}}$. The PTES energy is limited by

$$E_{k=\text{PTES},t} \leq V_{k=\text{PTES}} \rho c_{\text{p}} \left(T_{k=\text{PTES}}^{\text{top,max}} - T_{k=\text{PTES}}^{\text{top,min}}\right) \quad for\; t \in \tau. \quad (8)$$

The heat flow when discharging the storage can only be directly injected into the grid if the supply temperature is lower than the temperature of the PTES at the top. This is given by

$$\dot{Q}_{k=\text{PTES},t}^{\text{out,stor}} = \begin{Bmatrix} \dot{Q}_{k=\text{PTES},t}^{\text{out,stor}}, & T_{k=\text{PTES,t}}^{\text{top}} \geq T_t^{\text{supply}} \\ \frac{COP_t}{COP_t - 1} \dot{Q}_{k=\text{PTES},t}^{\text{out,stor}}, & T_{k=\text{PTES,t}}^{\text{top}} < T_t^{\text{supply}} \end{Bmatrix} \quad for\; t \in \tau. \quad (9)$$

The COP is calculated a priori based on the predicted temperature profile of $T_{k=\text{PTES,t}}^{\text{top}}$. The heat losses $\dot{Q}_{k=\text{PTES},t}^{\text{loss}}$ correlate with the geometry of the storage and decrease with increasing volume. The heat losses $\dot{Q}_{k=\text{PTES},t}^{\text{loss}}$ are calculated identically to [42]. However, in this study, we do not know the size of the surface yet due to the unknown size of the storage. Therefore, we applied a piecewise function [43] calculating the sides, top, and bottom area of the PTES depending on the volume. We use existing sites to get grid points and summarize them in Table 2. We calculate the areas for each storage based on the geometry of an obelisk and assume that the bottom and top areas are quadratic. Furthermore, we assume a standard correlation between the top area side length and the bottom area side length of 78 to 48 due to the detailed information of Dronninglund from [42].

Table 2: PTES information about the geometry and specific investments used for the piecewise functions. [2, 30, 44]

Site	Volume [m^3]	Total surface [m^2]	Angle [°]	Height [m]	Calculated bottom area [m^2]	Calculated top area [m^2]	Calculated side area [m^2]	Specific investments [€/m^3]

3. Results

The result section divides into examining the results of the regression model to predict the top and bottom temperature of a PTES charged by a solar thermal field. Afterward, the MILP model uses this profile to design the PTES and other energy converters in a district heating network. The design is evaluated by comparing it to the existing sites of Marstal and Dronninglund. Additionally, we simulate the storage heat losses in Marstal with our predicted temperatures and compare the error. To evaluate the heat pump control, we perform two optimization runs: the first is with the predicted temperature profile, and the second is with averaged temperatures – not using the regression model in the pre-processing. We then re-simulate the actual temperatures in the storage and calculate the electrical demand for the heat pump in both optimization runs. For the re-simulation, we take the energy level $E_{k=\mathrm{PTES},t}$ and divide by the volume, the specific heat capacity, and the density resulting in the current temperature delta. This temperature delta is added to $T_{k=\mathrm{PTES}}^{\mathrm{top,min}}$ and the COP of the heat pump is recalculated.

3.1. Polynimal Regression Results

Table 3: Polynomial regrssion results for three sites as training and one site as testing.

Dataset		Polynomial Regression		
train	test	RMSE	MAE	Accuracy
Marstal, Dronninglund, Florence	Wadelheim	0.6336	0.5687	0.5986
Marstal, Florence, Wadelheim	Dronninglund	0.8395	0.6668	0.2953
Dronninglund, Florence, Wadelheim	Marstal	0.5964	0.4906	0.6443
Marstal, Dronninglund, Wadelheim	Florence	0.2896	0.2337	0.9161

Table 3 shows the results for using three data sets as training and one dataset as testing. The accuracies for Wadelheim and Marstal are around 60 % due to the daily fluctuations in the demand. The result for Florence is realtively high with an accuracy of 91.6 %. The prediction accuracy for Dronninglund as testing is relatively low, at 29.5 %. The deterministic solution of the polynomial regression is given by

$$T_t^{\mathrm{PTES,top}} = 4.0255 T_t^{\mathrm{ambient}} + 2.2715 \gamma_t^{\mathrm{rad}} + 0.2065 \sin\left(2\pi \frac{t^{\mathrm{hour}}}{24}\right) + 2.7253 * \cos\left(2\pi \frac{t^{\mathrm{hour}}}{24}\right) - 23.6073 * \sin\left(2\pi \frac{t^{\mathrm{day}}}{365}\right) - 9.9604 * \cos\left(2\pi \frac{t^{\mathrm{day}}}{365}\right) + 56.6761, \quad (10)$$

where the temperatures have the unit of °C and the irradiance W/m^2. Before Eq. 10 can be used, the StandardScaler (see method section) has to be applied to every feature.

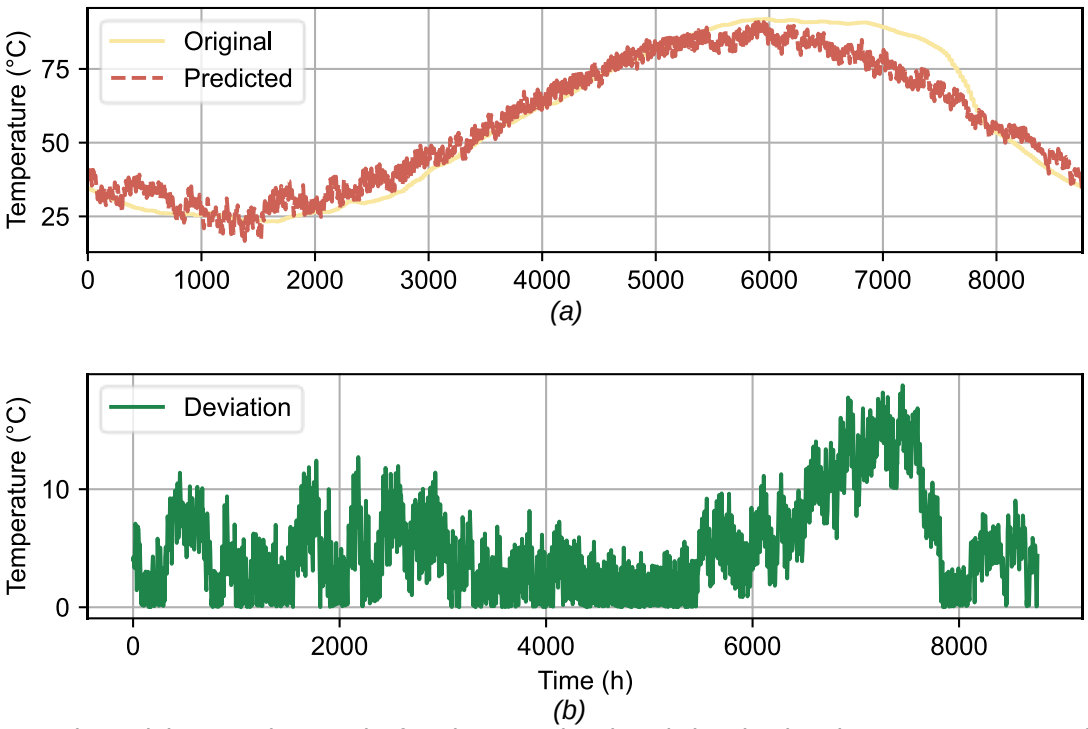

Figure 3: Polynomial regression results for Florence showing a) the simulated top temperature and the predicted top temperature and b) the deviation between the two temperature profiles. [33]

Figure 3 shows the simulated top temperature for the PTES in Florence [33] compared to the predicted temperature. A high correlation can be examined in Figure 3 a) between the two temperature profiles. However, the deviation has a maximum of 18 °C and an average of 5 °C. A deviation of 18 °C in the calculation for the COP of a 1 MW heat pump supplying 90 °C would result in an error of around 100 kW for the electrical input. This error indicates potential weaknesses in the modeling approach. To evaluate the effects on the geometry, we simulated the heat losses of the Marstal storage in 2014 based on the predicted top and bottom temperatures. The simulation results in a heat loss of 2391.85 MWh, causing an error of 17.7 % compared to the measured data [3].

3.2. Results for Designing the Energy System

The MILP model is applied to a fictional grid (see Figure 1). The design optimization of a central production unit results in a 250 kW central biomass boiler, a 12555 m^2 solar thermal field, a 26725 m^3 PTES, a 62 m^3 buffer storage, and a 958 kW heat pump. Furthermore, a decentral production unit consisting of a 50 kW biomass boiler is installed. The heat generation costs are 14.5 ct/kWh. The operation and investments of the system are displayed in Figure 4. The costs are based on the year 2020 using the Day-Ahead prices. The solar thermal field mainly loads the PTES in the summer. The heat pump also has the opportunity to charge the PTES. Due to the heat pump's partial load limit of 50 %, the biomass boilers cover peak loads. The buffer storage serves as a day-to-day flexibility supporting the heat pump operation. However, the heat flows of the buffer storage are not included in Figure 4, for clarity and due to the low impact on the energy system. The storage is mainly loaded in spring and summer, and the discharging starts mainly in October. In October, the temperatures in the storage are high enough to inject into the grid directly; therefore, the other units do not operate.

The temperature in the storage affects the electrical input for the heat pump, influencing the operational expenditures (opex). This effect is measured by resimulating the temperatures inside the storage and recalculating the COP. Based on the COP, the electrical power for the heat pump is recalculated. We also perform an optimization run without the predicted temperature profiles assuming a constant temperature inside the PTES. Using the constant temperature inside the PTES leads to a deviation of the electrical input for the heat pump of 45 %, while the predicted temperature profiles of the PTES cause an error of 29 %.

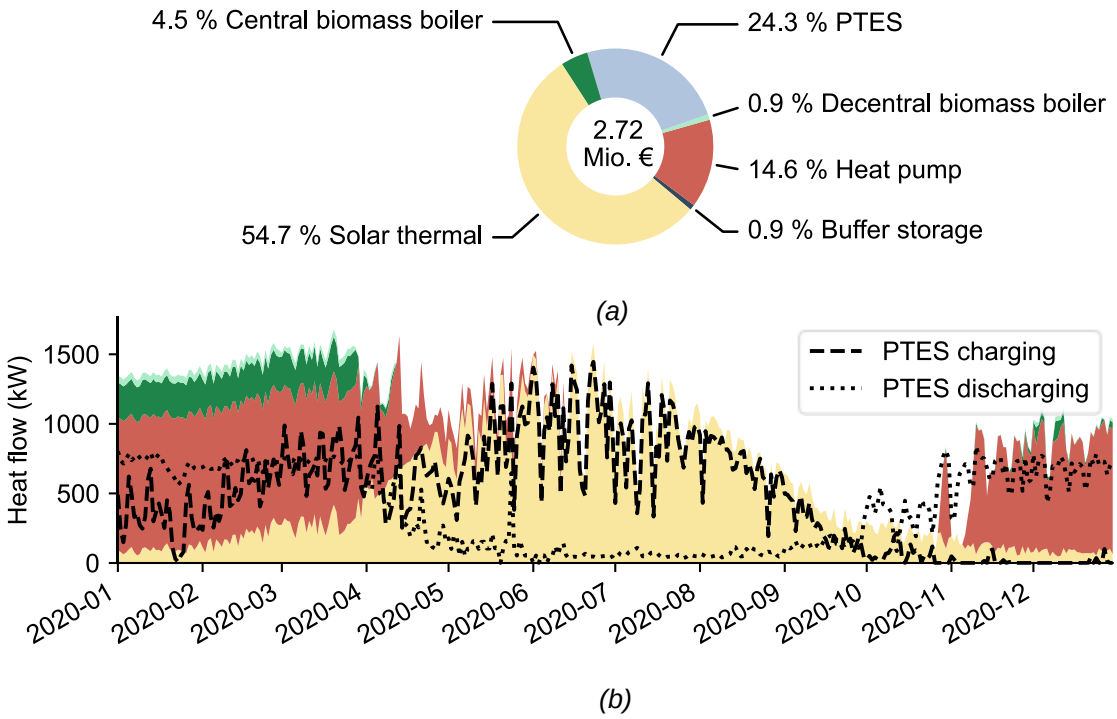

Figure 4: b) optimized operation of the energy system model and a) the investments in the energy system with the different shares for the energy converters and storages.

4. Discussion

The discussion divides into highlighting the benefits and drawbacks of the regression model and comparing the results of the energy system model with the existing sites in Marstal and Dronninglund.

4.1. Discussion of the Polynomial Regression Results

The difficulty of the regression model is the prediction of temperature profiles without knowing the demand or the volume of the PTES. Therefore, the model only has the time, the solar irradiance, and the ambient temperature as features. Using three storages as training data and Dronninglund as testing leads to a relatively low accuracy due to the considerable fluctuations in the temperature profile of Dronninglund. This clearly shows the disadvantages of the model because it cannot depict hourly or daily fluctuations. However, the prediction results improve up to 91 % for Florence. This improvement is due to the data being a simulation; therefore, no rapid changes are in the gradient. The regression model cannot replace a detailed storage simulation but can estimate the seasonal behavior at a given location for a pre-analysis.

4.1. Discussion of the Energy System Results

Utilizing the predicted temperature profiles in the energy system model leads to reasonable results, see Table 4. It should be noted that the energy system model is not applied to the demand structure in Marstal or Dronninglund due to the lack of data. Therefore, the results can only be compared relatively. The storage is about half the size compared to Marstal and Dronninglund; the same applies to the solar thermal field. The storage charging is 4362 MWh, while the storages in Marstal and Dronninglund are charged with 7813 MWh and 12760 MWh. The ratio volume to solar field is 2.13 m, while for Marstal and Dronninglund, it is 2.25 and 1.68 m. [13] suggests a ratio between 2 and 3 m, with 3 being relatively compared to our calculations and the existing sites. This comparison shows a correlation between the optimization results and the existing sites. Additionally, the results verify the approach of the piecewise functions to calculate the areas of the storage based on the volume due to the moderate deviation of 17.7 % compared to the measured data of Marstal in 2014.

A significant drawback is the deviation of the electrical input for the heat pump – 29 %. Utilizing the predicted temperature profiles increases the accuracy, but a deviation of 29 % is still not accurate. We also tested a binary-based model leaving the temperature calculation inside the optimization. We applied this model to the same use case and obtained a solution for a timestep of 24 h after 8 h computational time on a windows machine with 488 GB and an AMD EPYC 7542 32-Core Processor. Reducing the timestep length to 8 h led to computational times over 24 h. Therefore, we conclude that the model is not applicable. Feeding the optimization model with fixed temperature profiles already suggests a control strategy for the heat pump and

influences the results. The last option would be to assume a constant temperature inside the storage and calculate the COP based on a constant value. Based on this study, we suggest using a constant temperature inside the storage for the COP calculation and performing a more detailed simulation of the PTES with TRYNSYS or other simulation software mentioned in the state-of-the-art. This has the advantage that the energy system model already calculates the design of the PTES, and the simulation can focus on the control strategy. Assuming a constant temperature inside the PTES for the energy system model would allow loading the storage with other technologies. The regression model can only work if a seasonal behavior is present in the charging process; however, other technologies like air heat pumps would load the storage based on the electricity market.

Table 4: Comparison of results with the existing sites in Marstal and Dronninglund. [3]

Parameter	Marstal (2015)	Dronninglund (2015)	Energy System Results (2020)
Charging, MWh	7813	12760	4362
Discharging, MWh	5435	11983	3433
Thermal losses, MWh	2946	1275	853
Heat capacity, MWh	5430	5500	2086
T-max, °C	84	89	92
T-min, °C	20	10	23
Volume, m^3	75000	63000	26725
Solar gain, $kWh/m^2/a$	395	447	355
Solar field, m^2	33300	37573	12555
Ratio volume / solar field, m	2.25	1.68	2.13

5. Limitation of Results

The method is applied to a fictional grid with six consumers. The grid size does not represent the usual DHS, and larger grids would lead to higher computational times. However, the solver needed ca. 1 h, and the model is applied in the planning phase; therefore, the computational time can be slightly higher than in a control optimizations. Nevertheless, the method must be applied to larger grids to evaluate its performance.

6. Conclusion

In this study, a method is developed to design PTES supplied by solar thermal energy inside a DHS. Our approach utilizes historical data and identifies strong correlations between the modeling results and the existing sites. The results suggest a ratio of ca. 2 m for volume vs. solar field. For 1 GWh capacity of a PTES, an area of around 1500 m^2 combined with 37500 m^2 solar thermal collectors would be needed. Achieving a more accurate result, our model can be applied in the planning phase for a grid-based DHS supplying heat from and to different locations. The model can depict the decreasing specific investments and thermal losses due to an increasing volume. This behavior is achieved by a piecewise function taking the volume as input and the investments and geometry of the PTES as output.

The difficulty within the optimization is the control strategy of the heat pump, depending on the temperature inside the storage. We examined three possibilities:

1. Predicting the temperatures of the storage before the optimization and calculating the COP a priori
2. Assuming one constant temperature of the storage and calculating the COP a priori
3. Calculating the temperature and the COP during the optimization

The first option already induces a control strategy inside the optimization and causes an error of 29 % for the electrical input. The second option did not depict any temperature changes inside the storage and caused an error of 45 %. The third option was not applicable due to a high computational time. In conclusion, we suggest the second option, followed by a detailed simulation. This study showed the computational limits for a mathematical optimization in the design stage due to the fact that the dimension – the volume of the PTES – and operation – the temperature of the PTES – is a variable. In the future, new methods could be developed depicting volume and temperature as a variable and computing results in a practical manner.

Furthermore, it would be interesting to investigate different technologies supplying a PTES and compare it to solar thermal energy due to its high investments. For Power-to-Heat technologies, the investigation should optimize at the Day-Ahead market to react to price fluctuations. In addition, large grids should be examined due to the large space requirements for PTES charged by solar thermal energy.

Contributions and Acknowledgements

MS advised the research of the polynomial regression model, developed the energy system model, and wrote the manuscript. YX developed the polynomial regression model. MiR and MvB advised the development of the energy system model. MR acquired the finance for this research via the project ODH@Jülich.

Abstract:

Energy systems require flexibility to help with the penetration of variable renewable energy. A promising solution for flexibility provision is demand-side management (DSM) from industry. However, the extent of flexibility from industrial DSM depends on the characteristics of industrial processes. In this work, we investigate the potential of industrial DSM as a flexibility provider to a net-zero sector-coupled energy system. Specifically, we investigate the cost reductions and the change in deployment of other flexibility options due to industrial DSM. We examine three system configurations for the Swiss sector-coupled energy system, varying the attractiveness of alternative flexibility options. To consider the characteristics of industrial processes, we parameterize the study with three representative industrial process characteristics: load-shifting potential, storage capacity, and losses. Our results show that the value of flexibility from industrial DSM highly depends not only on the process characteristics, but also on the system's flexibility alternatives, particularly for flexibility over longer time horizons. Due to differences in flexibility alternatives, the maximum cost reductions from industrial DSM vary between 2% and 27%. Additionally, we find that the effects of the three investigated characteristics on cost reductions also depend on the interactions with the alternative flexibility options. Depending on the interactions, cost reductions may stagnate as flexibility from industrial DSM is enhanced. Our study shows that while industrial DSM can serve as a flexibility provider to a net-zero sector-coupled energy system, the value of industrial DSM highly depends on both the characteristics of industrial processes and the system's alternative flexibility options. Both aspects must be considered when evaluating the extent of flexibility from industrial DSM.

1. Introduction

Countries are increasingly setting net-zero emissions targets to address climate change [1]. To meet these targets, fossil fuels must be replaced by renewable energy sources in all energy-consuming sectors [2], and direct air carbon capture and storage (DACCS) must be implemented to abate residual emissions. As energy-consuming sectors transition away from fossil fuels, electrification becomes increasingly important as the medium for integrating renewables into other sectors. For example, the heating sector can be electrified by heat pumps and the mobility sector can be electrified by battery electric vehicles [3]. The resulting reliance of all energy sectors on the electricity sector leads to sector-coupling, where the electricity sector becomes the central pillar for the overall energy system. However, most renewable energy is intermittent, such that flexibility is needed for systems with a high share of variable renewable energy. Flexibility refers to an energy system's ability to cope with the variability and unpredictability that variable renewable energy introduces in different time scales, while reliably supplying all the demanded energy to end users [4]. Shaner et al. [5] show that the need for flexibility increases rapidly after 80% variable renewable energy share.

Flexibility can be provided from the supply side through storage, imports, and fossil-based electricity with carbon capture and storage (CCS). However, each of these options has limitations: storage technologies, such as batteries, are expensive and not suitable for long duration energy storage due to their self-discharge characteristic. [6–8]. Power-to-hydrogen is a storage technology that is stable over long time horizons, but has a low round-trip efficiency [8, 9]. Pumped hydro storage, while efficient, is subject to high capital costs, topographic limitations, and environmental concerns regarding surrounding areas [10]. Electricity imports are subject to availability abroad. Fossil fuel imports are also subject to availability abroad. Additionally, the required CCS is not widely accepted and can thus be difficult to scale due to both social and physical constraints [11].

Due to the limitations of supply-side flexibility, demand-side management (DSM) serves as a promising alternative. Demand-side management refers to the shifting of energy consumption patters to obtain a desired

energy consumption profile [12]. A good candidate for demand-side management is the industry sector due to its large energy demand, its potential for storing products over long time horizons, its already-existing metering infrastructure, and the avoidance of consumer behaviour change [13]. An example of industrial demand-side management is the shifting of production schedules to better-follow the availability of renewable electricity. For instance, an industrial process can over-produce during the daytime hours to take advantage of low prices caused by photovoltaic availability, store the overproduction, and under-produce during night-time hours such that the overall production stays the same. Promising example processes for industrial DSM are aluminum electrolysis, cement and raw mills, air separation, electric arc furnace and pulp production due to their high electricity demands and technical possibilities for load shifting [14].

The extent of flexibility from industrial DSM depends on several characteristics of industrial processes:

- **Load-shifting potential**: The percentage of the base industrial energetic demands that can be shifted to another time interval in response to volatility.
- **Storage capacity**: The amount of product that can be stored at a time.
- **DSM losses**: The losses associated with demand-side management, such as efficiency losses from off-design operation and product losses from storage.

These three characteristics influence the potential value from industrial DSM for the overall system. Promising industrial candidates can be identified by identifying promising combinations of these characteristics. Additionally, some of these characteristics can be influenced via financial incentives, e.g. the installation of larger storage capacities. Therefore, understanding the characteristics' effects on industrial DSM can help guide financial incentives.

Studies have shown how industrial DSM can affect the costs and environmental impacts for individual industrial sites [15–17]. Studies have also considered the contributions of industrial DSM from an overall system perspective [18, 19]. However, these studies have typically focused only on the electricity sector. For instance, Paulus et al. [18] analyzed the economic benefits of industrial DSM from energy-intensive industries to electricity markets. Papadaskalopoulos et al. [19] also studied the economic benefits of industrial DSM to the European power system by varying the load shifting potential. Thus far, to the best of our knowledge, no study has resolved the potential contributions of industrial DSM to a net-zero sector-coupled energy system.

In this study, we evaluate how varying degrees of industrial DSM affect the costs and the needs for other flexibility options of a net-zero energy system considering multiple sectors. Varying degrees of industrial DSM are modelled by varying the industrial process characteristics listed above. We aim to answer the following research questions:

1. What are the potential cost reductions of a net-zero sector-coupled energy system from industrial DSM?
2. How does industrial DSM interplay with other flexibility options?

To answer these research questions, we model the Swiss sector-coupled energy system using the linear optimization framework SecMOD [20]. We use a snapshot approach, constrain the system to net-zero emissions, and determine the system's cost-optimal investments and operation for varying degrees of industrial DSM. We do not consider costs associated with industrial DSM to determine an upper bound on the potential cost reductions. We consider three scenarios with varying assumptions regarding natural gas prices and use in power plants. By considering three scenarios, we can compare the contributions from industrial DSM across systems with varying flexibility alternatives. Of particular importance are the alternatives for long-duration flexibility, referring to durations longer than 12 hours. To represent industry, we create a generic, process-agnostic model comprised of the Swiss industry's electricity and heat requirements. This approach allows us to vary DSM characteristics without the need to model specific industries and processes. To model the varying degrees of industrial DSM, we perform a parameterized study by introducing parameters representative of industrial process characteristics. Our approach allows us to study the potential of industrial DSM as a flexibility provider to a net-zero sector-coupled energy system.

In Section 2., we briefly introduce the energy system model and discuss the modeling of industrial DSM in detail. Section 3., presents the results of the parameterized study. Finally, Section 4., summarizes the most important points of this study.

2. Modelling industrial DSM in Sector Coupled Energy Systems

As the focus of this study is industrial DSM, we only briefly summarize the Swiss energy system modelling in Section 2.1.. We describe the modelling of industry and the industrial DSM characteristics in more detail in Section 2.2.. Section 2.3. introduces the three scenarios.

2.1. Swiss Sector-coupled Energy system

The Swiss sector-coupled energy system is modelled with the open-source linear optimization framework SecMOD [20]. We consider the electricity, heat, and private mobility sectors within the energy system and focus on the year 2050 with an exogenous net-zero operational emissions constraint. Within the heat sector, we consider civil heating along with industrial heating at three temperature levels. Industry also has en electricity demand which we consider together with industrial heat demands (Section 2.2.). The optimization framework determines the cost-optimal investment and operation decisions to reach the net-zero emissions target, while ensuring that exogenous demands are met. Demands for civil electricity, civil heat, and private mobility are provided separately, while demands for industrial electricity and heat are provided in an aggregated fashion to represent Swiss industrial demands. Only operational emissions are considered for the net-zero target. The technology options included in the model of the sector-coupled energy system are shown in Table 1.

The energy system is modelled as a 1-node system. Hourly time series are provided and aggregated with a temporal resolution of 25 typical days. To allow for seasonal storage, the typical days are interlinked using the method developed by Kotzur et al. [21]. Note that Switzerland today has 8.8 TWh of seasonal storage from hydro reservoirs [22], comprising 14% of the overall electricity demand in 2019 [23].

Table 1: Technology options provided for modelling the Swiss sector-coupled energy system

Li-ion batteries pumped hydro storage	direct air capture	power-to-methane

**CCS_lowprice* and *CCS_highprice* scenarios

2.2. Implementation of Industrial Demand-side Management

In this section, we explain how industry is modelled within the energy system and how the industrial DSM characteristics were represented by three parameters. The hourly electricity and heat demands of Swiss industry are aggregated into a generic industrial process. This aggregated process produces 1 "good/hour", while consuming the hourly industrial energy demands for Switzerland. We use an industrial electricity demand of 6 TWh [24] and a heat demand of 20 TWh [25] in 2050. The heat demand is split into three temperature levels (Table 2) according to a report from the Swiss Federal Office of Energy [24]. The demands in Table 2 represent the base industrial energy demands, d^{base}_{energy}, from which the benefits of industrial DSM are explored. Industrial production is assumed constant throughout the year, such that an exogenous demand of 1 good/hour, or d^{base}_{goods}, is introduced. Thus, without industrial DSM, the hourly electricity and heat demands of Swiss industry must be supplied for every hour of the year. This assumption introduces a basis from which to measure the benefits from industrial DSM. However, the benefits may be greater or smaller depending on how the actual industrial energy demand profiles follow renewables availability.

Table 2: Base energy demands of Swiss industry, d^{base}_{energy}, for the production of 1 $\frac{good}{hour}$, or d^{base}_{goods}

Input/Output	Temperature Range	Value (MW)
electricity	–	685
low temperature heat	$< 200°C$	750
medium temperature heat	$200°C - 800°C$	907
high temperature heat	$> 800°C$	571

The contributions from industrial DSM are evaluated by performing a parameterized study on three parameters

representative of the industrial process characteristics introduced in Section 1. An industrial goods storage tank is introduced to serve as a buffer for industrial over and under-production (Figure 1). No investment or operating costs are associated with storage capacity to evaluate an upper bound on cost reductions from industrial DSM. The calculated cost reductions can then be compared to the real costs associated with the necessary storage capacities. The three modelled parameters are described below:

- **Load-shifting potential** (*iflex*): The load-shifting potential, referred to as *iflex*, represents to the fraction of the base load, d^{base}_{energy}, that can be shifted up or down at a given time step, t, similar to [19]. *Iflex* can take any value between 0 and 1, as shown in Equation (1).

$$0 \leq iflex \leq 1 \tag{1}$$

  An *iflex* value of 0 corresponds to no load-shifting potential and an *iflex* of 1 corresponds to the ability to shift 100% of the base load at a given time step, ranging from a complete shutdown to the doubling of base production.

- **Storage capacity** (t_{SC}): The storage capacity refers to the maximum amount of goods in the industrial storage tank, and limits the amount of goods can be stored at a time. We parameterize the storage capacity, SC, with the time interval t_{SC} over which the base demand of $1 good/hour$, or d^{base}_{goods}, can accumulate (Equation (2)).

$$SC = t_{SC} \cdot d^{base}_{goods} \qquad t_{SC} \in [12\ hours, 6\ months] \tag{2}$$

  For example, with a t_{SC} of $1 day$ the storage capacity is constrained to a day's worth of industrial demand. We range t_{SC} from 12 hours to 6 months in our parameterized study. Throughout this text, we refer to t_{SC} as the storage capacity.

- **DSM losses** (η): DSM losses refer to production lost as a result of industrial DSM. Losses can arise from off-design operation as well as storage leakage. To study the effect of DSM losses, we introduce the discharge efficiency, η, that represents the amount of goods that can be withdrawn from the storage of industrial goods per goods stored. A lower efficiency means that less goods can be withdrawn per goods stored and therefore more goods need to be produced to meet the overall demand. The discharge efficiency, η, can take any value from 0 to 1 as shown in Equation (3).

$$0 \leq \eta \leq 1 \tag{3}$$

  An η value of 0 corresponds to 100% product losses and an η value of 1 corresponding to no product losses. Note that while η only represents discharge efficiency associated with storage in our mathematical formulation, the wide η range investigated can be interpreted as also considering additional efficiency losses.

The relationship between the three parameters (*iflex*, t_{SC}, and η), the industrial production, and the storage can be seen schematically in Figure 1 as well as in Equations (4) to (8). Equation (4) constrains the production used at a given time step, $P(t)$, between the range defined by the *iflex* parameter.

$$d^{base}_{goods} \cdot (1 - iflex) \leq P(t) \leq d^{base}_{goods} \cdot (1 + iflex) \tag{4}$$

Equation (5) prevents the industry storage from acting as a source or sink for industrial products by setting the initial and final storage levels (SL) equal, similar to [15].

$$SL_{t=0} = SL_{t=T} \qquad T = 8760h \tag{5}$$

Equation (6) models the stored product. $in(t)$ refers to the product stored at time t and $out(t)$ refers to the product withdrawn.

$$SL(t+1) = SL(t) + in(t) - \frac{out(t)}{\eta} \tag{6}$$

Equation (7) shows how the demand of industrial goods is met at every time step with a combination of production, $P(t)$, and storage.

$$d^{base}_{goods} = P(t) - in(t) + out(t) \tag{7}$$

Finally, Equation (8) constrains the storage level with respect to the parameterized storage capacity, t_{SC}.

$$SL(t) \leq t_{SC} \cdot d^{base}_{goods} \tag{8}$$

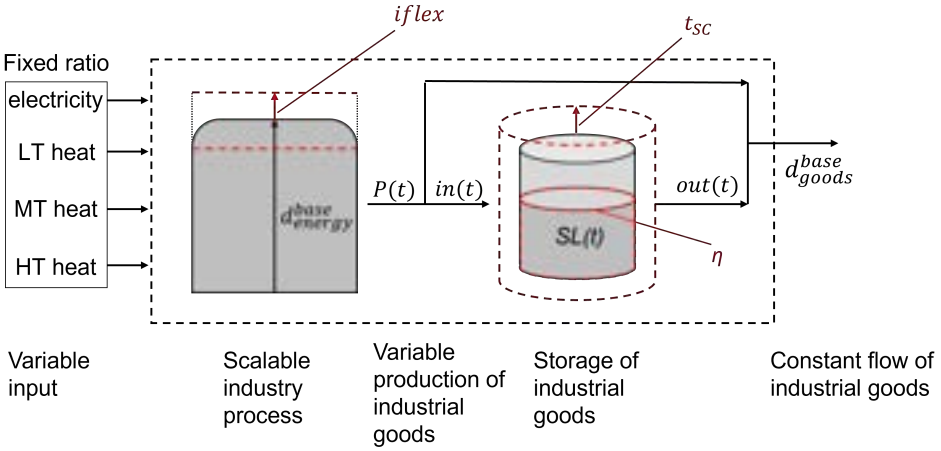

Figure 1: Schematic representation of the relationship between the industrial DSM parameters (*iflex*, t_{SC}, and η), industrial production, and storage of industrial goods. The three parameters are shown in red. *iflex* corresponds to load-shedding potential, t_{SC} correspods to the time interval over which the base industrial demand of $1 good/hour$, or d^{base}_{goods}, can accumulate. η corresponds to the storage discharge efficiency. LT, MT, and HT correspond to low, medium, and high temperature heat demands for Swiss industry. $P(t)$ is the production of industrial goods at time t. $in(t)$ and $out(t)$ are the product stored and withdrawn, respectively, and $SL(t)$ is the storage level.

2.3. Scenarios

Three scenarios represent different assumptions on natural gas prices and on the utilization of natural gas power plants as a flexibility option. The three scenarios, described below, allow us to compare the contributions from industrial DSM across systems with varying flexibility alternatives.

CCS_lowprice: This scenario includes the cheapest flexibility alternative to industrial DSM by allowing for electricity production from natural gas power plants with carbon capture and storage (CCS). It assumes a natural gas import price of 31€/MWh, representative of a stable historical average [26].

CCS_highprice: This scenario also allows for electricity production from natural gas power plants with carbon capture and storage (CCS) while assuming a high natural gas import price of 135 €/MWh, representative of the average for 2022 [26].

minCCS: This scenario includes the most expensive flexibility alternative to industrial DSM by only allowing for electricity production from renewable energy sources. This scenario represents an extreme case where both the use of CCS and fossil fuel imports are minimized. Natural gas can still be imported at a price of 31 €/MWh, but only for use in natural gas boilers for high and medium temperature heat. In this scenario, batteries become important as the flexibility alternative to industrial DSM.

3. Results and Discussion

The contributions from industrial DSM depend on both the industrial DSM characteristics, represented by the three parameters (*iflex*, t_{SC}, and η), and on the system characteristics, represented by the three scenarios. The most influential system characteristics are the alternative flexibility options, particularly over time horizons greater than 12 hours. Our results show that the system cost reductions from industrial DSM range from 1.7% to 27% due to the differing flexibility alternatives across scenarios. The flexibility alternatives also influence the relationships between the industrial DSM characteristics and the industrial DSM contributions.

In subsection 3.1. we discuss the effect of the load-shifting potential on the contributions from industrial DSM. In subsection 3.2., we discuss the effect of storage capacity, and in subsection 3.3. we discuss the effect of DSM

losses. We place particular emphasis on how the contributions vary depending on the system's alternative flexibility options.

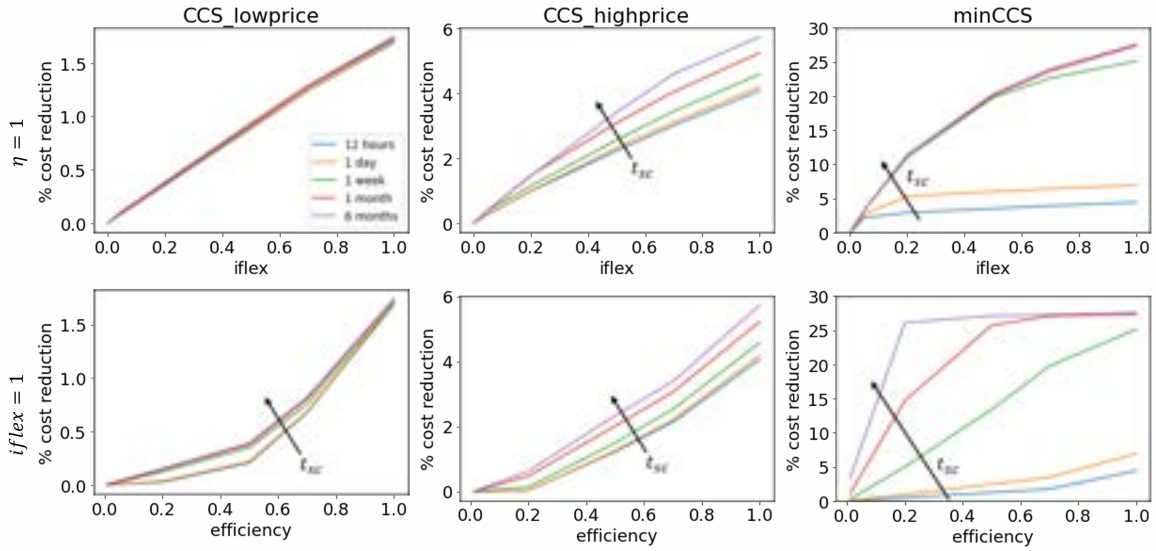

Figure 2: Top row: % cost reduction compared to a system with no industrial DSM as a function of load-shifting potential, *iflex*, for 100% discharge efficiency (η = 1). Bottom row: % cost reduction compared to a system with no industrial DSM as a function of discharge efficiency, η, for 100% load-shifting potential (*iflex* = 1). The columns correspond to scenarios and the colors correspond to storage capacities, t_{SC}. Arrows point in the direction of increasing storage capacity. The ranges for % cost reduction vary across scenarios.

3.1. Load-shifting Potential

Load-shifting potential can decrease the overall system costs for all scenarios (Figure 2). However, the magnitude of the maximum cost reduction differs significantly depending on the scenario: for the *CCS_lowprice* scenario, the maximum cost reduction is 1.7% whereas for the *minCCS* scenario, the maximum cost reduction is 27%. This magnitude difference is mainly driven by the attractiveness of industrial DSM as a flexibility provider over longer time horizons, as shown by the jump in cost reduction for the *minCCS* scenario between 1 day and 1 week storage capacities (Figure 2, top row, third column).

Additionally, the relationship between cost reduction and load-shifting potential differs across scenarios: the *CCS_lowprice* and *CCS_highprice* scenarios show a more linear relationship between cost reduction and *iflex* whereas the *minCCS* scenario shows a non-linear relationship (Figure 2, top row). The relationships are driven by the effect of increasing load-shifting potential on the implementation of the alternative flexibility options as explained in detail in the subsections below.

3.1.1. CCS_lowprice

In the *CCS_lowprice* scenario without industrial DSM, electricity from natural gas is used to balance both the intraday and the seasonal fluctuations in renewables availability. To help with the seasonal imbalance of PV availability, which peaks in the summer, direct air capture (DAC) with carbon capture and storage (CCS) is deployed flexibly, maximizing its CO_2 capture in the summer following PV availability (Figure 3, Reference). Once DAC capacity is installed, it can be deployed flexibly throughout the year while incurring no additional costs for the flexible operation. DAC capacity thus serves as a seasonal flexibility alternative to industrial DSM.

As load-shifting potential is introduced (assuming η = 1, t_{SC} = 12 *hours*), the electricity from natural gas needed to balance the intraday fluctuations reduces substantially due to the shifting of industrial production to daytime hours. Maximum load-shifting potential (*iflex* = 1) and a storage capacity of 12 hours (t_{SC} = 12 *hours*) reduces both natural gas imports and CO_2 stored by 19%. The cost reduction of 1.7% is mainly due to the decrease in natural gas imports. The imports decrease linearly for increasing load-shifting potential, driving the linear cost reduction observed in Figure 2.

Increasing storage capacity does not lead to significantly higher cost savings relative to the 1.7% observed for a 12 hour storage capacity. Increasing storage capacity leads to a flatter operation of DAC throughout the year (Figure 3, 6 months), decreasing DAC capital expenditures slighty. However, the decrease in capital expenditures is much smaller than the 1.7% cost reduction associated with intraday natural gas imports and

therefore increasing storage capacity does not greatly enhance the cost savings from industrial DSM in the CCS_lowprice scenario (Figure 2 top row, first column).

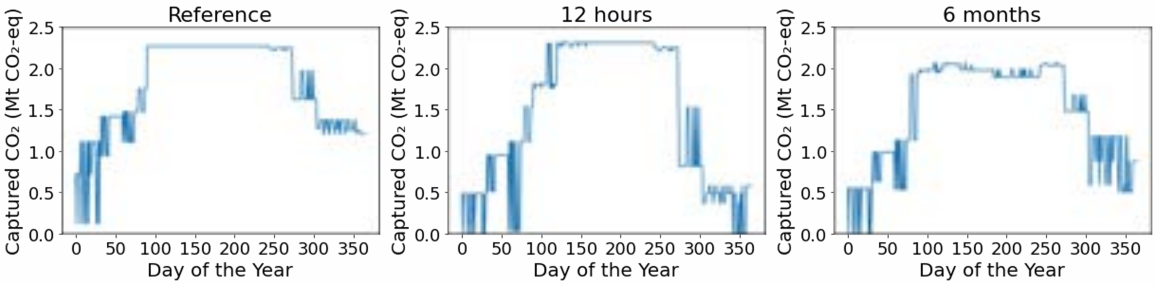

Figure 3: CCS_lowprice scenario: daily CO_2 captured across storage capacities. The Reference case corresponds to no industrial DSM. The 12 hour and 6 month storage capacity plots assume 100% load-shedding potential (*iflex* = 1) and 100% discharge efficiency (η = 1).

3.1.2. CCS_highprice

In the *CCS_highprice* scenario without industrial DSM, batteries are used in the winter to balance renewables fluctuations over several days. Additionally, electricity from natural gas is needed in the winter to supplement the lower renewables availability (Figure 4, Reference). As load-shifting potential is introduced (assuming η = 1, t_{SC} = 12 *hours*), the system no longer needs batteries to balance fluctuations over several days, but rather only to balance intraday fluctuations. Additionally, less electricity from natural gas is needed in the winter, reducing natural gas imports by to 25% (Figure 4, 12 hours). The reduction in battery capacity and in natural gas imports are the main drivers for cost reductions as industrial DSM is introduced. Because of the decreased need for natural gas combustion for electricity, less direct air capture is needed in the summer, thus freeing up some renewable electricity to produce methane for industrial heating. This effect further reduces the need for natural gas imports. As storage capacity increases, the long-duration flexibility offered by industrial DSM further decreases the amount of natural gas imports needed for electricity production in winter (Figure 4, 6 months). Thus, the maximum cost reduction for full load-shifting potential results from the long-duration flexibility offered by industrial DSM, displacing batteries at smaller storage capacities and electricity from natural gas at larger storage capacities.

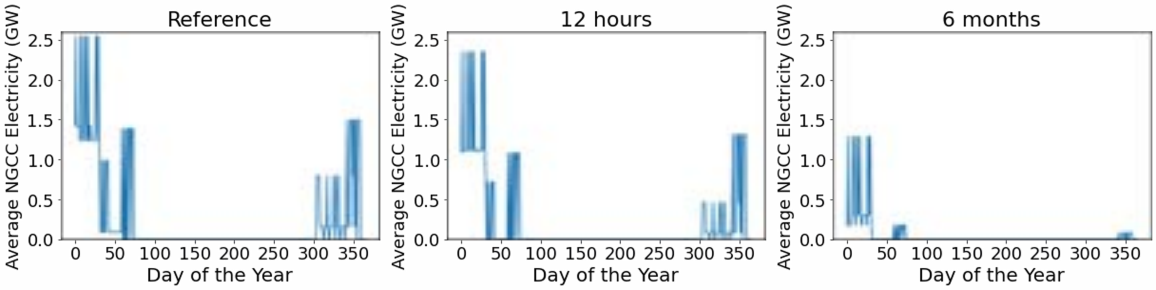

Figure 4: CCS_highprice scenario: average daily electricity production from natural gas combined cycle (NGCC) across storage capacities. The Reference case corresponds to no industrial DSM. The 12 hour and 6 month storage capacity plots assume 100% load-shedding potential (*iflex* = 1) and 100% discharge efficiency (η = 1).

3.1.3. minCCS

In the *minCCS* scenario without industrial DSM, battery storage is needed over several months to balance the fluctuations in renewables availability (Figure 5, Reference). Investment in Li-Ion battery capacity comprises 41% of the total system costs and is the largest cost contributor. As load-shifting potential is introduced (assuming η = 1, t_{SC} = 12 *hours*), the required battery capacity decreases, reducing costs by 4.4%. However, the reduction in installed battery capacity stagnates at low load-shifting potential (*iflex* = 0.05) (Figure 2): small load-shifting potential is sufficient to shave off peak battery capacity. Thus, for smaller storage capacities, a small amount of load-shifting potential yields most of the benefits from industrial DSM. As storage capacity increases, the battery capacities decrease significantly due to the long-duration flexibility that industrial DSM provides: a 6 month storage capacity reduces the battery capacity required for inter-day storage by 59% relative

to a 12 hour storage capacity (Figure 5, 6 months). The large reduction in battery capacity drives the highest cost reductions across all three scenarios of 27%. It must be noted that the *minCCS* scenario represents an extreme scenario with no imports of electricity or natural gas for electricity production. Thus, the magnitude of the cost reduction serves as an upper bound on reductions from industrial DSM.

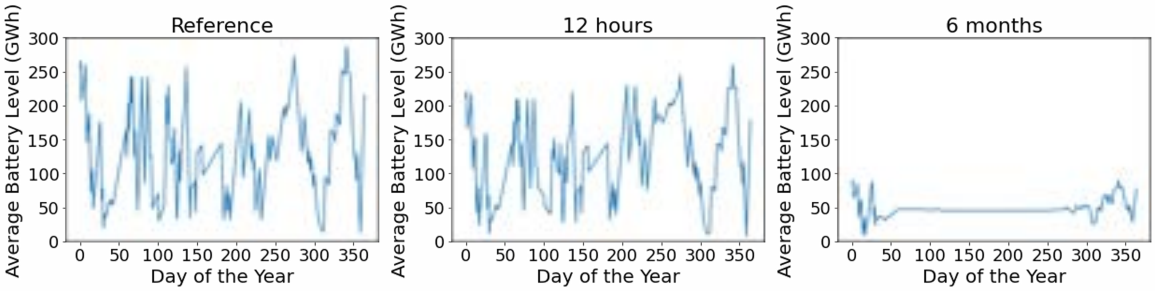

Figure 5: minCCS scenario: average daily battery storage level across storage capacities. The Reference case corresponds to no industrial DSM. The 12 hour and 6 month storage capacity plots assume 100% load-shedding potential (*iflex* = 1) and 100% discharge efficiency (η = 1).

3.2. Storage Capacity

The effect of storage capacity on the contributions from industrial DSM differs for each scenario and depends on whether industrial DSM provides a beneficial alternative for flexibility over longer time horizons. Storage capacity exhibits a saturation, above which contributions from industrial DSM stagnate. The saturation capacity is qualitatively determined based on the results and explained in the subsequent paragraphs.

In the *CCS_lowprice* scenario, storage capacity has little impact on the cost reductions associated with industrial DSM, as explained in section 3.1.1. The saturation capacity for the *CCS_lowprice* scenario can thus be observed at 12 hours. In the *CCS_highprice* scenario, natural gas imports exhibit a step decrease at a storage capacity of 1 month, indicating the displacement by industrial DSM for long-duration flexibility. The saturation capacity for the *CCS_highprice* scenario can thus be observed at 1 month. In the *minCCS* scenario, the installed battery capacity exhibits a step decrease at a storage capacity of 1 week. This phenomenon explains the jump in % cost reduction between 1 day and 1 week for the *minCCS* scenario shown in Figure 2. Storage capacities larger than 1 week do not lead to significant additional cost reductions for a system with 100% discharge efficiency. At lower discharge efficiencies, however, the effect of storage capacity can be more significant, as explained in section 3.3. and shown in Figure 2 (bottom row, third column).

All scenarios exhibit a maximum useful storage capacity determined by the duration, t_{SC}, at which industrial DSM displaces the long-duration flexibility alternatives. If industrial DSM contributes no long-duration flexibility benefits relative to the flexibility alternatives, then small storage capacities are sufficient to obtain the maximum cost reductions from industrial DSM.

3.3. DSM Losses

For all scenarios, efficiencies must be above a certain threshold to obtain benefits from industrial DSM. However, the threshold efficiency varies depending on the scenario, and can also be affected by the storage capacity. For the sake of comparison, we focus the following discussion on an *iflex* value of 1 and define a threshold efficiency as the efficiency at which 20% of the maximum cost reductions are reached (Figure 6, red lines).

In the *CCS_lowprice* and *CCS_highprice* scenarios, the threshold efficiency decreases by approximately 10% from a 12 hour to a 6 month storage capacity. However the threshold efficiencies differ. The *CCS_lowprice* scenario exhibits threshold efficiencies between 45% and 55% whereas the *CCS_highprice* scenario exhibits threshold efficiencies between 30% and 40%. In the worst case across both scenarios, corresponding to the *CCS_lowprice* scenario with a 12 hour storage capacity, cost reductions up to 20% can still be obtained with discharge efficiencies below 55%.

In the *minCCS* scenario, storage capacity has a more significant effect on the threshold efficiency (Figure 2, bottom row, third column). The threshold efficiency decreases from 37% to 3% from a 12 hour to a 6 month storage capacity (Figure 6, row 3). In the case of a 6 month storage capacity and low efficiencies around 3%, the system shifts its use of renewable electricity in the summer from synthetic methane production to additional industrial production. The system overproduces industrial goods throughout the summer, requiring large storage capacities. As a result of reducing synthetic methane production, more natural gas for heat

production is imported. However, importing additional natural gas is significantly cheaper than the battery capacities needed without industrial DSM, and thus large cost reductions are seen even at low efficiencies when storage capacities enabling seasonal storage are available. For smaller storage capacities, the significant overproduction during the summer is not possible and thus higher efficiencies are needed to yield comparable cost reductions to the 6 month storage capacity.

Our results show that industrial DSM can reduce costs even for efficiencies as low as 3%, depending on the costs of the system's flexibility alternatives. Therefore, even processes with high storage losses or low part-load efficiencies could reduce system costs through industrial DSM.

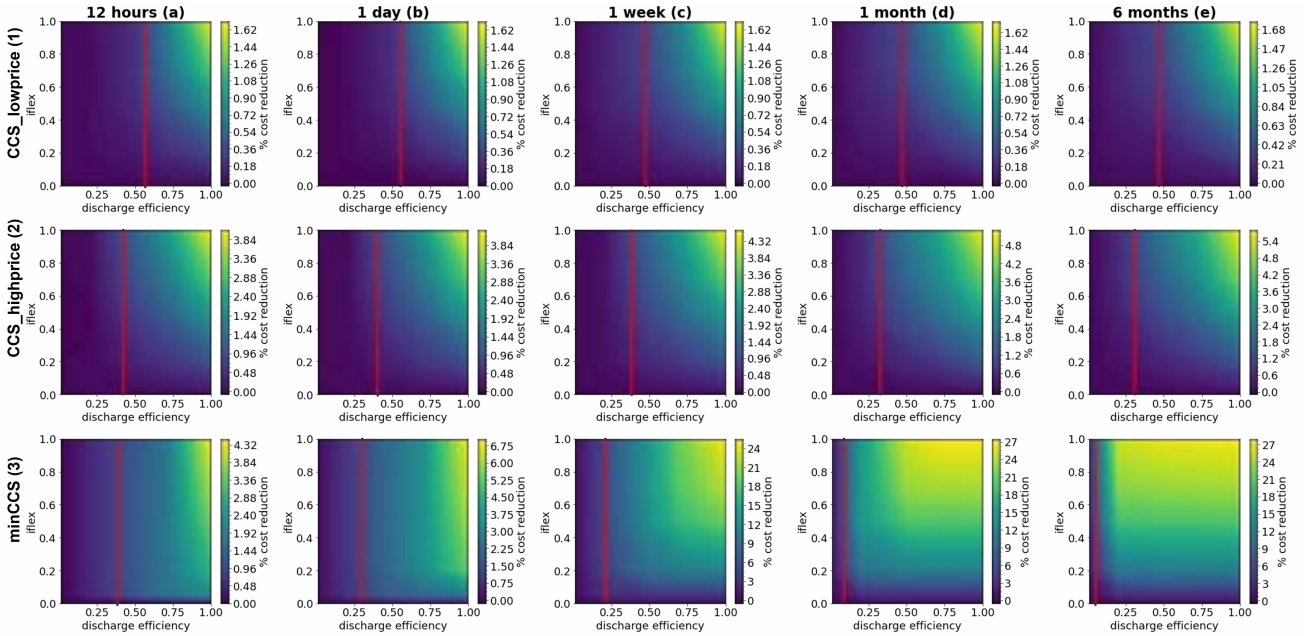

Figure 6: % cost reduction for the net-zero sector-coupled system for different values of iflex and discharge efficiency, η, vs. the reference case of zero iflex and η. Rows correspond to scenarios (numbers) and columns correspond to the storage capacity in terms of the storage capacity time interval, t_{SC}, over which the demand for goods, d_{goods}^{base}, is accumulated (lower case letters). Red lines indicate the efficiency corresponding to 20% of the maximum cost reduction, when considering *iflex* = 1.

4. Conclusions

In this study, we investigate the potential of industrial DSM as a flexibility provider to a net-zero sector-coupled energy system. Specifically, we investigate cost reductions and the change in deployment of other flexibility options due to industrial DSM. We focus on the Swiss sector-coupled energy system comprised of the electricity, heating, and private transportation sectors. To study the effects of industrial DSM, we carry out a parameterized study with three parameters representative of industrial DSM characteristics: load-shifting potential, storage capacity, and DSM losses. We consider three scenarios ranging from cheapest alternative flexibility to industrial DSM to most expensive.

We find that industrial DSM reduces costs for all three scenarios. However, the magnitude of the cost reduction depends on the system's alternative flexibility options, particularly for flexibility over time horizons longer than 12 hours. Thus, the value of industrial DSM must be evaluated within the context of the overall energy system. In a system with inexpensive natural gas imports and the ability to produce electricity from cheap natural gas with CCS (*CCS_lowprice* scenario), industrial DSM reduces costs by up to 1.7%. In a system with electricity only from renewable energy sources (*minCCS* scenario), the maximum cost savings from industrial DSM are 27%. The difference arises because in the *CCS_lowprice* scenario, direct air capture serves as an inexpensive alternative long-duration flexibility option whereas in the *minCCS* scenario, batteries serve as an expensive long-duration flexibility option. Therefore, potential cost reductions from industrial DSM for the *minCCS* scenario are much higher.

We also find that while cost reductions from industrial DSM depend on the industrial DSM characteristics, the influence of the characteristics on cost reductions depends on the interactions with the system's alternative flexibility options. For example, increasing load-shifting potential can have either a linear or a non-linear effect on cost reductions depending on the resulting deployment of the alternative flexibility options. Depending on

the relationship, small load-shifting potential may be sufficient to yield large cost reductions for the system. Storage capacity reaches a saturation capacity, above which contributions from industrial DSM stagnate. The saturation capacity depends on the long-duration flexibility benefits that industrial DSM provides. If industrial DSM provides little to no long-duration flexibility benefits, such as in the *CCS_lowprice* scenario, smaller storage capacities are sufficient to obtain most cost reductions from industrial DSM. Otherwise, contributions stagnate beyond the capacity at which industrial DSM displaces the alternative long-duration flexibility options. Regarding DSM losses, industrial DSM can reduce system costs despite high DSM losses depending on the costs of the alternative long-duration flexibility options. The *minCCS* scenario exhibits 20% of the maximum cost reductions from industrial DSM with only 3% efficiency due to the high costs of Li-ion batteries.

Based on our study, we conclude that while industrial DSM can serve as a flexibility provider to a net-zero sector-coupled energy system, the magnitude of the contributions highly depends on the flexibility alternatives for the system. Particularly, industrial DSM is most beneficial when industrial products can be stored seasonally and long-duration flexibility options are missing or expensive. Therefore, both the characteristics of industrial processes and the system's characteristics must be considered when evaluating flexibility provision from industrial DSM.

In this work, we aggregate all Swiss industry energy demands and assume that the energy demands can be shifted all together. As our results show potential, future research should focus on obtaining a more precise estimate of the potential flexibility provision from industrial DSM in Switzerland. We suggest differentiating between industries and introducing industry-specific, time-dependent energy demand profiles. The ranges of the considered industrial DSM parameters can also be adapted to better-fit the operation of the specific industries. Additionally, we suggest comparing the resulting system cost reductions from industrial DSM to the costs that industries would incur to implement DSM measures, such as investments in over-capacities and storage containers. This comparison would allow for a better estimate of the cost benefits from industrial DSM to the Swiss energy system.

Abstract:
The process industry is facing the green transition from conventional to renewable energy sources. Executing it in a cost-effective manner will require increased energy efficiency, electrification, and a clear overall strategy from the beginning. A prerequisite for a strong strategy is an energy mapping that describes the energy use within an industrial facility. However, creating such a mapping can be expensive and time-consuming.

The primary goal of the proposed process mapping methodology is to effectively obtain production and energy data from industrial plants in a short time. This can be analyzed to provide a generic, holistic, and flexible model. The model is a step towards creating a software tool that generates energy flow mappings for industrial end-users to make energy optimization decisions. In addition to documenting energy flows, the tool supports the continuous improvement of the energy mapping itself and the actual energy use.

The required data is collected by reviewing existing specifications of production facilities, complemented with interviews with personnel working on the production lines, as well as other on-site investigations. The information is then entered into the developed model, which produces energy flow mapping as output. The model' s output can then be used to gain an overview of the primary energy used and identify future opportunities for energy optimization, electrification, and decarbonization of industrial sites. An industry use case has successfully illustrated the performance of the model reaching 88% accuracy.

Energy mapping, Generic model, Support tool, Green transition, Decarbonization of industry

1. Introduction

The global challenge of achieving emission reductions and climate neutrality necessitates the prioritization of resources across various industries and sectors worldwide. In many countries, including Denmark, the manufacturing industry significantly contributes to energy use and greenhouse gas emissions. In Denmark specifically, the manufacturing industry accounts for 160 PJ or 21% of final energy use [1]. Consequently, optimizing energy use becomes crucial when it comes to industrial processes. However, energy mapping can be costly, as it requires a detailed understanding of the process at hand.

Recent studies indicate that the current trends and implementation of existing policies aimed at reducing primary energy use in Europe will not achieve a 20% improvement in energy efficiency [2]. Various barriers hinder the adoption of energy-efficient technologies and practices, as categorized by Sorrell et al. [3]] in a taxonomy that compiles important contributions from literature. These barriers are divided into economic, organizational, and behavioral aspects, with fifteen different barriers identified as significant in literature. The study highlights the high cost associated with gathering, analyzing, and applying information, as well as the lack of information leading to missed opportunities for cost-effective energy efficiency. Additionally, the

perceived cost of energy conservation has been recognized as a barrier to industrial energy efficiency investments in Greece [4].

Furthermore, Bunse et al. [5] conducted a review of methodologies for incorporating energy efficiency performance into production management and found that most industrial companies still lack effective methods to comprehensively and practically address energy efficiency. The authors attribute the gap between industrial needs and scientific literature to several reasons, including the complexity of production sites, which often operate multiple production processes to meet business needs, variability in energy intensity factors across different products, and isolated analysis of specific energy use without considering production operations. Consequently, there is potential for misleading conclusions when attempting to account for all variables associated with energy efficiency. Additionally, the authors note that analyzing thermal energy usage is more challenging in practice compared to analyzing electrical usage.

Currently, existing software designed for energy mapping focuses on the entire process operation, requiring a high level of detail and many input parameters. In many cases, these parameters are unknown, resulting in unnecessary efforts on details that may have little importance for actual energy optimization. Alternatively, using Excel software as a tool for energy mapping is challenged by the complexity of systems, causing the program to become too slow for practical use. Additionally, achieving accurate results with Excel requires decent experience in energy mapping and the calculation tool.

Energy mapping is currently mandated under the European Union's Energy Efficiency Directive (EED) [6]. It is the first step in performing mandatory energy audits every four years, to develop projects that increase energy efficiency. Complying with the DS/EN ISO 50001 "Energy Management Systems" also requires companies to perform an "Energy Review" with the same core ideas, establishing key performance indicators (KPIs) and identifying significant energy users (SEUs).

The primary goal of the project presented in this study is to develop a generic, holistic, and flexible process mapping methodology that efficiently obtains production and energy data from industrial plants within a short time frame. The aim is to describe at least 85% of thermal energy used at any industrial facility, using only a few days on-site with qualified staff and an additional day for preparations and fine-tuning. This approach enables the creation of energy mappings in a cost-effective and efficient manner, contributing significantly to the transition towards a greener process industry. By making energy audits cheaper and faster, the number of energy mappings created each year is expected to increase, thereby reducing energy use and quantifying optimization potential [7]. Moreover, studies [8,9] have demonstrated that energy efficiency measures can have a broader impact beyond energy savings, such as process, facility, and organizational levels. These measures can also lead to non-energy benefits, such as increased productivity, improved product quality, reduced costs of environmental compliance, decreased carbon and emission footprint, and lower waste disposal expenses, among others. Worrell et al. [10] have compiled a comprehensive list of non-energy benefits associated with energy efficiency technologies.

In addition, the model presented in this study is a step towards creating a software tool that generates energy flow mappings for industrial end-users, enabling decision-making with energy optimization in mind. The tool supports the continuous improvement of the energy mapping itself and actual energy use. It also serves as the foundation for continuous generation of energy savings, turning a single-shot approach to energy mapping into an ongoing cyclic process, aligning well with the current trend towards increasing energy efficiency targets.

Such a tool can provide sufficient data from numerous manufacturers required to train machine algorithms designed for energy management in different types of processing activities, introducing the digital twin concept for industrial energy systems, intelligent recommendations, and demand-side management in the future.

2. Method

2.1. Generic process mapping approach

The primary goal of the proposed process mapping methodology is to effectively obtain production and energy data from industrial plants in a short time. This data can then be analyzed to provide a generic, holistic, and adaptable model that covers the following perspectives.

- The model should be generic in nature, making it applicable to diverse production plants, ranging from small and medium-sized companies (which typically face obstacles towards energy-efficiency measures) to large-sized companies.
- It should pursue a holistic perspective on the relationship between manufacturing processes and energy usage, encompassing all relevant processes and energy flows.

- The model should be adaptable to changes in the production environment, such as equipment relocation or process improvement.
- It should provide a data set for multi-dimensional evaluation, including energy savings, electrification, and carbon neutrality strategies in all relevant fields of action. Additionally, it should support the continuous improvement of energy mapping.

The methodology consists of four main steps and several sub-steps, as illustrated in Figure 1, and described in the following text. These steps are generally applied to all production lines and can be scaled up and/or aggregated to the factory level. The outcome of the calculations and data validation also serves as the basis for iteratively improving the quality of the energy mapping. By gradually adding more sensor data and reducing uncertainties one node at a time, the user can maintain an overview of the overall plant operation while working with individual components.

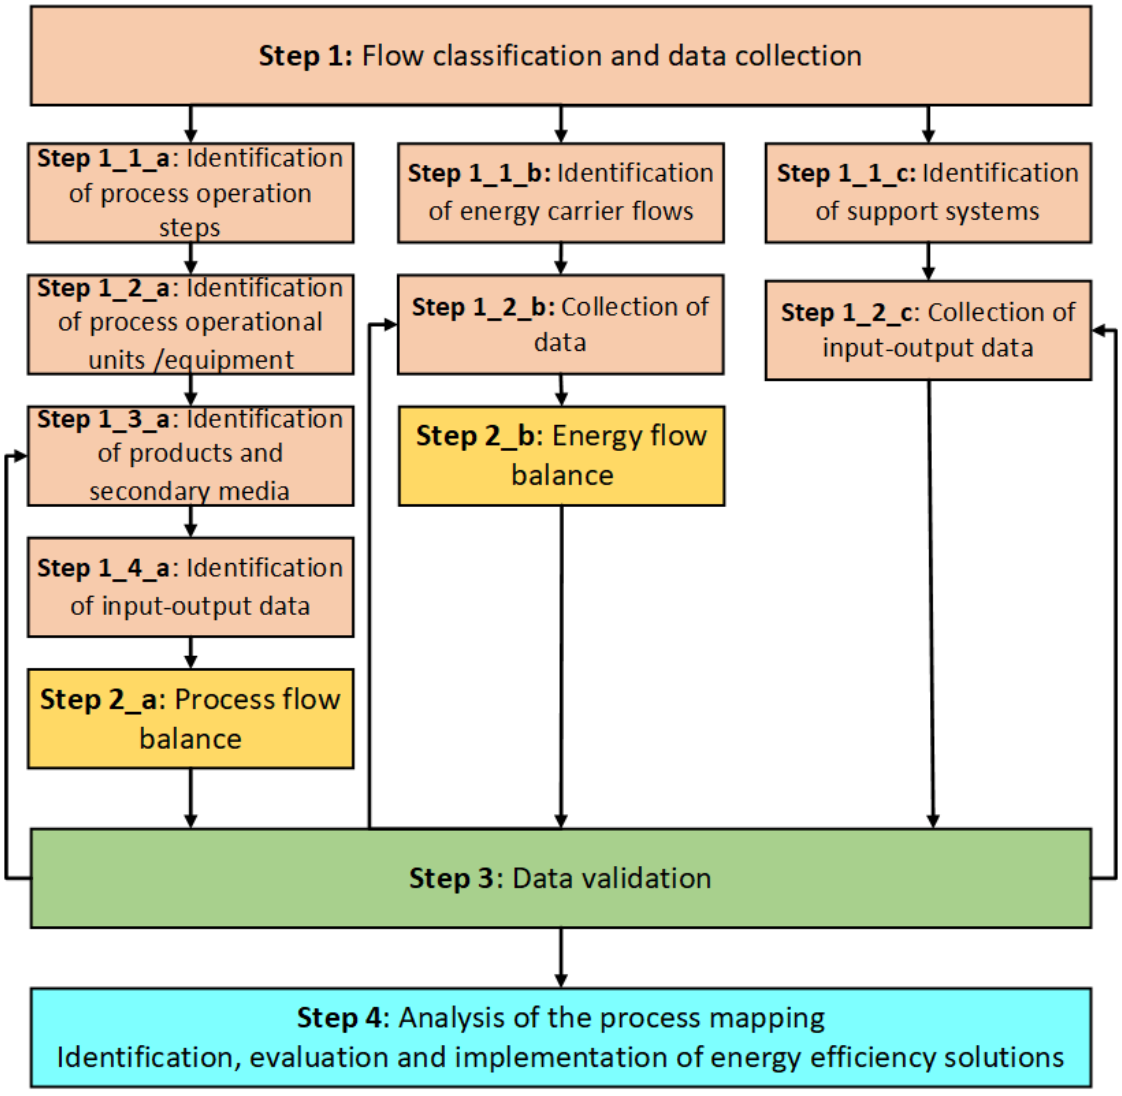

Figure. 1. The proposed methodology consists of 4 main steps and several sub-steps

Step 1: Flow classifications and data collection

Effective flow classifications and data collection are essential for developing a comprehensive understanding of energy use within production plants. This understanding will lead to the identification of areas of energy inefficiency and waste, facilitating the development of strategies for overall energy efficiency improvement in the future. Flow classifications involve categorizing energy usage based on its source, form, and utilization within a production process. This includes identifying the various inputs and outputs of energy within the facility, as well as how energy is transformed and used by different machines, equipment, and production lines. Data collection is the process of gathering and analyzing information on energy usage in a production environment, which can be done in various ways.

To further understand the amount of energy use in production plants, it is crucial to map out the flow of energy within an industrial facility, categorize energy usage, and analyze its correlation with production processes and outputs. Raw materials are consumed in production processes, which convert them into products, along with potential by-products that may or may not be desirable. These processes often require a significant amount of energy, which is partially utilized for value-added activities contributing to the final form and composition of products. However, the remaining energy is wasted in the form of heat losses and emissions. It is important to understand not only the operation of the equipment but also the actual energy requirement from the process. This is achieved by establishing a process flow balance, which involves tracing the flow of the product through process operations (POs) from start to finish and accounting for the mass and energy balance of each PO, as explained briefly in step 2. Energy mapping utilizes streams to track the conversion paths of different forms of primary inputs, such as chemical energy, electrical energy, and thermal energy.

The concept of flows allows for the design of a structure that can serve as the foundation for a software application. The data structure should be designed with various processes in mind and be tested with a variety of applications and industries. By applying these steps to a production environment, the relationship between process, equipment, and energy usage is highlighted, providing insights into how production activities function within an industrial facility and how energy and production are interconnected.

Production flow (sub-steps: 1_1_a -1_4_a)

Step 1_1_a: Identification of the process operational steps

The entire production line can be further divided into different process operational steps. Each process step can be defined and labeled according to production specifications or internal factory documents. Understanding the current production system and breaking it down into appropriate steps will provide a solid foundation for the energy mapping and future assessments. This involves identifying the individual process steps, their sequence, and the inputs and outputs for each step.

Step 1_2_a: Identification of the process operational units/equipment

Once an industrial process has been selected, the next step is to describe the existing process steps and their corresponding unit operations and equipment. This can be achieved by assuming that the product flow passes through several blocks, which can be arranged in parallel, series, or loops. Each block represents a unit operation with significant energy demand, such as pasteurization, boiling, evaporation, drying, and distillation, along with their respective subprocesses, if applicable. The equipment used for each process is then identified, along with the quantity of equipment per step. While a real production plant may consist of many process operation units and components, the focus should be on those with the highest energy demand. Table 1 presents list of process operational units and equipment that can be included in this part.

It is important to note that there may be many interconnections between the process step and process equipment, as well as primary and secondary production flows, but simplification is necessary to illustrate that each product will only follow one main path through the process.

To ensure consistency throughout the energy mapping process, the basic operational blocks developed in the previous step should be reused. This necessitates testing the proposed blocks and interconnections in various production plants and refining them to establish a robust foundation for future implementation in the software tool.

Table 1. List of process operational units and equipment that can be included

Process operational units and equipment				
Mechanical	**Thermal (indirect)**	**Thermal (direct)**	**Electric**	**Heat transfer**
- Collector - Mixing, stirring, suspension, sedimentation, wetting, absorption - Splitters - Separation of flows, filtration, extraction, centrifuge, decanters, press	- Evaporator - indirect drying - Boiling - Baking - Distillation - Reactor	- Drying - Stripping	- Compressor - Induction cooker	- Warm up - Cooling - Pasteurization - fermentation

Step 1_3_a: Identification of the products and secondary media

The amount and type of raw materials used in the production process, as well as the flow of products through the process, should be recorded annually and updated regularly. This information can be used to track changes in the amount and type of raw materials used in the production process, as well as changes in the flow of products through the process.

Apart from the main production flow, it is important to identify the secondary media used in each operational unit to heat up, cool down, pasteurize, or wash the main product flow. These secondary media could be anything used to transfer heat to or from the product flow, such as air, water, or steam, etc.

For example, in a drying operation, hot air might be blown into the dryer to heat up the product. In a pasteurization or washing operation, hot water might be sprayed into the unit to pasteurize the main product or to wash the equipment used in the production line. In some cases, steam might be injected directly into the product flow to increase the temperature of the product flow or change its consistency. In all these cases, the secondary media requires energy, which should be accounted for in the energy use of the operational unit process.

Additionally, this information can also be used to evaluate the effectiveness of different energy-saving strategies, such as optimizing the use of secondary media or using alternative methods to heat up, cool down, or pasteurize the product flow in the future**.**

Step 1_4_a: Collection of input-output data

In this step, all inlet and outlet data of the product and secondary flows in production lines are collected, along with their respective state conditions, such as temperature, pressure, mass flow rates, specific heat, and other relevant parameters.

If energy meters are installed at this step, the information can be gathered from the energy monitoring system. Otherwise, the required data is collected by reviewing existing production specifications complemented with interviews with personnel, such as production associates, supervisors, and managers, as well as other on-site investigations, information from control rooms, and manual calculation of the remaining required information.

Step 1_1_b: Identification of energy carrier flows through the facility

The main objective of this step is to identify the main energy supply systems, including electricity, heating and cooling utilities, and their corresponding purchasing, conversion, and transmission processes.

Energy carrier flows are the sources of energy that supply electricity, steam, or other forms of energy required for powering equipment, heating, and cooling in an industrial plant. These sources can either be purchased from outside (i.e., electricity from the grid or heat from district heating network) or generated on-site by converting primary energy sources, such as natural gas, oil, coal, biomass, or renewable sources, such as solar, wind, or geothermal energy.

To convert primary energy sources into usable energy, various types of equipment, such as boilers, cooling systems, heat pumps, turbines, generators, and motors, are used. These systems can transform energy from one form to another. Heating utility refers to systems or equipment that provide heat energy to a process or facility. The source of heat energy can be steam, hot water, thermal oil, or combustion gases from a furnace, boiler, or heat pump. On the other hand, cooling utility removes heat energy from a process or facility by consuming a certain amount of electricity, depending on the system's coefficient of performance (COP). Cooling utilities can be supplied through cooling towers, chillers, or refrigeration systems, and the source of cooling energy can be air, water, or other fluids. These heating and cooling utilities are commonly used in various industrial processes, such as chemical reactions, food processing, and manufacturing, where temperature control is critical. The temperature and flow rate of the heating and cooling utilities are usually monitored and controlled to ensure that process conditions are maintained within the desired range.

Energy transmission refers to the distribution of energy from the source to the end-use consumers, which can involve various transmission systems, such as pipelines for transporting natural gas or liquids, electrical grids for transmitting electricity, and piping systems for delivering steam, hot water or cooled fluid. The end-use consumers can be divided into different categories of production processes, support systems, space heating, or even direct delivery to a district heating network.

In addition to supplying energy, industrial plants can also implement various energy recovery and conservation measures to improve efficiency and reduce costs. Heat recovery systems can capture waste heat from one process and reuse it in another, reducing the need for additional energy input. Compressed air systems can

be optimized to reduce energy consumption, and motors and pumps can be upgraded to more energy-efficient models.

Step 1_2_b: Collection of data
Data collection for electricity consumption, heating, and cooling utilities in an industrial plant typically involves gathering information on various aspects, such as:

- Electricity consumption: This typically involves identifying the equipment with the highest electricity consumption, such as motors, pumps, fans, compressors, and conveyors. The common methods of collecting electricity consumption data can be smart meters, manual meters, and billing data.

- Heating and cooling utilities: This includes the amount of heat generated by the heating equipment (e.g., boilers, furnaces, heat exchangers), the type of fuel used (e.g., natural gas, oil, biomass), and the efficiency of the heating systems. It also includes the amount of cooling generated by the cooling equipment (e.g., chillers, cooling towers, heat exchangers), the type of refrigerant or cooling medium used (e.g., water, glycol), and the efficiency of the cooling system.

Excess heat recovery: Any excess heat that is recovered from process equipment or buildings and reused for other applications. This includes information on the heat recovery equipment (e.g., heat exchangers) and the amount of heat recovered.

The required data for the last parts can be collected through various means, such as using sensors and meters installed on the heating and cooling equipment and piping network to monitor temperature, pressure, flow rate, and energy use. Data can also be collected manually by taking measurements at specific intervals or by reviewing equipment logs and maintenance records or interviewing personnel.

Step 1_1_c: Identification of support systems
In an industrial plant, support systems are crucial for the efficient and safe operation of the facility. One important support system is cleaning in place (CIP), which allows for the cleaning of process equipment and piping without disassembly. Additionally, industrial plants may have other support systems in place, such as:

- Water treatment systems: Since industrial processes often require large amounts of water, water treatment systems may be necessary to ensure that the water is safe for use and meets the required quality standards.
- Waste treatment systems: Industrial processes can generate waste products that must be treated or disposed of properly to prevent environmental contamination.

Step 1_2_c: Collection of input-output data
To collect energy data for support systems in industrial plants, it is typically necessary to gather information on equipment specifications and energy requirements for running the systems that support the main production process. Energy meters can be installed on the equipment to measure usage, while energy bills and consumption records can be reviewed to track energy use. Here are some examples of energy data that may be collected for support systems:

- Electrical power consumption: Monitoring the power consumption of motors, pumps, and other electrical equipment used to support the manufacturing process can help determine the energy usage of support systems.
- Steam consumption: Measuring the amount of steam used to support the manufacturing process can help determine the energy usage of the steam system.
- Water consumption: Measuring the amount of water used to support the production process can help determine the energy usage of the water supply and treatment systems.

Step 2_a: Process flow balances

This step involves conducting energy and mass balances for each unit operation that comprises the industrial processes. Inlet and outlet process streams, along with their respective state conditions (such as temperature, pressure, mass flow, specific heat, etc.), which are collected in previous steps, are used to determine the energy and mass balances of the production throughout the facility based on the first law of thermodynamics.

By conducting the process flow balance, we can understand the energy requirements of the process. Each cooling and heating demand yields a specific energy demand that can be calculated. These demands will vary depending on the amount of product input into the model. All these individual demands are then summed up

to establish the process energy requirement, both in terms of heating and cooling. These energy demands can be reduced and optimized.

Step 2_b: Energy flow balance

An energy flow balance is carried out in addition to the process flow balance, to describe the energy flow through and the efficiency of the utility systems at the process site. It involves four overall sub-steps: “Purchase”, “Conversion”, “Distribution”, and “Energy Use”. The starting point of this balance “Purchase” is the energy bill, based on energy consumed as purchased fuels.

To illustrate, consider the example of a natural gas boiler producing steam for a process. In the “Purchase” sub-step, the purchased energy is examined from the company's bookkeeping to determine the gas input for the boilers. In the “Conversion” sub-step, all conversion losses related to producing steam from natural gas in the boiler are accounted for, including flue gas loss, radiation loss, blowdown, and deaerator. Additionally, conversion gains can be estimated, such as the introduction of valuable heat from waste heat through a heat pump.

The “Distribution” sub-step involves accounting for all distribution losses related to distributing the steam on the process facility, mainly consisting of heat loss from piping and condensate losses. Subtracting all losses from the known purchased amount yields the amount of steam consumed on site. Finally, the “Energy Use” step is the output of the energy flow balance. Figure 2 provides an example of energy supply and energy use and their interconnection, corresponding to four sub-steps of step 2_b.

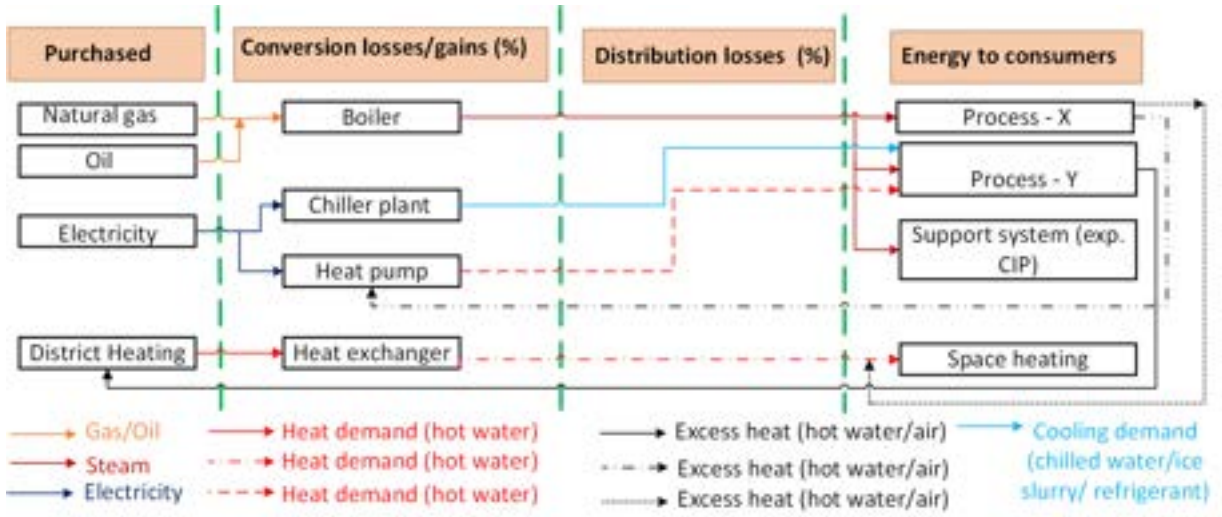

Figure. *2*. An example of energy supply and energy use and their interconnection, corresponding to the four sub-steps of step 2_b. Different arrows of the same color correspond to different temperature levels of similar media

Step 3: Data validation

In an ideal energy mapping scenario, the energy flow balance output (i.e., “Energy use” calculated in step 2-b) should equal the energy requirement calculated from the process flow balance (calculated in step 2-a). However, due to measurement uncertainties, poor data quality, and generalizations of complex processes, some deviation from this ideal situation can be expected. The accuracy of the energy mapping can then be determined as follows.

$$Accuracy = \frac{(Process\ energy\ requierment + Conversion\ losses + Conversion\ gains + Distribution\ losses)}{(Purchased\ energy + Conversion\ gains)} \quad (1)$$

Step 4: Analysis of the process map (including evaluation of energy efficiency solutions and implementation)

Once all the necessary data has been collected, the energy mapping analysis can be completed, and the outputs can be generated. The immediate outputs of a thorough energy mapping exercise include:

- Simple energy overview: This involves identifying trends, patterns, and areas of high energy demand within the production line. Such an analysis can help identify significant energy users (SEUs), equipment KPIs, and efficiencies that can be easily developed and maintained to comply with ISO certifications.
- Pinch analysis: This involves analyzing the energy use in the process in relation to the temperature requirements. The analysis determines the minimum possible demands for heating and cooling utilities. This information can be used for further process integration studies, the integration of heat pumps into the process, and the optimal selection of utilities.

2.2. Case study

The methodology was implemented for a case study to provide a preliminary assessment of its quality. The case study involved a production plant for fishmeal and fish oil. The site descriptions and outcomes of the implementation are detailed below. It should be noted that the proposed method was evaluated up to the end of step 3, while step 4 will be continued in future work.

The production site specializes in the manufacturing of fishmeal and fish oil, operating 24/7. The plant processes fish by-products, such as the remains of fish that are not used for human consumption, to create high-quality protein and oil products. The process begins with the delivery of raw materials to the plant, where they are sorted. The fish is then cooked and pressed to extract the liquid portion, which is separated into fish oil and water. The solid portion is dried and ground into fishmeal. The resulting products are packaged and shipped to customers worldwide. Fishmeal is a valuable source of protein and other nutrients used in animal feed, while fish oil is a rich source of omega-3 fatty acids, which are essential for human health and used in dietary supplements, pharmaceuticals, and other industrial applications.

3. Results

The first three steps of the proposed methodology have been implemented in a production line, and the required data has been collected and evaluated. The results provide a visual representation of the process and energy relationship for the presented production line and are briefly summarized below.

3.1. Case study

Figure 3 and 4 show the general overview of the process steps and process units (sub-step 1_1_a and 1_2_a of the proposed methodology). The process steps identified for the plants are the main production line to produce fish meal, oil cleanser, and deodorization. The identified process steps related to the main production line include process operational units, such as the cooker, presser, dryer, decanter, evaporator, and centrifuge. The oil cleanser and deodorization include process operational units, such as the centrifuge, filter, stripper, and scrub.

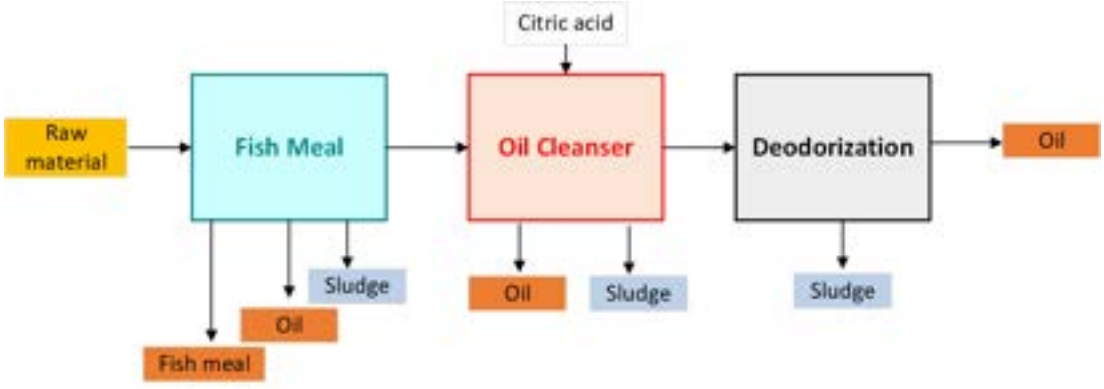

Figure. 3. The process operational steps for the presented case study, corresponding to step 1_1_a of the proposed methodology

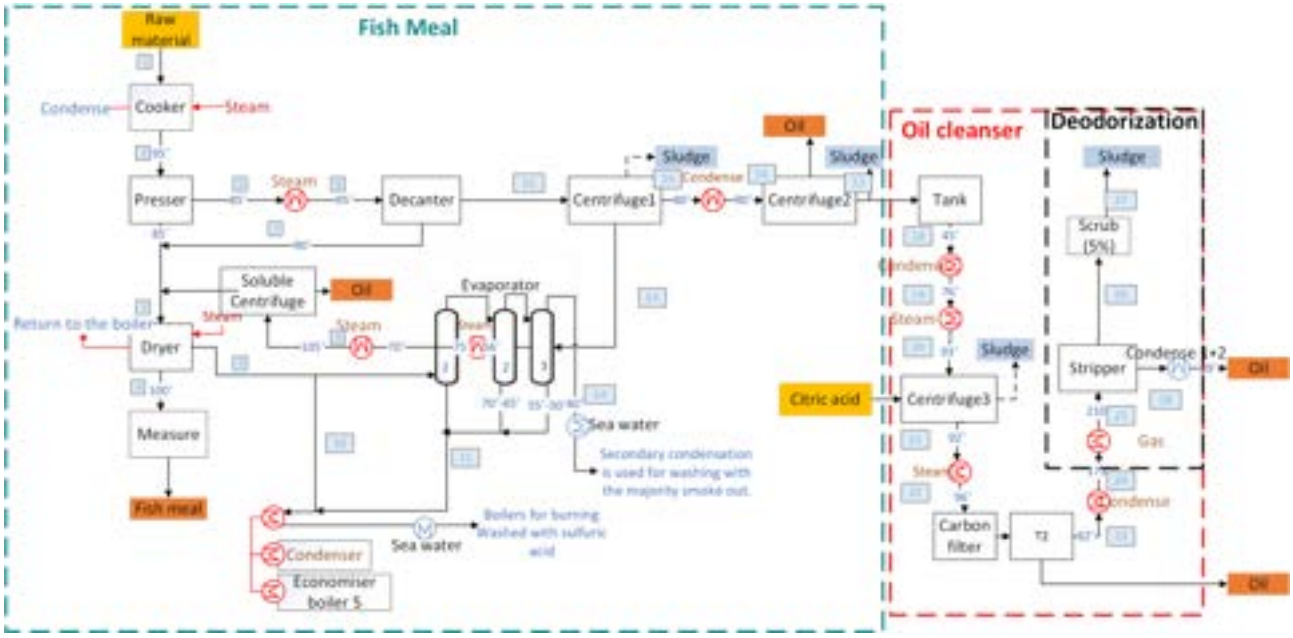

Figure. 4. The process operational units for the case study, corresponding to step 1_2_a of the proposed methodology.

Figure 5 presents the process flow balance (sub-step 2-a), considering the process step related to the main production line to produce fish meal and process operational units that influence the mass balances or final energy use. The required data, including temperature, mass flows, and recipes (fraction of water, fat, and solid), are introduced as input and output data of the main production flow.

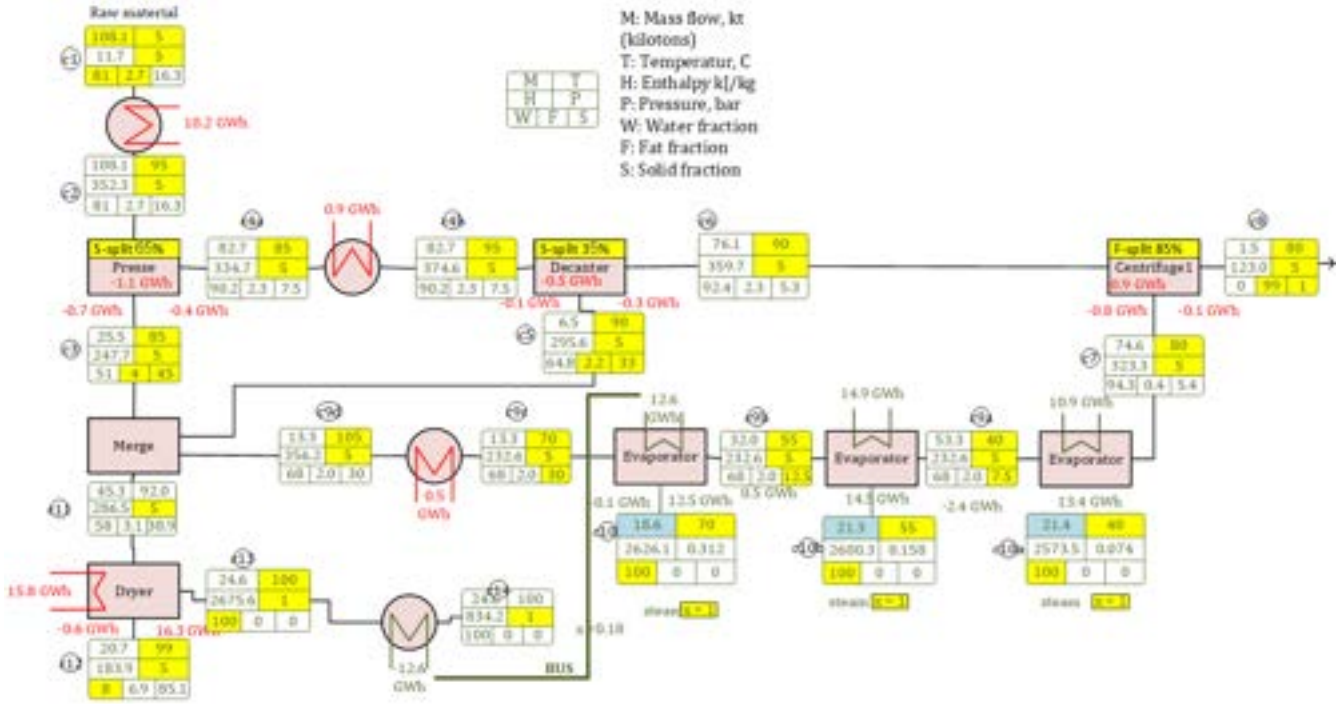

Figure. 5. The mass and energy balance for the case study, corresponding to step 2_a of the proposed methodology.

It should be mentioned that the mass and energy balance presented in Figure 5 belongs only to one type of material. However, in practice, the company has handled three different types of raw materials, equal to 108143, 919221, and 70293 tons/year, which requires a total of 73242561 kWh heating demand.

Figure 6 presents steps 1_1_b, 1_2_b, and 2_b including the identification of energy flows, data collection, and energy flow balances for the presented case study. The steam is generated by five steam boilers mainly

run on oil and natural gas. Table 2 presents the amount of energy calculated in the four sub-steps of step 2_b. It should be mentioned that since the production plant does not have a significant user of a support system such as CIP, steps 1_1_c and 1_2_c have been neglected.

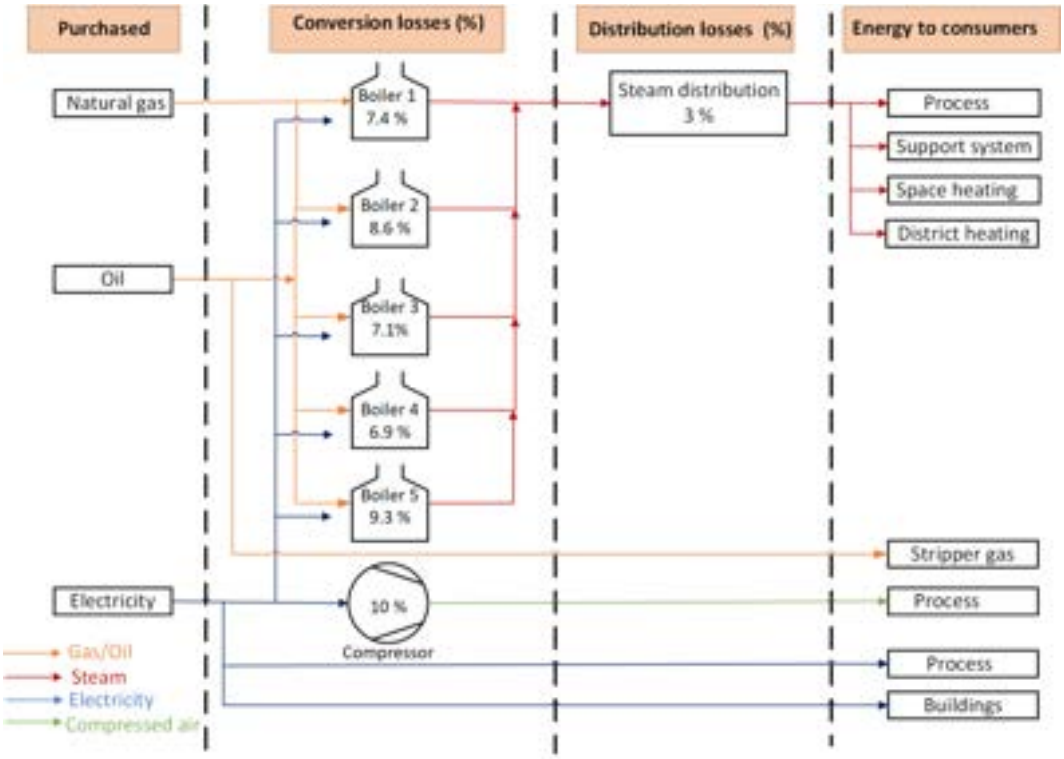

Figure. 6. The energy flows, data collection, and energy flow balances for the presented case study, corresponding to steps 1_1_b, 1_2_b, and 2_b of the proposed methodology

Table 2. The required amount of energy in *four overall sub-steps: "Purchase", "Conversion", "Distribution", and "Energy Use",*

		Heating utility			
		Purchase fuel	**Conversion losses**	**Distribution losses**	**Energy (steam) to end-use consumers**
Equipment	5 steam boilers Using natural gas and oil, with 0.92 - 0.94 % efficiency slightly differ for different boilers	Natural gas: 115184432 kWh Oil: 7619 kWh Total steam produced: 22993535 kWh	6-9 % ≃1701522 kWh for each boiler depending on efficiency Total steam: 105954221 kWh	3 % 3178626 kWh Total steam: 102775585 kWh	Production flow: 73.242.562 kWh (obtained from step 2_a) Space heating: 6.277.252 kWh Delivery to district heating 13.026.300 kWh

Finally, from step 3, Eq.1, an 88 % accuracy of the mapping can be obtained.

4. Discussion

The proposed methodology acknowledges the challenges that may arise when verifying step 3, particularly in diverse and complex production plants. It is crucial to ensure that the interconnections between production flow, secondary media, and utilities are accurately represented to obtain correct values for the process and

energy flow balance. To address this, further verification and validation of the methodology should be conducted across a range of production plants with varying complexities. This will help establish the methodology's robustness and reliability, allowing for adjustments and improvements as necessary.

A comprehensive guideline should also be developed to assist users, especially those in the manufacturing industry who may not be well-versed in energy mapping techniques. The guideline should provide clear instructions and explanations, enabling users to effectively follow and utilize the software developed based on the proposed methodology. To ensure the usability and practicality of the software, it is essential to involve a diverse group of participants in case studies representing different industries. This will enable real-world testing and feedback from consultants, engineers, and production managers who possess domain-specific knowledge and experience. Their involvement will help identify potential challenges, provide valuable insights, and ensure that the software meets the requirements and expectations of various industries. By conducting extensive testing and gathering feedback, the methodology and accompanying software can be refined and optimized to maximize their effectiveness and usability in different production environments.

Figure 7 illustrates a screenshot of the software that is currently under development. The software aims to represent the steps outlined in the methodology and provide a user-friendly interface for conducting energy mapping in production plants. Before the software is officially launched, it is essential to thoroughly test and evaluate its performance and functionality. This testing phase should involve different groups, as mentioned above. By involving these diverse groups, their valuable insights and feedback can be gathered to identify any potential issues, improve usability, and ensure that the software meets the specific needs and requirements of different production environments.

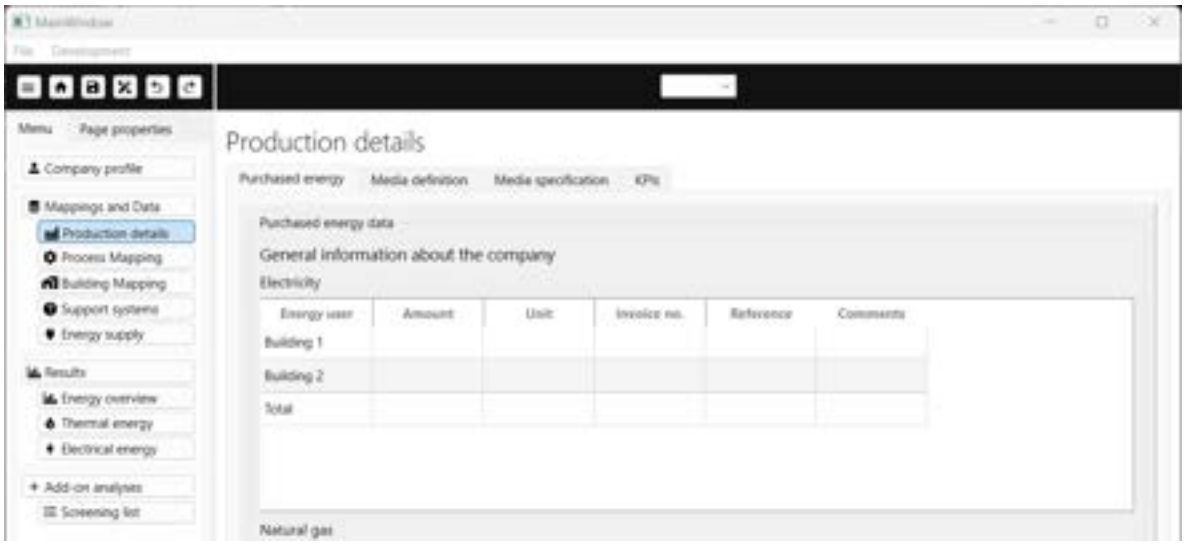

Figure. 7. Screen shot of the current software in the development phase

Conclusion

The paper presented a generic methodology to accelerate the energy mapping of production lines. The performance of individual process steps is modeled with a few inputs following the steps presented in the following methodology. Process operational units representing different operational steps are identified. A few readily available data are collected, while the rest are defined by exploiting engineering judgment, such as the experience of the involved industrial partners visiting the plant, and estimated default values. Being able to bypass blind spots with regards to sensor data allows us to continue the work without costly and time-consuming measurement campaigns. The procedures developed in the proposed methodology thus enable the user to complete an energy mapping that may have been much more difficult to carry out otherwise.

The methodology was implemented in a case study as an examples of Danish food industry. By implementing the methodology in a case study, it was demonstrated that the necessary data can be collected and evaluated effectively, representing 88% accuracy.

The results of the case study showcased the potential of the methodology in visualizing the process and energy relationships within production lines. This enables the identification of significant energy users, equipment key performance indicators (KPIs), and opportunities for improving energy efficiency.

Acknowledgments

The work was financially supported by EUDP, the research and development fund of the Danish Energy Association, under the project (64022-1073) “Efficient Energy Mapping and Analysis for Optimization and Green Transition of Industrial Processes”. The authors thanks FF Skagen A/S for their participation as a case study in the project.

Simplified dispatching method for unlocking energy flexibilities of decentralized energy systems for the day-ahead and balancing power market

Joram Wasserfall[a], Mahmoud Ouso[a] and Stefan Kirschbaum[a]

[a] Society for the Advancement of Applied Computer Science (GFaI), Berlin, Germany, wasserfall@gfai.de

Abstract:

The expansion of renewable energies in the power supply and the shutdown of conventional power plants can only succeed with an advancing flexibilization of the energy system. Decentralized energy systems, such as the energy supply system of a chemical site, can contribute to this, by unlocking the still unused potential for flexibilization. In order to lower the barriers to market participation, user-friendly and simple methods for the economic evaluation of flexibility with regard to the day-ahead and balancing power market are necessary.
Accordingly, in this work a simplified dispatching method considering the day-ahead and the balancing power market in Germany for the mentioned distributed energy systems is developed using mixed-integer linear programming. Linear constraints commonly used in dispatching problems, such as energy balances, conversion efficiencies, and technical constraints, are coupled with new constraints representing the participation in the day-ahead and balancing power market. For the balancing power market the reserve of capacity and the balancing of energy with the uncertainty of calls are taken into account. As a result, the method can be used for day-ahead dispatching by considering the day-ahead energy market and the balancing power market simultaneously.
Because the developed simplified method has low computation times compared to stochastic optimization, for example, it can additionally be applied for hourly resolved annual input data. These evaluations can support strategic planning by determining the economic value of flexibility in the event of market participation. Thus, the results form a starting point for further decisions to unlock unused flexibility.

1. Introduction

1.1 Multi market participation

The expansion of renewable energies in the power supply and the shutdown of conventional power plants can only succeed with an advancing flexibilization of the energy system. Decentralized, small energy systems, such as the energy supply system of a chemical site, can contribute to this, by identifying the existing flexibilities in a first step and offering them on the market in a second step. However, marketing these distributed energy systems goes along with challenges because the systems are complex and the different demands on the site can only be supplied through an integrated operation. In practice, the dispatching is realized in simple systems based on heuristic rules, such as the definition of a switch-on sequence, or in more complex systems based on experienced methods, such as mathematical optimization. Typically, the unit commitment of the decentralized energy systems, such as hybrid renewable systems [1] or combined cooling, heat, and power generation systems [2] is optimized for the participation on the day-ahead market. In most cases, due to the availability of robust and efficient solving methods, mixed-integer linear programming (MILP) formulations are used to minimize economic parameters, such as total operating cost [1–4]. The models, which are mainly based on energy balances, conversion efficiencies, and technical conditions, such as part load behaviour, can be applied to a wide range of large, real world optimization problems. Following this, dispatching can be managed for the day-ahead market of distributed energy systems with several technologies, including renewable energy systems, cogeneration systems, energy storages, or conventional generation [5–7].

The expansion of fluctuating renewable energy sources increases supply uncertainty in the power grid. As a result more short-term system balancing is needed [8,9]. Thus, the demand of flexibility on the short-term markets will also increase in the future. In this changing market environment, it may be economically worthwhile

for the decentralized energy systems to identify their flexible capacity and monetize it on either the balancing-power market or the continuous intraday market in addition to the aforementioned participation on the day-ahead market. However, simultaneous participation in different energy markets is a complex problem that leads to a sequential decision-making process. In Germany and similarly in other European power markets, for example, the balancing reserve capacity auction starts in the morning on the day before delivery. Shortly thereafter, trading on the day-ahead market closes, and the continuous trading on the intraday market starts finally. In this marketing procedure, flexibility that has been already traded on one market can no longer be offered on another market. The optimal behavior with coordinated bidding in the mentioned multiple markets is usually computed by multi-stage stochastic optimization problems [10–12]. In these approaches, uncertainties, such as the request of control energy or the acceptance of a bid in the balancing power market, can be handled. The literature of multi market participation can be classified based on the model complexity of the market on the one hand and on the nature of the portfolio of assets in form of the complexity of the energy system on the other hand. On the market side, the work from [13] considers the day-ahead and balancing power market using averaged prices of capacity and energy without optimizing price bids. Other works optimize only the bids of the capacity price [14] or only the bids of the energy price [15] for balancing power. An even more detailed modeling of the balancing power market taking into account the relevant market rules for capacity and work can be found in [16]. In addition to the aforementioned works with the coupled marketing on the day-ahead and balancing power market, there are more complex models with the additional consideration of the intraday market [12,17,18]. On the energy system side, the developed methods are applied on hydro power plants [19,20], a virtual power plant [21,22], a portfolio with biogas power plants and photovoltaic systems [17], combined heat and power plants [13,23], a cement mill [16], energy storages [24], or a distributed multi-energy system [12].

1.2 Contribution of this work

The presented multi market participation of a decentralized energy system is a cross-sectional topic from the field of energy system engineering with the unit commitment problem and the field of operations research with the optimal trading problem for multiple markets. The combination of these areas leads to the multi-stage stochastic optimization problems that are formulated for the energy system to participate in the multi-market setting. The detailed modeling of the day-ahead, intraday and balancing power market leads to a complex problem with a large scenario tree that is additionally linked to an often no less complicated energy system model. Thus, in case studies, the complexity is usually reduced to keep the problems manageable [17, 24]. However, the methods mentioned remain complicated to handle, for example, due to the modeling of scenario trees, discretization of bid prices or the use of possible reduction methods.

Accordingly, this paper presents an alternative deterministic method that simplifies the described complexity on the market side, taking into account the day-ahead and the balancing power market in Germany, resulting in the following advantages:

1) As complexity on the market side is reduced, complexity on the energy system side can be maintained, and common unit commitment models with constraints for start costs, load changes, or piecewise linear characteristics can be used. Thus, an easy integration into possibly existing dispatching procedures using existing MILP-models is possible.
2) Due to the low computation times, the developed method can be used not only for dispatching but also for strategic planning by using hourly resolved annual input data. In comparison, the temporal resolution of the mentioned case studies is, for example, a quarter-hourly resolution of 18 typical days [18] or an hourly resolution for four typical weeks [13]. However, based on such results, the economic value of the different flexibilities or units in the energy system in case of a market participation can be quickly determined. These evaluations are of interest to companies planning to enter a specific market. They form a starting point for further decisions to unlock the unused flexibility.

Another aspect that is relevant in the energy transition is the changing actor structure. As more and more small players, who do not have the capacity to apply multilevel stochastic programming methods, enter the market, the demand on user-friendly, simplified methods increases. For the small market players, such as the operators of decentralized energy systems, the market entry is accompanied by technical and economic risks, which are caused by the additional personnel and administrative effort on the one hand and by the changed operation modes of the units, which are adapted to the market, on the other hand. Based on the developed method, some of the risks can be minimized, because the behavior of the energy system during market participation is calculated while the economic value of the flexible capacities can be estimated.

2.Simplified dispatching method for the day-ahead and balancing power market

The proposed method allocates the flexible capacity of a distributed energy system to the balancing power and the day-ahead market. In a first chapter 2.1, the constraints for the German short term electricity and balancing power market are presented. In order to investigate the mechanisms of the balancing power market,

historical data is analysed in a subchapter. Based on this, subchapter 2.2 presents the developed methods with their respective modelling equations.

2.1 Short term electricity and balancing power market in Germany

Germany's electricity market design is similar to the EU's overall electricity market design, but with some specific characteristics and features. The design of the balancing power market in Germany has undergone some adjustments in recent years. To ensure consistent market constraints, we focus on the rules for the period 08/01/2019 to 07/31/2020 in this work.

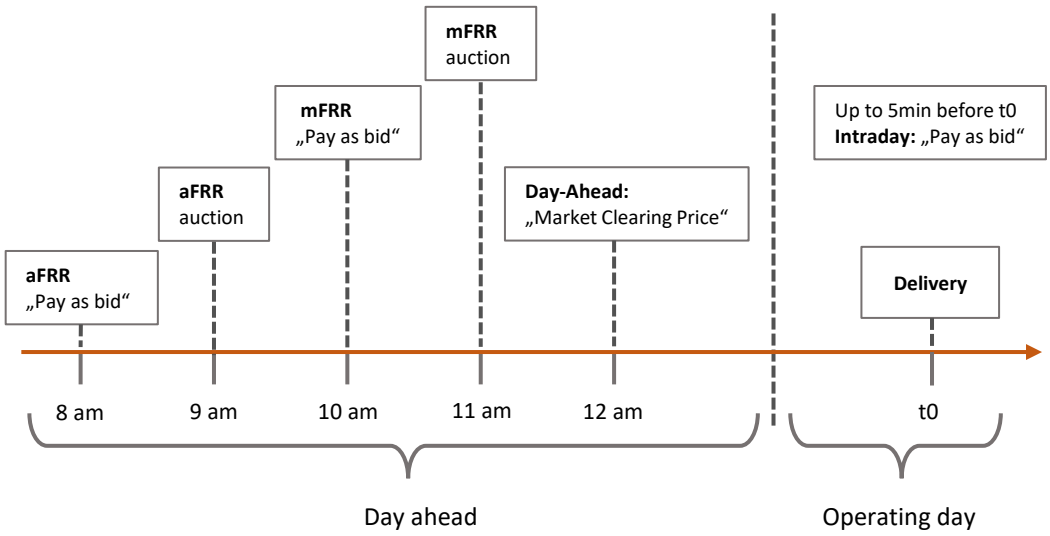

Figure 1: Germany's electricity market design with trading deadlines for the secondary (aFRR) and tertiary (mFRR) reserve of the balancing power market, followed by the day-ahead auction and the continuous intraday trading.

day-ahead market. In the balancing power market, balancing power is traded in the form of automatic frequency restoration reserve (aFRR) and frequency restoration reserve with manual activation (mFRR) in pay-as-bid procedures. For both products, suppliers can submit bids for 4-hour time slices for positive or negative control energy. In addition to the capacity quantity, the participants offer a price for the reserve of the capacity and an energy price for the actual request of balancing power. The tenders have to be submitted for aFRR by 9 a.m. The auction results are published at 10 a.m. This is followed by an equivalent procedure for the mFRR with the results being published at 11 a.m. The transmission system operator (TSO) realizes in a two-stage procedure the procurement of aFRR and mFRR. In the first stage, a merit order is used to select which suppliers are accepted. The decision is based on the capacity price bids and the total balancing power demand, which is determined by the TSO. In the second stage, a merit order for the operating day is formed from all the suppliers accepted in the first stage. The merit order is based on the energy price bids. If balancing power is needed, the suppliers with the lowest energy prices are called up first. In this paper, we focus on the aFRR market, which is the most important balancing power market in Germany with the highest demands [25].

On the day-ahead market, electricity is traded in hourly contracts for the following day. The market closes at 12 p.m., and results are published at 1 p.m. Trading on this market is subject to the market-clearing principle, where the last accepted bid sets the price for all transactions.

2.1.1 Historical data of the balancing power market

This Section analyzes the historical data of the balancing power market for the mentioned one-year period 08/01/2019 to 07/31/2020. The evaluations are based on raw data with a resolution of four seconds from the platform regelleistung.net [26]. In a first step, the request probabilities for positive and negative aFRR are calculated as a function of the energy price bids for the respective 4 h time slices of a day, as illustrated in Figure 2. Following the work of [27], the request probability results from the number of all 4-second blocks with request of aFRR for the respective energy price, divided by the total number of 4-second blocks. The results show a decrease of the request probability with increasing energy prices for positive and negative aFRR. For positive aFRR, the most frequent calls were made in the range below 40 EUR/MWh with a probability of about 50 %. In the energy price range from 40 EUR/MWh to 100 EUR/MWh, there is a large gradient where the number of requests strongly depends on the energy prices offered.

For the negative aFRR, electricity is supplied from the grid during the request, leading to profitable negative energy prices, as seen in Figure 2 (right). The request probabilities for negative aFRR are highest at energy prices below minus 20 EUR/MWh with 50%.

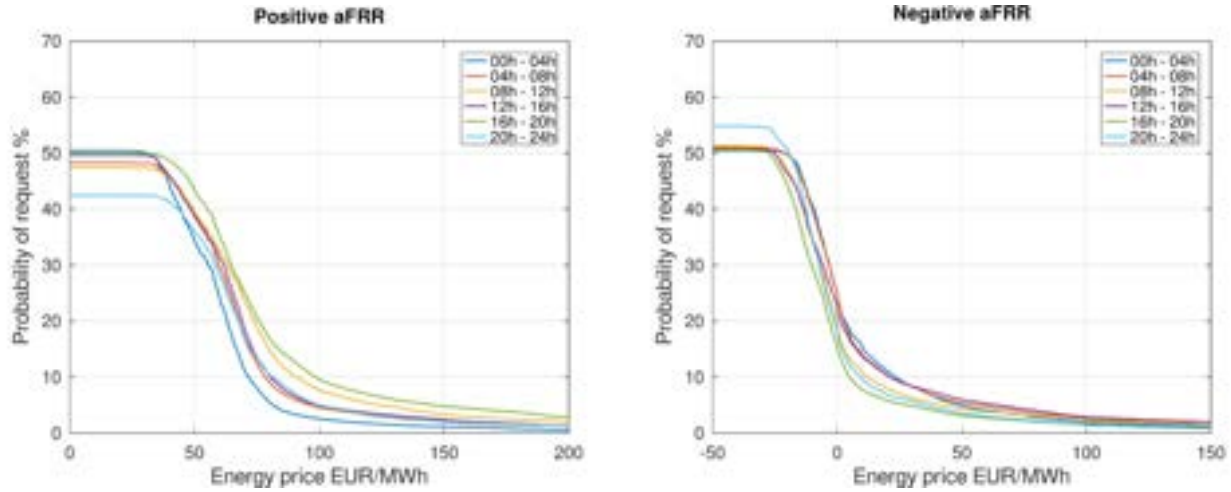

Figure 2: Probabilities of request as a function of energy price bids for positive aFRR (left) and negative aFRR (right) for the period 08/01/2019 to 07/31/2020.

Following the work of [27], the theoretical potential of the profits regarding the balancing power requests can be determined on the basis of the historical data, as shown in Figure 3 (left) for positive aFRR. This potential of profit can be calculated for different flexible capacities in form of different marginal costs. The marginal costs were assumed to be constant costs that are incurred when the balancing power is requested. These results give an insight into the relationship between the energy price bid, the energy system with the respective marginal costs, and the possible profits regarding the balancing requests. The balancing providers have to manage the trade-off between the bids for energy prices and the corresponding request probabilities: Low energy prices lead to high requests with low revenues per request, and high energy prices lead to low requests but with high revenues per request on the other side. As seen in Figure 3 (left), in theory there are optimal electricity bids that resolve the mentioned trade-off with maximum potential of profit. This maximum potential of profit decreases rapidly with increasing marginal costs, as illustrated in Figure 3 (right).

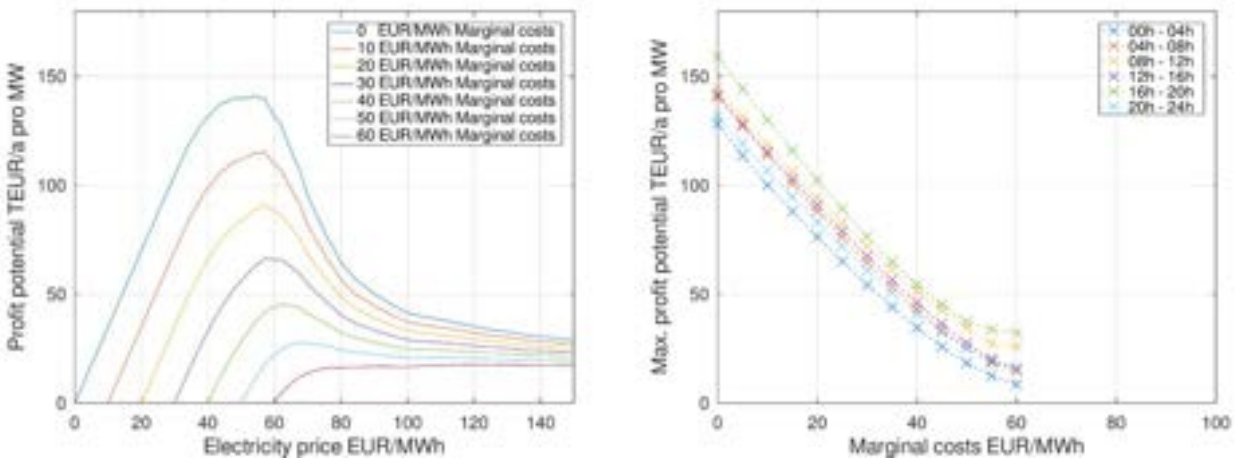

Figure 3: Potential of profit from positive aFRR requests for different marginal costs of electricity generation as a function of energy price bids (left) and the maximum potential of profit as a function of the marginal costs (right) the period 08/01/2019 to 07/31/2020.

2.2 Formulation of the developed dispatching methods

The developed methods optimize the participation of a distributed energy system in the balancing power and day-ahead market for the next day (*d-1*), as seen in Figure 1. In this paper, we focus on the market of aFRR, which is the most important balancing power market in Germany [25]. The coupled multi-market optimization can resolve the trade-off faced by flexibility providers in deciding which of the two markets to operate in. The methods are based on a mixed-integer linear programming (MILP) model of the energy system. This approach is commonly used for unit commitment by minimizing the operating costs of the system under linear constraints such as energy balances, efficiencies, and technical constraints for the day-ahead market [3,4].

In the following Section, the two developed methods *Perfect forecast* and *Virtual capacity price* are presented. The method *Perfect forecast* calculates an upper limit of the possible profits for a first estimation

of the market potential. The method *Virtual capacity price* uses a 2-stage modeling approach that represents the balancing power market in more detail. In the presentation of the methods, we focus on the formulation of the market constraints because modeling the energy system is implemented according to the aforementioned common formulations. Note that all MILP variables are formatted in bold style while normal font style is used for all coefficients.

One-stage algorithm: Perfect forecast

The basis of the *Perfect forecast* method is the assumption that the exact request of balancing power on the day of marketing *d-1* is known. The power reserve is modeled using integer variables for positive $\boldsymbol{BP_t^+}$ and negative $\boldsymbol{BP_t^-}$ balancing power for each time step $t \in T$. Each integer variable represents the acquisition in discrete 1 [MW] steps. The variables are coupled to represent the respective 4 h time slices of the aFRR product, as illustrated in Figure 4.

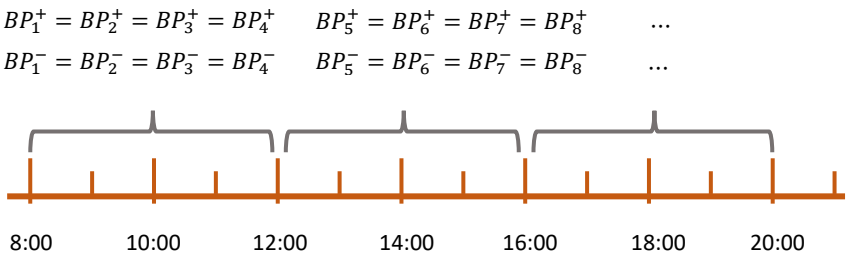

Figure 4: Modelling of positive and negative balancing power for the respective 4h time slices using integer variables, representing the acquisition in discrete 1 [MW] steps.

Based on the mentioned variables, a technical constraint with the blocking of the respective unit capacity for the balancing power market is modeled, using the electrical power $\boldsymbol{\dot{P}_{el,t}}$ with the associated minimum partial load $\dot{P}_{min}$ and nominal load $\dot{P}_{max}$ of the unit. The blocking is reduced to allow the request of balancing power with $\boldsymbol{\dot{P}_{req,t}}$.

$$\dot{P}_{min} + \boldsymbol{BP_t^-} \geq \boldsymbol{\dot{P}_{el,t}} + \boldsymbol{\dot{P}_{req,t}} \geq \dot{P}_{max} - \boldsymbol{BP_t^+}, \qquad \forall\, t \in T \tag{1}$$

Note that, in this formulation, it is assumed that the unit is not capable of fast start-ups and can offer balancing power only in the range between the minimum part load and the nominal load. The request of balancing power is calculated with the factors f_t^- and f_t^+. The factors represent a specific time series of requested balancing power for a given energy price pe and were created from historical data:

$$\boldsymbol{\dot{P}_{req,t}} = -\boldsymbol{BP_t^-} \cdot f_t^- + \boldsymbol{BP_t^+} \cdot f_t^+, \qquad \forall\, t \in T \tag{2}$$

The revenues on the balancing power market for the capacity reserve is formulated with the average, historical capacity prices for positive and negative pc_t^- balance of the pay-as-bid procedure. By using the average prices, it is assumed that with these average price bids, the surcharge for the balancing power offered in the pay-as-bid procedure is always accepted. The revenues acquired from requests are calculated using the energy prices pe^- and pe^t. Both revenues are added to the common target function of the operational cost *OPEX* of the energy system model.

$$\boldsymbol{OPEX_{BP,t}} = -\boldsymbol{BP_t^-}(f_t^- \cdot pe^- + pc_t^-) - \boldsymbol{BP_t^+}(f_t^+ \cdot pe^+ + pc_t^+), \qquad \forall\, t \in T \tag{3}$$

In summary, this formulation means that when deciding whether participation in the balancing power market is worthwhile, the optimization simultaneously takes into account the request of balancing power with the respective remuneration via the energy price. In this respect, the model can perfectly predict during optimization on *d-1* at which exact points in time balancing power will be requested.

The revenues from the day-ahead market participation equals the electricity fed into the grid $\boldsymbol{\dot{P}_{el,t}^{DA,fed-in}}$ and purchased from the grid $\boldsymbol{\dot{P}_{el,t}^{DA,pur}}$ multiplied with the day-ahead market price for selling $pe_t^{DA,sell}$ and buying $pe_t^{DA,buy}$.

$$\boldsymbol{OPEX_{DA,t}} = -\boldsymbol{\dot{P}_{el,t}^{DA,fed-in}} \cdot pe_t^{DA,sell} + \boldsymbol{\dot{P}_{el,t}^{DA,pur}} \cdot pe_t^{DA,buy}, \qquad \forall\, t \in T \tag{4}$$

Because the prices of the day-ahead market are well predictable on *d-1*, the method uses the exact historical data of the market clearing price.

Two-stage algorithm: Virtual capacity pricing

Compared to the *Perfect forecast* method, the *Virtual capacity pricing* algorithm takes uncertainties of the balancing power market into account. For this purpose, an averaged statement about the balancing power requests on the following day is made on *d-1*, based on historical request probabilities. In detail, the procedure is as follows:

Stage 1: In addition to the average capacity price pc_t^+ and pc_t^-, a virtual capacity price $pc_{\mathrm{virtual,t}}$ is integrated into the model.

$$\boldsymbol{OPEX_{BP,t}} = -\boldsymbol{BP_t^-}(f_t^- \cdot pe^- + pc_t^- + pc_{virtual,t}^-) - \boldsymbol{BP_t^+}(f_t^+ \cdot pe^+ + pc_t^+ + pc_{virtual,t}^+), \qquad \forall\, t \in T \qquad (5)$$

This virtual price is calculated with historical data and reflects the averaged revenues from a possible balancing power call on the operating day. Specific balancing power requests are not considered in this stage by setting the request factors· f_t^- and f_t^+ to zero in equation (2). In this stage, the optimization model can calculate the trade-off between the participation on the balancing power market with the possible reserve of power and the day-ahead market based on the resulting capacity price.

Stage 2: In this stage, the market participation from stage 1 is fixed. The virtual capacity price is removed and the historical requests are imposed with a fixed energy price. This stage calculates in detail how the power system behaves after the optimal marketing on *d-1* from stage 1 on the operating day while responding to the specific balancing power requests.

The challenge of the methodology is the calculation of the virtual capacity price, which has a large impact on the optimization results. Exact details of these difficulties are presented in the case study. All equations not mentioned in this method are formulated equal to the *Perfect forcast* method.

3. Case study for market participation of an ideal-typical utility infrastructure of a chemical site

3.1 Input parameters and solving method

The methods proposed are applied to an ideal-typical utility infrastructure (iCV) of a chemical site from [28]. The utility infrastructure supplies electricity and heat for the local chemical companies. The layout of the supply structure is shown in Figure 5. The heat demand consists of a medium-pressure (31 bar) and a low-pressure (6 bar) steam demand. The primary process unit is a gas turbine with 114 MW electrical power followed by a heat recovery steam generator with 150 MW thermal power. In addition to the heat recovery steam generator, two separate gas-fired steam generators and an electrode boiler can provide steam. The high-pressure steam can be expanded to 31 bar and 6 bar via a turbine system, generating additional electricity. The supply structure is generally operated on a heat-led basis to cover the 31 bar and 6 bar steam demand. Differences between electricity generation and electricity demand are balanced by the purchase of electricity from the grid.

Table 1: Data sources for the case study of the iCV model.

Parameter	Data source	Parameter	Data source
Electricity demand	Bauer et al. [28]	Capacity price balancing power market	Regelleistung.net [26]
Steam demand 31bar		Energy price balancing power market	
Steam demand 6bar			
Gas price	EPEX SPOT [29]	Day-ahead market price	Bundesnetzagentur SMARD.de [30]

The overall iCV energy system participates in the day-ahead market (DA) and the gas turbine additionally participates in the balancing power market (BP) for aFRR. The gas turbine in the iCV model generates electricity and steam and this coupled generation is tightly integrated in the overall energy system. Therefore, the entire iCV energy system must be considered to analyze the multi-market participation of the gas turbine.

Historical data from the period August 2019 to July 2020 are used to ensure consistent market constraints for the balancing power market. An overview of the data sources for the relevant input parameters is shown in Table 1. All optimization problems are calculated with Gurobi 9.5.0 on an Intel Core i5-8250U processor with 8GB RAM with hourly resolved annual input data. All solving parameters are set to default values with a relative gap of 1e-3. To handle the time-coupled constraints such as the coupling of time steps for the 4 h time slices of the balancing power market, a rolling horizon approach with a time horizon of 24 h was applied in all optimization runs [31].

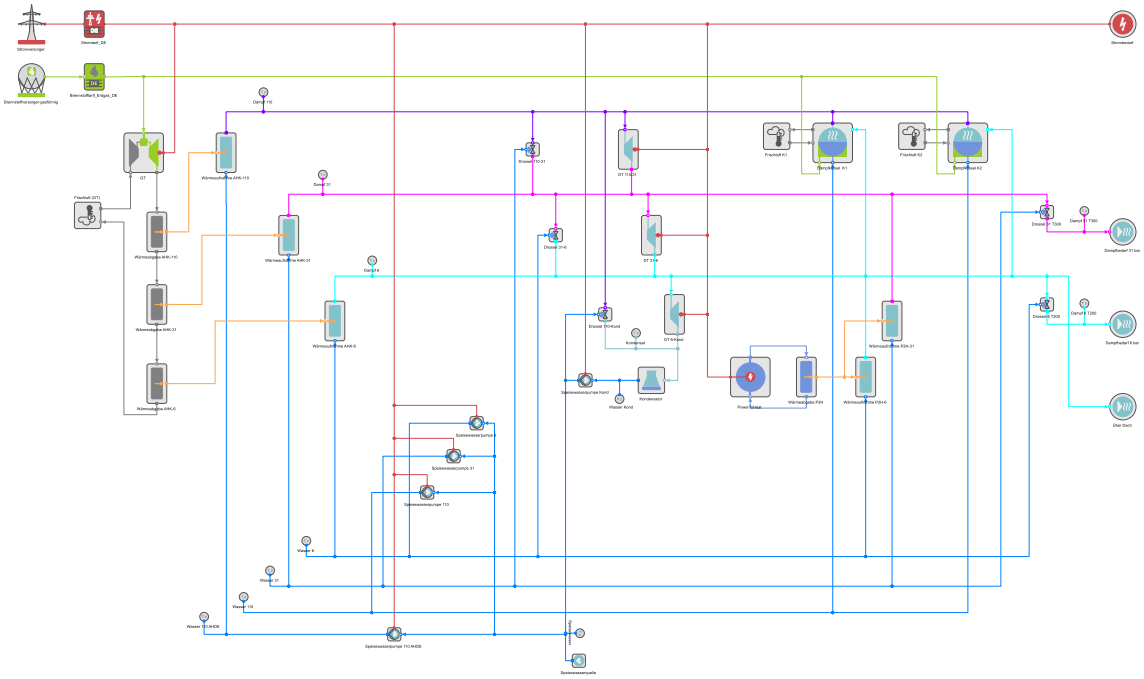

Figure 5: Layout of the ideal-typical utility infrastructure of a chemical site by [28] in the software TOP-Energy. A gas turbine with heat recovery steam generator, two gas-fired steam generators and a power-to-heat unit can produce steam, which is expanded to 31 bar and 6 bar by a turbine system to cover the heat demands.

3.2 Perfect forecast method

The operation of the gas turbine for the case of marketing on the day-ahead market is shown in Figure 6, as a function of the ratio of electricity price to clean gas price R. For low ratios of R with low electricity prices, electricity generation on site using the gas turbine is not worthwhile. For values of approximately R≥1.2, own generation is profitable with the operation at full load with 114 MW electrical power.

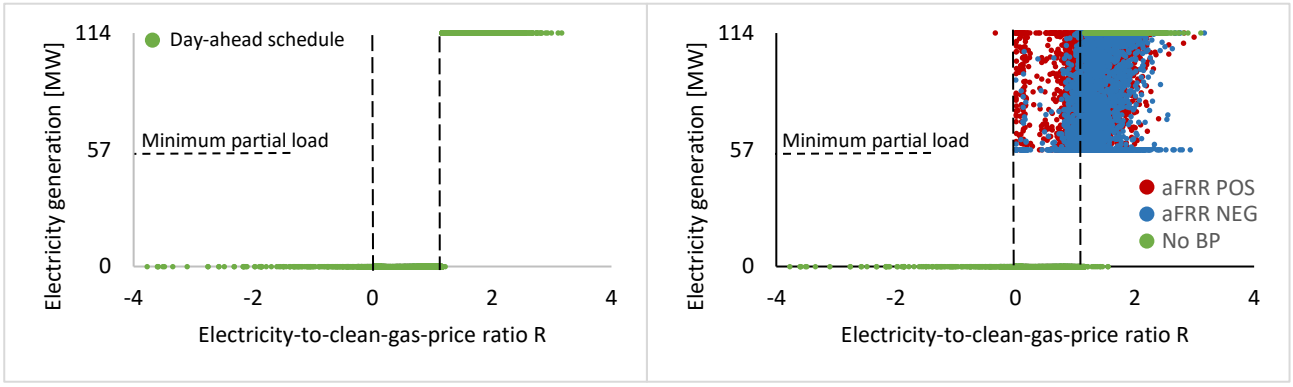

Figure 6: Electricity generation of the gas turbine for the case of marketing on the day-ahead market (left) and marketing on the day-ahead and balancing power market for aFRR using the *Perfect forecast* method (right) as a function of the electricity-to-clean-gas-price ratio R.

Compared to the pure day-ahead marketing, Figure 6 (right) shows the result of the coupled marketing on the day-ahead and balancing power market. The gas turbine is not capable of fast start-ups and can offer balancing power only in the range between the minimum part load and the nominal load with a maximum flexibility of 57 MW. In a range around the turnover point with R=1.2, the marketing of positive and negative aFRR is worthwhile. During the respective marketing of balancing power, the gas turbine operates flexible in the range above the minimum part load to control the balancing requests.

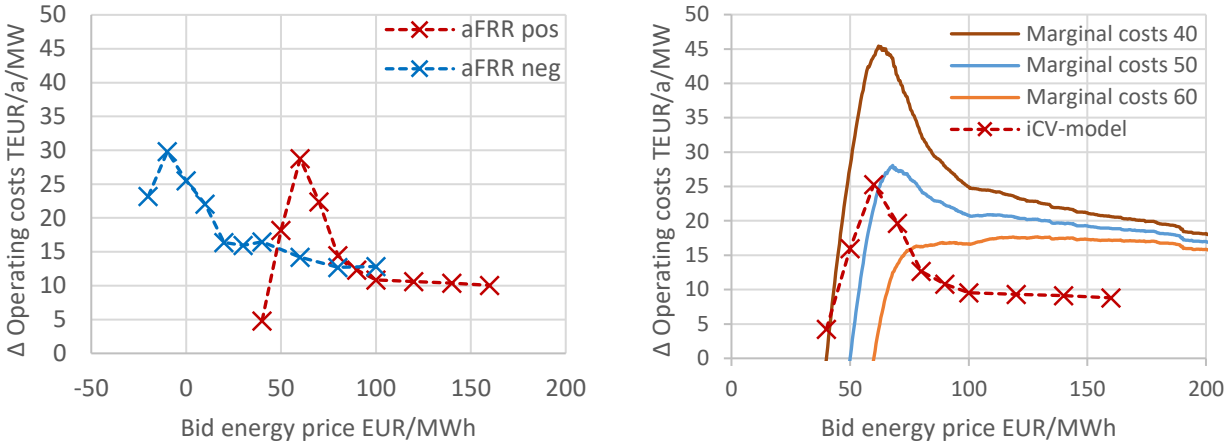

Figure 7: Delta of operational costs (DA – DA and BP marketing) per MW of gas turbine flexibility as function of the energy price bid for positive and negative aFRR (left) and the comparison to the theoretical potential of profit for positive aFRR for different marginal costs in EUR/MWh, as originally presented in Figure 3 (right).

The influence of revenues from the marketing of positive and negative aFRR on energy price bids is presented in Figure 7 (left). The revenues are illustrated as difference of operating costs between the scenario with day-ahead marketing and the scenario with day-ahead and balancing power marketing. Both curves show an optimum with maximum revenues at 60 EUR/MWh for positive aFRR and –10 EUR/MWh for negative aFRR. However, the optimal energy price bid depends on the marginal costs of the unit, as analyzed in Section 2.1.1. A comparison of the discussed theoretical profit to the results of the iCV-model for positive aFRR is shown in Figure 7 (left) for different marginal costs. The average marginal costs of the gas turbine can be estimated at 40 EUR/MWh for the iCV-model, taking into account the coupled generation of electricity and steam. The curve of the iCV-model corresponds qualitavely to the theoretical evaluation when the same marginal costs are assumed, with the same energy price bid at the optimum. This result shows that a reasonable energy price bid can be estimated using historical data and marginal costs of the unit participating in the market. Quantitatively, the revenues of the iCV-model are lower, because the model takes into account the entire energy system with more precise technical constraints, such as partial load behavior.

3.3 Virtual capacity pricing

In the 2-stage algorithm *Virtual capacity pricing*, a constant virtual price is added to the original capacity price time series in the first stage. The results of the algorithm depend on the level of this virtual price accordingly, as shown in Figure 8.

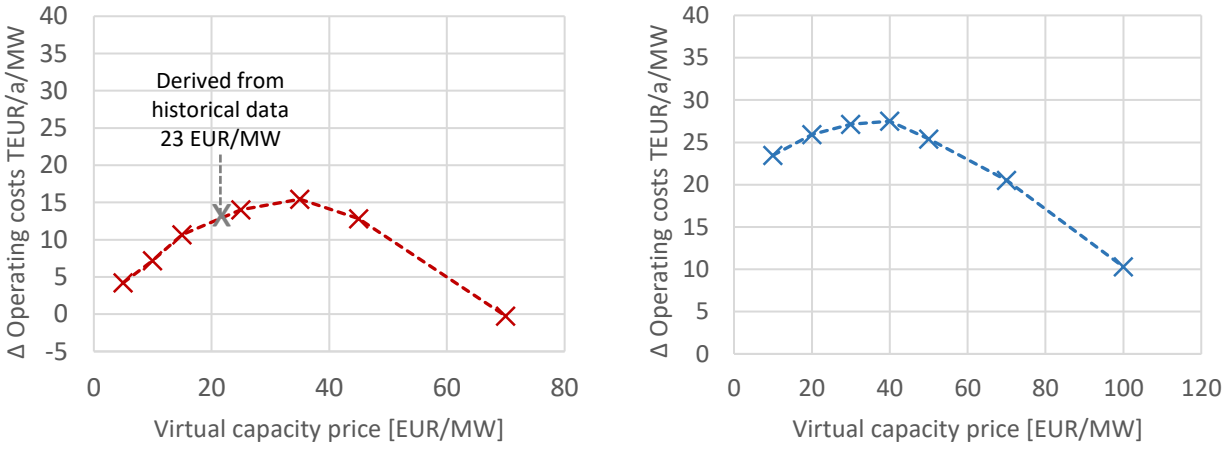

Figure 8: Delta of operational costs (DA – DA and BP marketing) per MW of gas turbine flexibility as function of the virtual capacity price for positive (left) and negative aFRR (right).

For both positive and negative aFRR, the revenues on the balancing power market are underestimated if a too small virtual capacity price is chosen. In these cases, only a few time slices are purchased on the balancing power market in the first stage of the algorithm, resulting in low total revenues in the second stage of the optimization. The choice of a too large virtual capacity price causes a possibly too strong marketing of

balancing power in the model. This also leads to a non-optimal operation in the second stage with lower total revenues. At the highest virtual power capacity for positive aFRR, economic losses even occur compared to the pure day-ahead marketing. The best results are achieved for positive aFRR at a virtual capacity price of 35 EUR/MW and for negative aFRR at a virtual capacity price of 40 EUR/MW.

The challenge of the methodology is to determine a suitable virtual capacity price without performing a parameter study as illustrated in Figure 8. For this purpose, a price can be calculated in advance from the theoretical profit potential of the balancing power market using historic data, as demonstrated in Figure 3. However, the marginal costs of the unit participating in the market must be estimated for this purpose. In the case study, the approximate marginal costs of the gas turbine are 40 EUR/MWh. In theory, such a unit can generate about 50 TEUR/MW per year with balancing requests following the evaluations in Figure 3. From this, an average virtual capacity price of 23 EUR/MW can be calculated. Although this value does not meet the optimum of 35 EUR/MW, it still provides a good estimation for setting a reasonable virtual capacity price.

3.4 Evaluation and comparison with simple trading strategies

A comparison of the developed methods *Perfect forecast* and *Virtual capacity price* is shown in Figure 9. In both methods, the total revenues on the balancing power market consist of a small share of revenues from the capacity reserve and a main share of revenues from balancing power requests. When deciding whether participation in the balancing power market is worthwhile or not, the *Perfect forecast* method can simultaneously take into account the balancing requests with the respective revenues. In doing so, the model can preferentially select profitable time slices with many request calls. Accordingly, the results for this methodology in Figure 9 show high revenues from balancing power requests compared to the *Virtual capacity price* method. The total number of purchased time slices on the balancing power market is similar for both methods. However, more negative time slices are marketed in the *Virtual capacity price* method compared to the *Perfect forecast* method, resulting in increased use of the gas turbine with higher fuel costs and lower electricity costs due to the higher on site electricity generation.

In summary, the results of the presented *Perfect forecast* method with the total revenues of 55 TEUR/MW provide a theoretical profit potential of the market. A more realistic view, in which no exact requests are predicted on *d-1*, is calculated by the *Virtual power price* method leading to lower total revenues of 33 TEUR/MW.

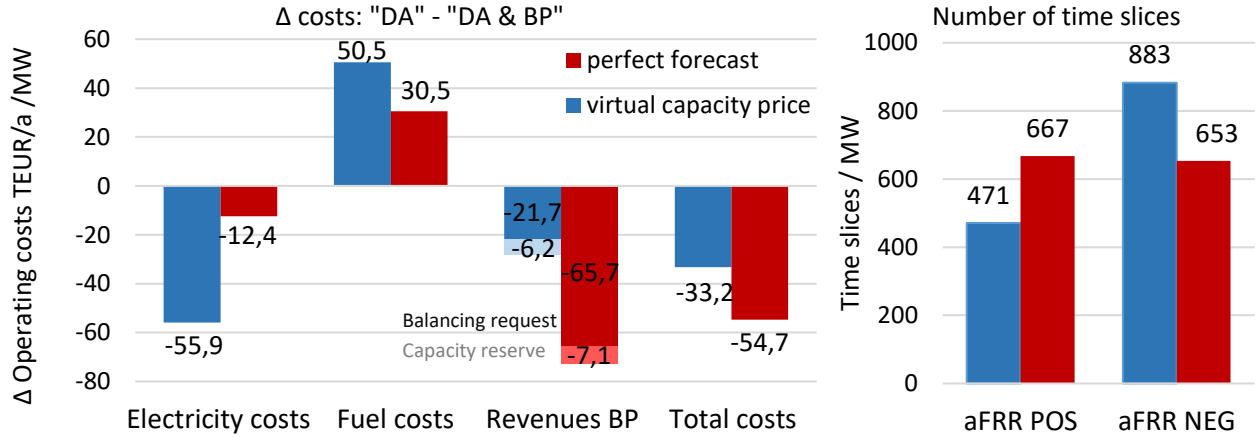

Figure 9: Delta of cost components (DA – DA and BP marketing) for electricity, fuel and balancing power (aFRR) per MW of gas turbine flexibility (left) and the number of aFRR time slices acquired (right).

In summary, the results of the presented *Perfect forecast* method with the total revenues of 55 TEUR/MW provide a theoretical profit potential of the market. A more realistic view, in which no exact requests are predicted on *d-1*, is calculated by the *Virtual power price* method leading to lower total revenues of 33 TEUR/MW.

The presented results are compared with different simple bidding strategies for the balancing power market in the following Section. These simple bidding strategies are based on the optimal gas turbine commitment for the scenario where the energy system participates only on the day-ahead market, as illustrated in Figure 6 (left). Accordingly, the following presented strategies 1a), 1b), 2a) and 2b) are derived from the optimal gas turbine schedule, as also shown in Figure 10.

1a) The day-ahead schedule is not adjusted and negative balancing power is marketed at the times when the gas turbine is running at full load. In this strategy, a maximum capacity price and a maximum energy price are bid. It is assumed that by bidding the high energy price, no balancing power is requested.

1b) As in 1a) but a bidding strategy with a medium capacity price and a medium energy price with consideration of balancing requests.

2a) The day-ahead schedule is adjusted. At the times when the gas turbine is off, the turbine is ramped up to market positive balancing power. At times when the gas turbine is on, negative balancing power is marketed. For positive and negative balancing power, an average capacity price and an average energy price are used, taking into account balancing power requests.

2b) The day-ahead schedule is adjusted. At the times when the gas turbine is on, the gas turbine is shut down to minimum partial load in order to offer positive balancing power. For the positive balancing power, an average capacity price and an average energy price are used, taking into account balancing power requests.

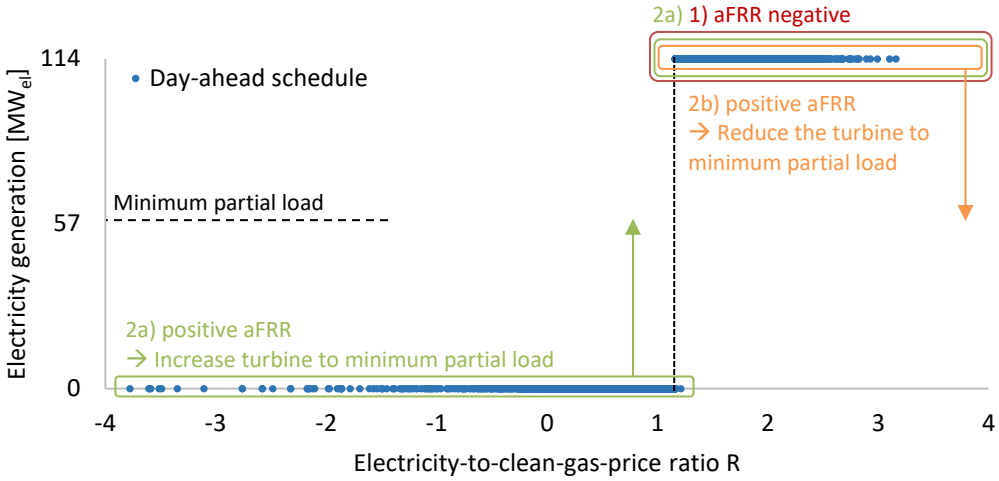

Figure 10: Simple bidding strategies 1), 2a) and 2b) for the balancing power market based on the optimal day-ahead schedule (without BP) of the gas turbine.

The overall results are shown in Figure 11 for the presented four bidding strategies (schedule adjusted) and the developed methods *Perfect forecast* and *Virtual capacity price* (Coupled optimization). The first three bidding strategies 1a), 1b) and 2a) show small revenues between 2.2 TEUR/MW to 5.5 TEUR/MW. In strategy 1a) the high energy price bid leads to the avoidance of balancing power requests. However, we have shown that balancing power requests are relevant for the generation of profits and, accordingly, higher revenues are found in strategy 1b), which considers requests. In bidding strategies 2a) and 2b) the day-ahead schedule is adjusted leading to strongly different revenues. In strategy 2a) very low revenues are generated, whereas strategy 2b) leads to significant profits with 18 TEUR/MW per year.

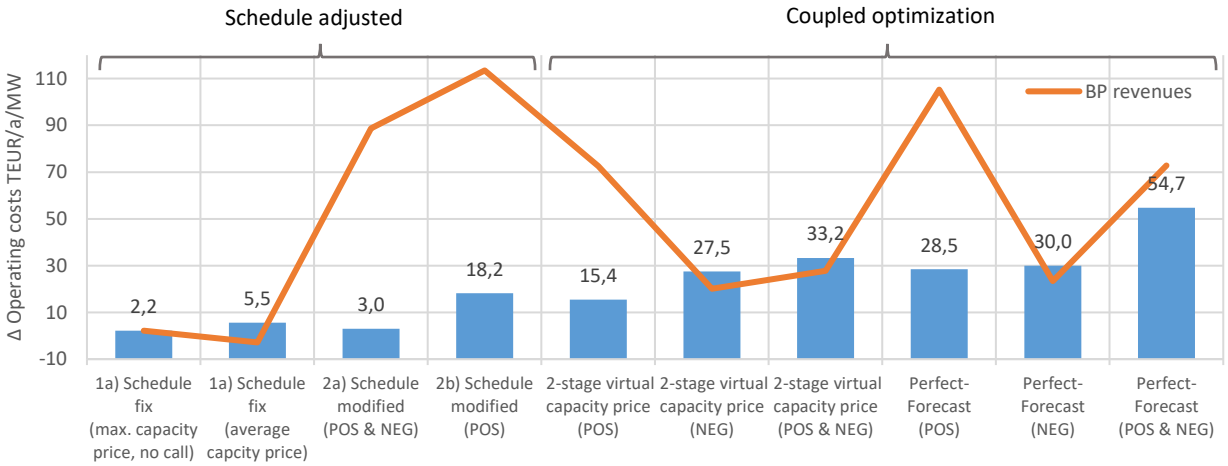

Figure 11: Delta of operational costs (DA – DA and BP marketing) per MW of gas turbine flexibility for the presented four simple bidding strategies (schedule adjusted) and the developed methods *Perfect forecast* and *Virtual power price* (Coupled optimization).

Basically, the simple bidding strategies for the balancing power market based on the day-ahead schedule can generate profits. However, this scheduling "by hand" is not ideal and the revenues are fluctuating and difficult to estimate. In comparison, marketing with the presented simplified optimization methods can generate higher revenues. The one-stage *Perfect forecast* method provides a theoretical potential of profit based on historical

data, resulting in the maximum revenues in Figure 11. The *Virtual capacity price* method takes into account the uncertainties of the requests in a simple way, providing a more realistic market potential with lower revenues.

4. Conclusion

The results of the case study demonstrate that the developed methods manage the coupled marketing of a distributed energy system on the day-ahead and balancing power market in a simplified way. For the methods, historical data can be used to determine reasonable values for energy price bids and virtual capacity prices by considering the marginal cost of the corresponding unit.

The disadvantages of the simplified methods are caused by the complexity reduction of the market side. In reality, market participation leads to a sequential decision-making process that is not modeled in detail. Accordingly, it is not possible to compute optimal bidding strategies taking into account uncertainties, as is the case by using common multi-level stochastic programming approaches.

However, the main advantage of the methods is the low complexity, compared to e.g. stochastic optimization, leading to a high user-friendliness with an easy integration into possibly existing dispatching procedures. The methods can additionally be used for strategic planning to quickly estimate the economic value for different flexibel capcities in the energy system in case of a market participation, as seen in the case study. These evaluations are of interest to companies planning to enter a specific market. In particular, as more and more small players enter the market in the context of the energy transition who do not have the capacity to apply multi-level stochastic programming methods, the demand for user-friendly, simplified methods is increasing. However, the developed methods must be extended in the future for the complete short-term electricity market. For this purpose, the opportunity of intraday trading must be taken into account at *d-1*.

Abstract:

The current building stock is responsible for a large part of the final energy consumption in Europe and most of it presents the greatest potential for energy savings. One of the most important steps in the retrofitting process is to understand its pre-retrofitting stage energy performance, and the building energy simulation (BES) models can play a significant role in that sense. In this paper, a building case study has been monitored during a whole year. A methodology has been developed specifically for the pre-processing procedure of the building monitored data. Then, based on the available detailed building drawings, building operational data and the data sets obtained after data calibration, a first approach of a BES model is carried out. In addition, some window samples have been tested in the Laboratory of Building Quality Control of the Basque Government to measure their thermal transmittance. These samples will be introduced in the BES model in future works, to evaluate the reduction in heating demand after the windows replacement. A sensibility analysis of the recorded data justifies their good quality. In consequence, the accumulated heating energy supplied by the boiler reaches a value of 44.05 MWh in the monitored year and the total electric energy consumption is 16.71 MWh.

Building energy simulation model; data pre-processing; energy retrofitting; thermal transmittance calculation.

1. Introduction

This paper is developed under the scope of the AGORA project, founded by Next Generation EU. The project aims to bring to the market a holistic smart solution capable of promoting more sustainable energy and water consumption from producer to final consumer. The tool developed will be tested in some pilot buildings, such as the Faculty of Nursing and Health Science “Building 2” of the University of Burgos in Spain.

In recent years, building energy simulation (BES) is playing a significant role for designing and optimising buildings, but also for pre-rehabilitation procedures. A high level of accuracy in BES results can only be achieved through optimization of three factors as determined by Waltz [1]: (1) an intimate understanding of the simulation tool; (2) an intimate understanding of the building to be simulated and (3) a careful analysis and critique of output data. In their research, [2] presented a critical review of data-driven methods for BES modelling and their practical applications for improving building performance. The paper focuses on methods based on larger datasets and demonstrates that the insights obtained from big building data can be extremely helpful for enriching the existing knowledge repository regarding building energy modelling. However, [3] determined that due to the complexity of the built environment and the prevalence of large numbers of independent interacting variables, it is difficult to achieve an accurate representation of real-world building operation. The difference between measured and calculated energy consumption is known as the “energy performance gap” and reducing this gap is an important task to provide confidence in the models for evaluating energy efficiency. Therefore, calibrating the BES model by reducing discrepancies between model outputs with measured data is a key process to achieve more accurate and reliable results.

In their work [4] focus on reducing the technical issues which are one of the main causes of the energy performance gap, e.g., poorly adjusted thermal parameters in the envelope, inefficient boiler operation or lack of adjustment in parameters of heat pumps, baseboard radiators or air handling units, etc. As a result of the

calibration process, they obtained a whole building calibrated BES model that considers the building's envelope behaviour and incorporates into the simulation the detailed behaviour of its HVAC systems.

Other researchers like [5] proposed a systematic feature-selection procedure for developing the BES model which integrates a statistical analysis, apart from building physics and engineering experiences. This includes data pre-processing based on domain knowledge, implementation of filter methods to remove irrelevant and redundant data and feature grouping through wrapper method to search for the best feature set. In the building context, [6] points out that data pre-processing can be very challenging considering the relatively poor data quality and the intrinsic complexity of building operations. A review done by [7] considers existing case studies and methods for calibrating whole building energy models related to measured data. This research describes a systematic, evidence-based methodology to calibrate these models. In terms of data-driven methods, [8] presented a review of data-driven building energy consumption prediction studies with a particular focus on scopes of prediction, data properties and data pre-processing methods used, among others.

A new method was developed by [9] involving dynamic simulation and on-site measurements aiming to evaluate refurbishment solutions for a historical building. The authors demonstrate how a specific calibration of the dynamic model using only indoor temperature measurements can overcome the problem of in situ measurements of thermal parameters (U-values). In this field, there exist some standardized methods to determine the thermal resistance and thermal transmittance of different building components. Several research studies ([10], [11]) have been carried out to analyse and compare different approaches to thermal transmittance measurements, which pay particular attention to the hot box method.

2. Objectives

This paper analyses and models the energy performance of a real pilot building based on available sensor data. A specific data pre-processing approach is developed and applied to obtain clean and useful data to interpret and apply into a BES model by using the DesignBuilder software.

The case study is related to an academic in-use building located in Burgos, Spain, described in detail in section 4. The building was retrofitted some years ago and the effect of the windows replacement over the heating demand wants to be tested. In collaboration with the Laboratory of Building Quality Control (LBQC) of the Basque Government, some window samples have been characterized under standard rules. The obtained thermal transmittance of the windows is used to characterize the BES model.

According to [3], an accurate calibration process relies on the importance of occupant behaviour as well as the need for instrumentation to monitor its behaviour. For that reason, as the occupant behaviour is not been currently controlled in the pilot building, the calibration process will be addressed in future work. However, this article describes the first steps to achieve a calibrated BES model.

3. Methodology

The methodology described in this section is applied in the case study presented in Section 4, following the similar calibration procedures found in the literature and divided into two main actions:

- On the one hand, the monitored data of the building is acquired and subsequently processed to implement it into a BES model. Therefore, the building has been modelled using the DesignBuilder software to carry out an energy performance simulation.
- On the other hand, a set of window samples were tested in the laboratory and characterized through their performance in a guarded hot box. As a result, the real heat transmission coefficient (U-value) of these windows was accurately determined. The process and samples are described in detail in Section 3.3.

3.1. Monitoring system

An advanced monitoring system was installed in the case study building (see Section 4) whose data were available from the 1st of May 2021 to the 31st of May 2022 and have been registered on a sub-hourly basis. Unfortunately, and due to technical problems, not all monitored parameters have been recorded during some time periods, so some blackouts have been identified and discussed in more detail in Section 3.2. Monitored variables are classified into outdoor conditions, indoor conditions, and general consumptions (including lighting and heating consumptions).

- Outdoor conditions gather two measured parameters obtained from the weather station in the adjoining building: outdoor ambient temperature (ºC) and relative humidity (%). These variables are used to calibrate the climate data file for the BES model.
- Indoor conditions are composed of three parameters: indoor temperature (ºC), relative humidity (%) and CO_2 concentration (ppm). The monitoring system consists of THERMOKON WRF04-CO2-RH-LON sensors located in each room (see Figure 1). These parameters are used to compare BES results.
- Heating consumption is monitored by a KAMSTRUP MULTICAL 602, which is a thermal energy meter connected to a KAMSTRUP ULTRAFLOW 54 flowmeter monitoring the return water volumetric flow (m^3/h). The MULTICAL 602 also receives the monitored temperature of the delivery and return circulating water

(ºC) via two Pt500. The monitoring system calculates energy based on the EN 1434-1:2007 formula, in which the international temperature scale from 1990 (ITS-90) and the pressure definition of 16 bar is used. The energy calculation can in a simplified way be expressed as indicated in Eq. (1):

$$\mathrm{E_t}[Wh] = \mathrm{V_{wa}}[\mathrm{m^3}] \cdot k_{wa}\left[\frac{Wh}{m^3 \cdot K}\right] \cdot (\theta_{inlet}[K] - \theta_{outlet}[K]) \quad (1)$$

where k is the thermal coefficient of water which is a function of the properties of the energy-conveying liquid at the relevant temperatures and pressure. The calculated energy is registered in Wh units and expressed as accumulated energy. These parameters are used to compare BES results and to define heating schedules.

- Lighting consumptions are monitored with eight NICO 8101L clamp ammeters that monitor two electrical parameters: current (A) and accumulated electrical energy consumption (Wh). One of them is located in the boiler and the rest are in each room[1]. These parameters are also used to compare BES results, as well as to define lighting schedules.

Figure 1 depicts the sensors installed in the building.

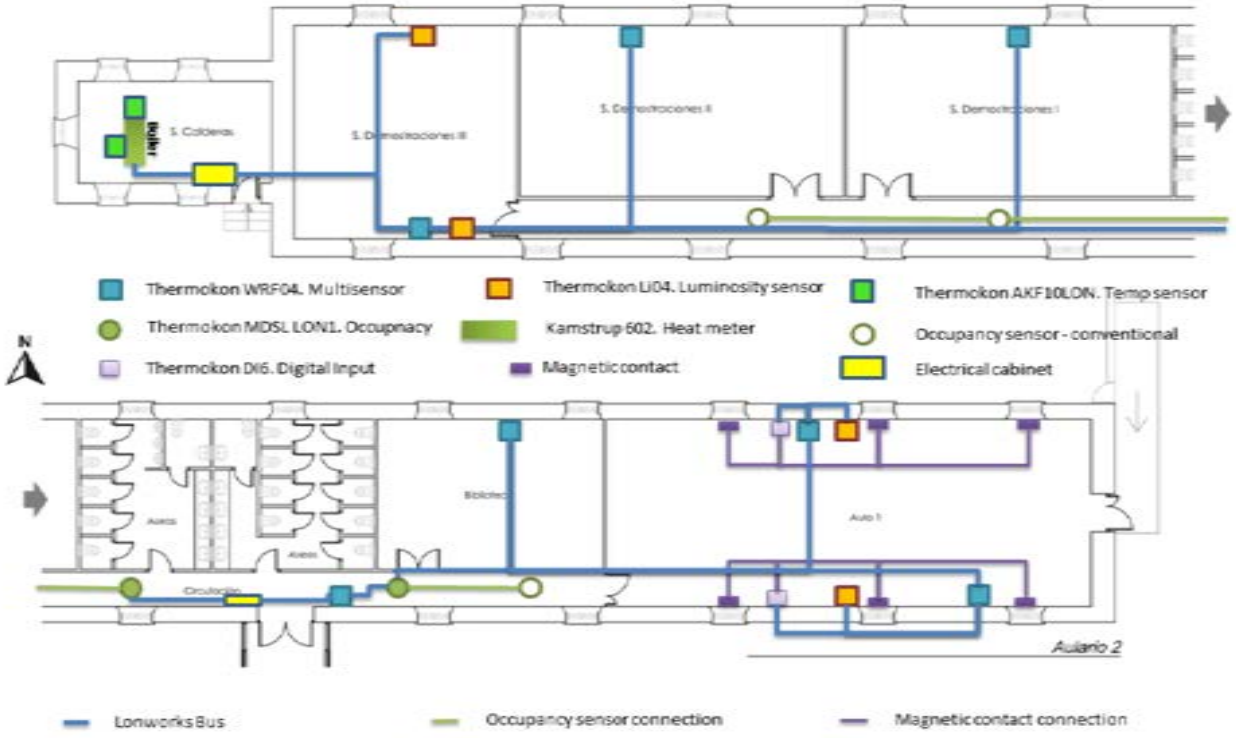

Figure 1. Distribution of monitoring devices within the building.

3.2. Data analysis

This section describes the initial data calibration procedure after collecting them.

3.2.1. Data pre-processing

Data pre-processing is an essential part of any data-driven BES model. This process, according to [12], aims to detect the outliers (i.e., any incorrect or outlier data) that may distort the results. As explained by [8], data pre-processing may include data cleaning, data integration and data transformation.

3.2.1.1. Data cleaning

Data cleaning is defined by [8] as the process of detecting and correcting the incomplete, incorrect, inaccurate, irrelevant and/or noisy parts of the data.

To begin with, a specific cleaning procedure was developed by using different filters on the raw data files. This step aims to correct the effect of outliers, e.g., taking away noisy data and detecting resets in the accumulated energy register.

For the particular case of the monitored energy, the heating energy from the boiler and the lighting energy at each time step has been calculated as expressed in Eq. (2):

[1] Note: data are not available for Demonstration Room III.

$$E_t[Wh] = \Delta E_{register}(t) - \Delta E_{register}(t-1) \quad (2)$$

Besides, for the particular case of outdoor conditions, the registered data were cumulated or averaged, respectively, in periods of 30 minutes, to make them coincident with the minimum simulation time interval allowed by DesignBuilder. After that, hourly, monthly and annual data were also obtained. Unfortunately, the monitored outdoor data was incomplete since the data for some periods were not available due to technical problems and were considered as blackouts. Nevertheless, the observed lack of data does not affect the results since they last few hours during the monitored year, and only on four occasions, the interruption period affects two or more consecutive days, as indicated in Figure 2. This process for the identification of blackouts has been repeated for each variable and then superimposed on the annual calendar, and as a result, it has been seen that the interruption periods coincide for all the variables recorded.

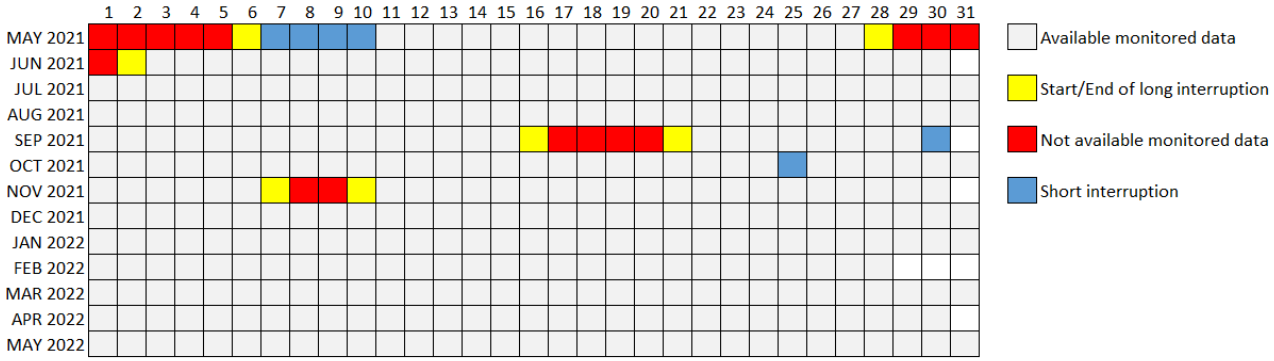

Figure 2. Identification of blackouts on the monitored data during one year.

The period of study covers a whole year from June 2021 to end of May 2022, in order to avoid blackouts detected in May of 2021.

3.2.1.2. Data integration

According to [8], data integration is the process of combining multiple data from different sources. Therefore, since the variables recorded by each sensor were stored in different monthly files, an essential task was to unify the data in an annual one.

In this work, the blackouts detected in the outdoor conditions file (see Figure 2) were substituted with hourly data taken from Meteostat. To verify the suitability of the Meteostat data, three days on which monitored data were available were randomly selected and compared with the Meteostat data from those days. The results obtained for temperature and relative humidity show minor differences, as shown in Figure 3, so the Meteostat data have been justified as suitable.

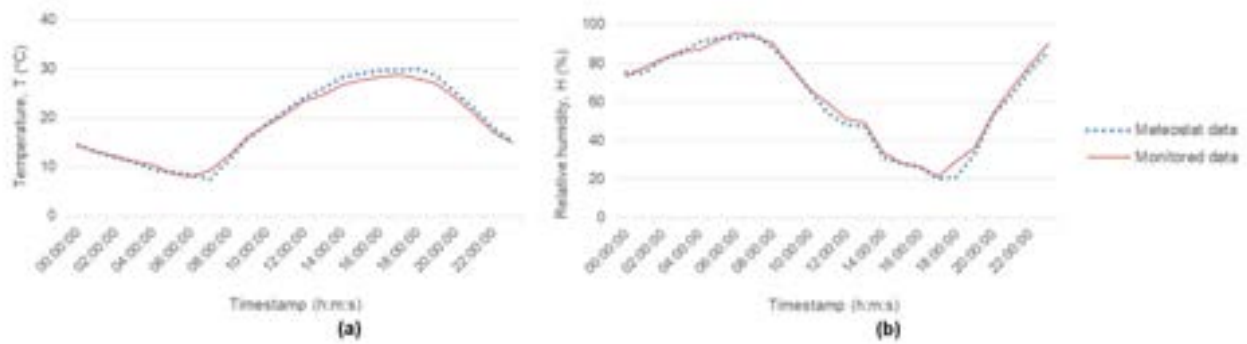

Figure 3. Comparison between meteorological data from Meteostat and monitoring data considering outdoor temperature (a) and relative humidity (b).

3.2.1.3. Data transformation

As mentioned by [8], data transformation is the process of transforming the data into the required format. Data transformation may include normalization, smoothing, aggregation/ disaggregation, and/or generalization of the data.

In this case, in order to compare the analysis with simulation results, data collected on a minute basis (apart from the previous outdoor conditions data) were averaged and/or cumulated in 30-minute intervals and then hourly data were obtained. However, inasmuch as the data were not homogenously registered (i.e. the time interval between timestamps was not constant) it required further treatment. Fortunately, it was identified that the time-step took values multiples of five in the vast majority of the cases, so, the original data series were converted into 5 minutes step values. For this purpose, the variables have been considered to remain constant between each timestamp. After that, a method based on an analogy with a linear equation has been applied

in order to obtain average values for sub-hourly, hourly, daily and monthly data series. All the intensive variables have been calculated as averages, but the energy-related parameters, which are the extensive ones, have been calculated as a sum of the values registered within each interval.

Once the database consists of hourly average series and blackouts are fulfilled, the files are prepared for implementation in future work. As an example, the specific case of the outdoor conditions file requires adapting the format to DesignBuilder software. This software operates with EnergyPlus Weather File (EPW) format and integrates a Climate Data File Processor allowing the user to convert an EPW file into another type. Therefore, in this case, the data file was converted into a CSV file, to substitute the “default input data” with the monitored registered data. Another option is to calculate the heating days (HD) during the simulation period according to monitored data and implement the annual values in DesignBuilder, without modifying the standard climate data file.

3.2.2. Data interpretation

After the data pre-processing, the obtained data needs to be interpreted. This process aims to extract useful information from the monitored variables such as operational schedules, occupation schedules and input parameters for modelling the BES model. The more reliable information is obtained, the more input data and model parameters will be available and the higher the accuracy of the calibration will be [13]. Once the data files are correctly organized, operational periods of the building during the year must be established. Then, a typical sub-operational period has been chosen for each season defined in the previous step. The results of the monitoring demonstrate that there are weekly patterns which are repeated during the academic course, so typical weeks were defined for each month to obtain operational schedules of the heating system and lighting system.

3.3. Thermal characterization of windows

As is already said, the Laboratory of Control Quality of Buildings (LCQB) of the Basque Government deals with, among others, the characterization of building components to research new construction solutions and enhance the thermal performance of the active and passive systems. Because of that, some windows were tested in order to further implement them in building refurbishment, as can be in the building of this case study.

One of the objectives of future work is to analyse the increase in the efficiency of the building after changing the windows, according to the simulation results. Therefore, in order to describe their thermal behaviour, the most important parameter is the thermal transmittance (U). In this work, the method described by UNE-EN ISO 12567-1 of the hot box method was implemented in the LCQB to characterize the thermal transmittance of the studied windows.

3.3.1. Guarded hot box Method

This test method is carried out under UNE-EN ISO 12567-1:2011 to determine the thermal transmittance of doors and windows. Based on the UNE standard, a sample solution is located between two different spaces called chambers (see Figure 4): the hot chamber where the measurement box is located, and the cold chamber, which is used to simulate the exterior conditions, as [11] explained in their work. Therefore, there is a heating system on the hot chamber and a cooling system on the cold one to create a temperature difference (normally 20ºC). Then, by measuring the temperature difference and the heat flow passing through the sample, the thermal resistance of the window can be calculated. Once there is a steady-state condition in both chambers, the heat flow inside the chamber equals the heat input required to keep the hot side at a constant temperature [11].

In this work, U-values from four different windows are measured thanks to the guarded hot box tests developed in the LQCB, where the temperature difference between the hot and cold chambers is 20ºC and the average temperature of the sample is 10ºC. Multiple sensors are located in the sample, the chamber and the sample holder (frame). The employed metering chamber has a section of 1.63 x 1.88 m^2 while the normalized size of the samples is 1.23 x 1.48 m^2, with a sample holder of 1.63 x 1.88 m^2 (see Figure 4).

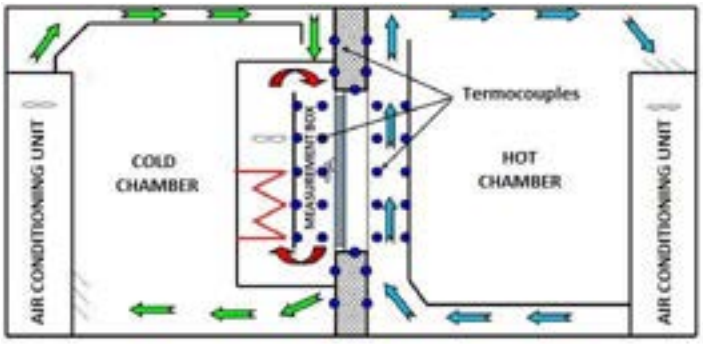

Figure 4. Chambers scheme of the guarded hot box employed for window testing. Source: Building Quality Control Laboratory of the Basque Country.

The measured thermal transmittance (U_m) of the window system is calculated according to the standard UNE-EN ISO 12537-1:2002 with Eq. (3).

$$U_m\left(\frac{W}{m^2 \cdot K}\right) = \frac{\frac{\Phi\,(W)}{A\,(m^2)}}{\theta_{ni} - \theta_{ne}(K)} \quad (3)$$

This measured U_m, must be corrected in order to obtain the normalized thermal transmittance U_w. Therefore, it is necessary to include the thermal resistances of inner and outer surfaces, see Figure 5 and Eq. (4). The normalized value of $R_{(s,t)st}$ takes a value of 0.17 (m^2·K)/W in Europe.

$$U_w\left(\frac{W}{m^2 \cdot K}\right) = \frac{1}{\frac{1}{U_m} - R_{s,t} + R_{(s,t)st}} \quad (4)$$

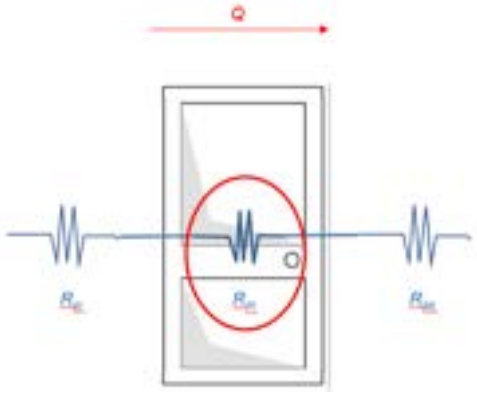

Figure 5. Thermal resistances characterization. Source: Building Quality Control Laboratory of the Basque Country.

3.3.2. Tested windows

Since the thermal properties of building envelope systems significantly alter the overall energy performance of buildings, so these properties must be accurately determined. In this case, the building façade was previously refurbished so special attention will be paid to the windows replacement. Additionally, four glazing systems have been selected from the experimental test. The normalized thermal transmittance (U_w) determined during those tests is shown in Table 1 for each glazing system illustrated in Figure 6.

Table 1. Features of the glazing systems with a dimension of 1.23 m x 1.48 m.

Window	Glazing composition	U_w, W/(m^2·K)	Profile	Shutter box
TW-0412-50	4+4 / CAM 16 argon / 3+3	1.38 ± 0.07	PVC	PVC isolated with EPS, e = 1.5 cm
TW-0412-48	4+4 / CAM 16 air / 6	1.55 ± 0.08	PVC with aluminium reinforcement	-
TW-0412-7	Fixed sash: 3+3 / CAM 10 air / 4+4 Tit-and-turn sash: 4+4 / CAM 12 air / 4	3,07 ± 0.16	Aluminium, e = 14 cm	PVC, 1.22 m x 0.185 m, e = 18.5 cm
TW-0412-21	Fixed sash and casement sash: 4+4 / CAM 15 air / 10	3.14 ± 0.16	Lacquered aluminium, e = 12.8 cm	-

Figure 6. Tested samples of (a) TW-01412-50, (b) TW-0412-48, (c) TW-0412-7 and (d) TW-0412-21.

3.4. Building energy simulation model

To initiate the calibration of the BES model, different data sources have been used such as monitoring, building and construction detail drawings and personal audits. As a result, operational periods and schedules have been obtained for their implementation in the BES model. This includes heating and lighting schedules, weather data and also tested thermal transmittance values. Natural ventilation has not been considered.

Thermal zones have been determined by considering use and conditioning characteristics, so in this case, each room is taken as an individual thermal zone.

The envelope features have been modelled accurately by considering U-values calculated theoretically during walk-through audits. In the case of windows, the U-value determined during the guarded hot box method has been used.

PV modules have been integrated into façades and roofs as shown in the building drawings and modelled with a constant 15% efficiency.

4. Case study

The proposed methodology is applied to a single-floor occupied building, in particular, Building 2 of the Faculty of Nursing and Health Science of the University of Burgos, located in the city of Burgos in Spain (characterized by a moderate continental climate). The building has an academic use, so the occupation is related to the academic schedule and calendar, but in reality, it varies greatly from the expected occupancy. This building is a former Military Hospital built in 1880 with a single rectangular floor of 545.49 m^2, composed of five classrooms and two bathrooms, connected by a longitudinal corridor (see Figure 7). Over the years, the building has faced different rehabilitations and after the last one, two façade solutions were installed above the original wall. Table 2, Table 3 and Table 4 show the main construction and thermal characteristics of the building envelope.

The ventilated façade is predominant above the others, only in the Boiler Room have remained the original walls of the building. The non-ventilated panels have a total width of 2.3 m and have been installed between windows. The South orientation contains integrated photovoltaic modules and some ventilated PV modules have been integrated into the westernmost part of the South façade.

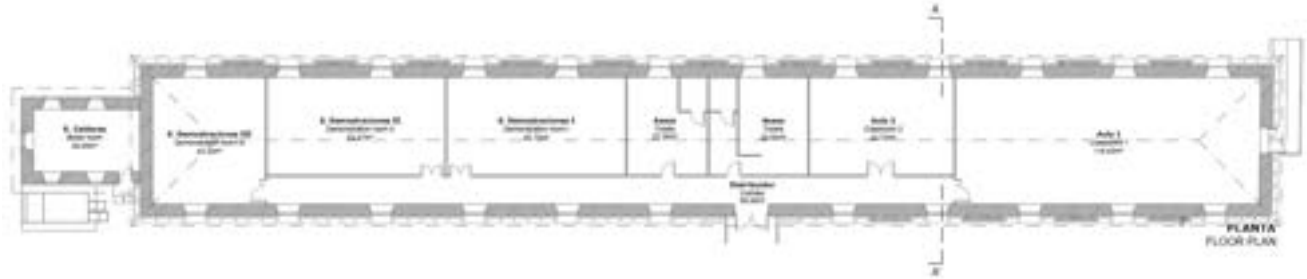

Figure 7. Indoor distribution of Building 2.

Table 2. Dimensions of building and envelope components.

Number of floors	1
Overhang height	5.15 to 5.31 m
Ridge height	7.70 m (approx.)
Constructed surface	545.49 m^2
Conditioned surface	431.39 m^2
Total façade surface	789.77 m^2; 752.22 m^2 (without openings)
East façade area	43.35 m^2; 40.55 m^2 (without openings)
West façade area	23.83 + 15.64 = 39.47 m^2; 38.81 m^2 (without openings)
South façade area	323.19 + 21.62 = 344.81 m^2; 295.27 + 18.59 = 313.86 m^2 (without openings)
North façade area	337.43 + 21.71 = 359.14 m^2; 311.61 + 20.39 = 332.00 m^2 (without openings)
Total openings surface	64.55 m^2
% openings east façade	2.80 m^2; 6,46%
% openings west façade	0.66 m^2; 1.67%
% openings south façade	30.95 m^2; 8.98%
% openings north façade	27.14 m^2; 7.56%
Roof area on the ground floor	623.51 m^2 (approx.)
Roof inclination	28º (approx.).

Table 3. Composition and thermal characteristics of the different layers of the opaque envelope.

Original wall	Masonry load-bearing wall, e = 62 cm
	Garnishing and plastering of gypsum, e = 1.5 cm
	U = 1.40 W/(m^2·K)
Ventilated façade (ULMA)	Mineral wool, e = 5 cm

Roof composition	Mixed trusses (metal and wood)
	Pine wood decking 800x150mm, e = 2.5 cm
	Ceramic flat tile of baked clay. Double side and upper lace
	U = 2.40 W/(m^2·K)
False ceiling	Mineral wool rigid panel, e = 8 cm
	Smooth laminated plasterboard (accessible roof) 60x60 cm, e = 1.5 cm
Slab composition	Metal beam, ceramic vault, compression layer + mesh
	U = 2.10 W/(m^2·K)
Non-slip laminate flooring	High density fibreboard, e = 1.25 cm
Window type	Wooden pre-frame 70 mm x 50 mm
	Mixed carpentry. PVC profiles and Wood finished.
	Exterior double low-e glass 4+12+6 mm
	Aluminium sheet in window perimeter trims and lower closure in ventilated façade, e = 0.2 cm
	U = 2.20 W/(m^2·K)

Regarding the thermal facilities, the building has two high-efficiency condensing gas boilers Remeha 65 PRO of 61 kW each, which supply heat through two independent circuits, both to Building 2 and to adjoining Building 3, in which another European project is being developed. The thermal demand only corresponds to the heating system, neither cooling nor DHW systems are operating in the building.

Referring to electricity generation, there are also photovoltaic panels as mentioned before. The PV installation is divided into three systems, independently connected to three inverters as indicated in Table 5. Besides, the lighting of the entire pavilion is composed of 2x32 W fluorescent lamps with a protection box at the entrance.

Table 5. Characterization of the PV system.

PV characteristics	Ventilated façade (ULMA)	Non-ventilated façade (STAM)	Roof (SOLARWALL)	Complete System
Power, kW_p	4.95	4.16	4.42	13.53
PV module model	VS21 C24 P99	SPS istem 260P plus	SPS istem 260P plus	-

Inverter Power, kW_{AC}	3.6	3.6	4.0	-

5. Results

In this section, the analysed data are interpreted and the preliminary BES model is depicted, which will be fully calibrated in future research. The results of the methodology described in Section 3 are presented below.

From the data analysis, hourly average data and monthly and annual averages were obtained. Besides, operational schedules for heating and lighting systems have also been obtained.

The monitoring of the heating system during June 2021 and May 2022 shows a standard distribution of the heating demand according to the Burgos climate zone. As observed in Figure 8, higher heating demands

correspond to the cold period from November to April and lower heating demands are required in September, October and May. Summer months from May to the last of August represent a non-heating period. The accumulated heating energy supplied by the boiler reaches a value of **44.05 MWh** in the monitored year, which means an average supply of **80.82 kWh/m^2·year**.

Due to the academic use of the building, the operational schedules of heating and lighting systems have a weekly basis and vary according to the academic timetable and calendar. Four typical weeks were selected, see Figure 9. The heating system operates in a defined time period from Monday to Friday, being off during weekends and holidays.

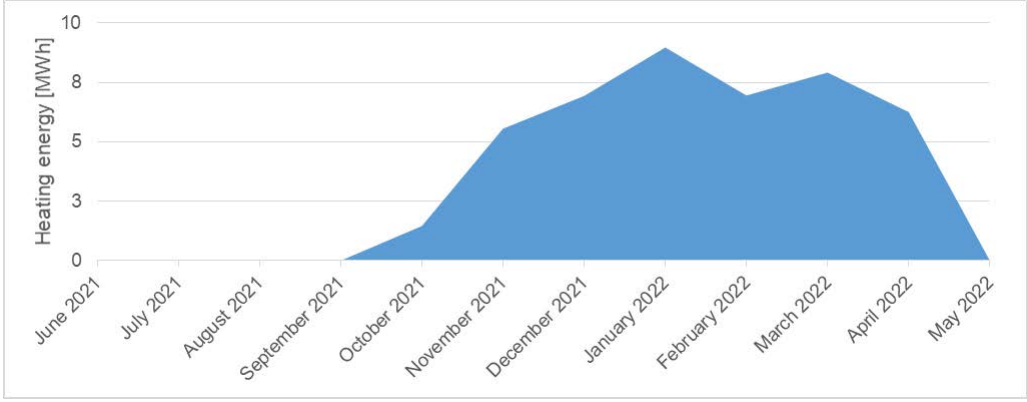

Figure 8. Annual distribution of heating energy attending to the measured data in the monitored period from June 2021 to May 2022.

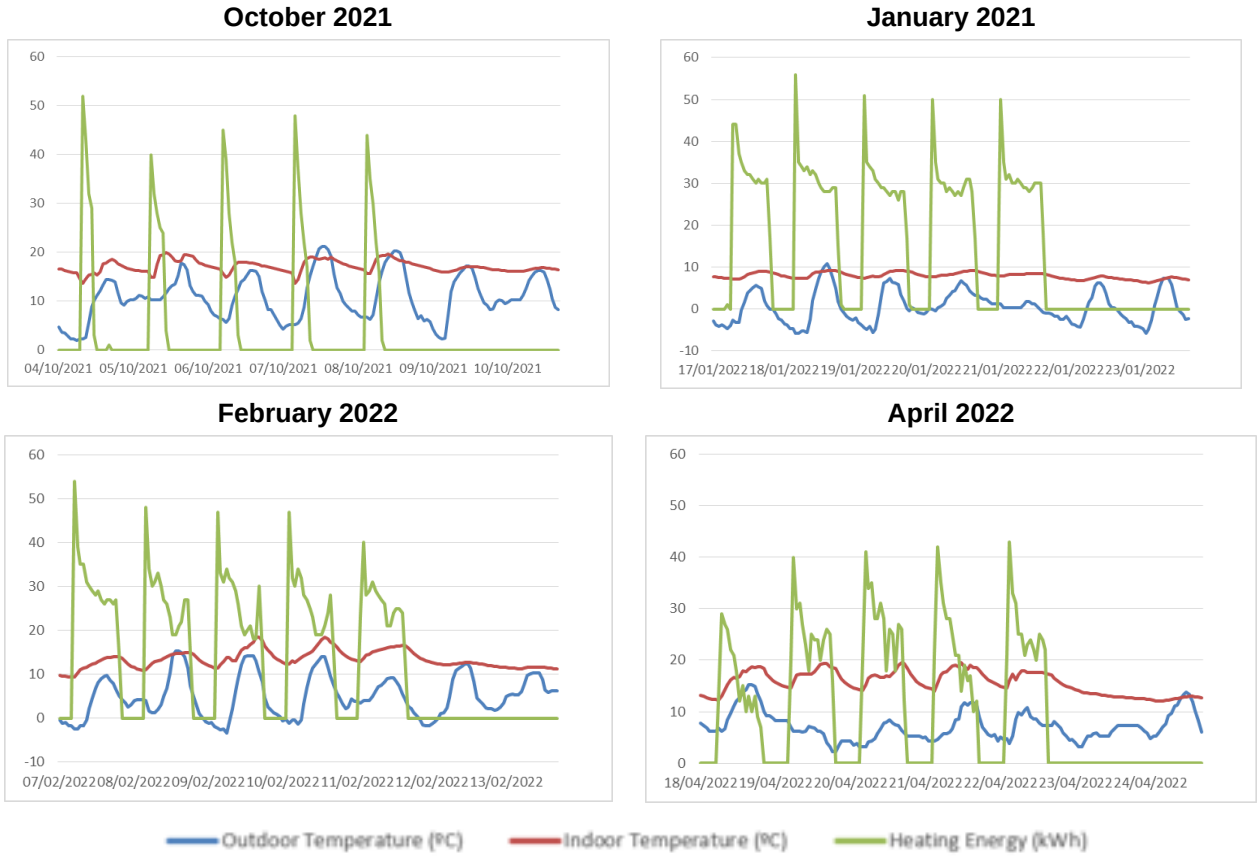

Figure 9. Typical week selected for calibrating the operational schedule of the heating system.

As appreciated in Figure 9, the highest recorded energy data correspond to the “start-up” of the heating systems during the morning and decrease during the day as external and internal gains increase. The boiler charge varies during the day according to the indoor conditions, see Figure 10.

In contrast to the heating system, there does not seem to be a clear operating pattern for the lighting system. This is due to a presence sensor in the building, as well as the variability in the occupancy period of the different classrooms. However, it has been identified that the auxiliary energy required by the building and its equipment is around 100 Wh with an electric current of 2 A. The total energy consumption measured in the building in the monitored period is **16.71 MWh** and an average of **30.66 kWh/m^2·year,** being gathered in Table 6 the data classified by zones.

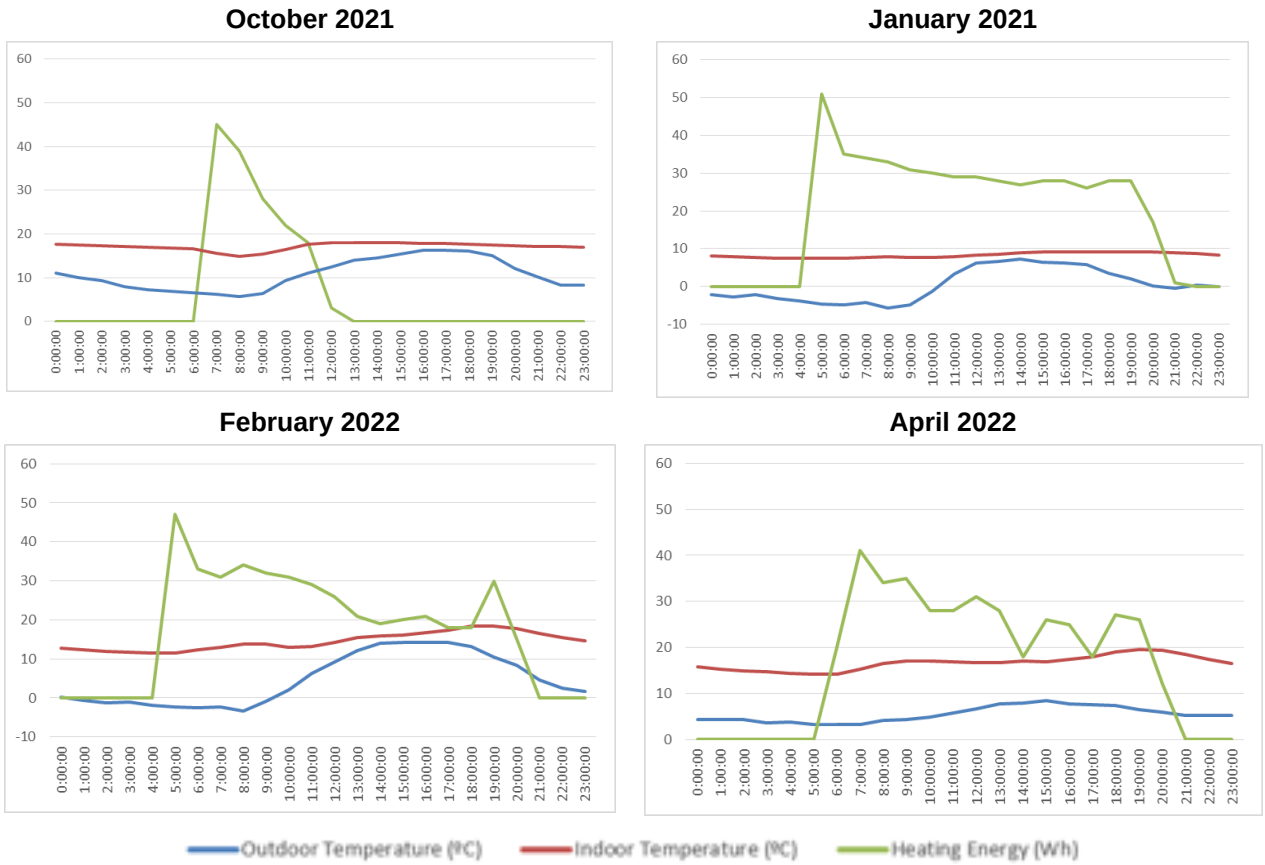

Figure 10. Typical days selected for calibrating the operational schedule of the heating system.

Table 6. Electrical energy consumption classified by zones in the period from June 2021 to May 2022.

Classroom 1	**Classroom 2**	**Toilets (right)**	**Toilets (left)**
2556.15 kWh/year	6762.37 kWh/year	3099.57 kWh/year	671.41 kWh/year
21.92 kWh/m^2·year	125.30 kWh/m^2·year	108.41 kWh/m^2·year	28.71 kWh/m^2·year
213.01 kWh/month	563.53 kWh/month	258.30 kWh/month	55.95 kWh/month
15.30%	**40.47%**	**18.55%**	4.02%
Demonstration room I	**Demonstration room II**	**Corridor**	**Boiler room**
926.11 kWh/year	125.59 kWh/year	1261.96 kWh/year	1307.05 kWh/year
17.56 kWh/m^2·year	2.39 kWh/m^2·year	22.16 kWh/m^2·year	30.17 kWh/m^2·year
77.18 kWh/month	10.47 kWh/month	105.16 kWh/month	108.92 kWh/month
5.54%	0.75%	7.55%	7.82%

From the data shown in Table 6, it can be interpreted that a large part of the teaching activity in the building takes place in Classroom 2 and that most of the occupants of the building are women since the women's toilet (right) has a higher annual electricity consumption. The building has been modelled in DesignBuilder according to constructive detail drawings and walk-through audits as shown in Figure 11.

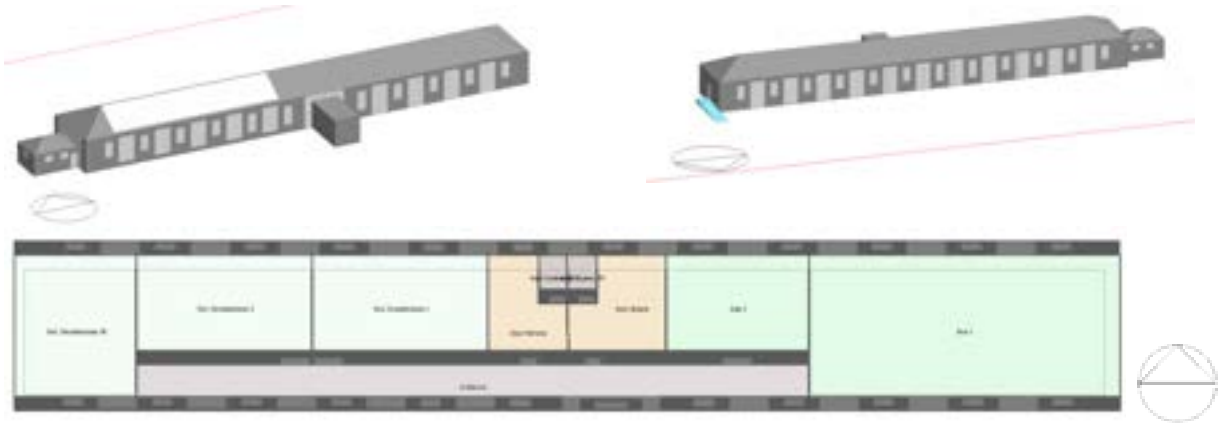

Figure 11. Visualization of building model created in DesignBuilder according to constructive details.

6. Conclusions and discussion of results

A data calibration process has been developed in this paper and deployed to implement it in a BES model calibration of Building 2 of the Faculty of Nursing and Health Science of the University of Burgos. It is necessary to define a specific methodology to accurately calibrate the monitored data. Including experimentally tested thermal transmittance values reduce uncertainties and, thus, also the energy performance gap of the BES model. In this study, the available monitoring data have been pre-processed and accurately prepared for implementing them into the BES model, so these data are used in the whole model calibration procedure. In this first part of the research, data have first been used to better understand the in-use operational schedule of the building. In addition, some of the monitored variables have been implemented as inputs to the model and others as outputs to verify the accuracy of the model calibration in future research.

The more complex step consists on the data pre-processing, including data cleaning and transformation, where a specific and accurate methodology was developed for the case study, in order to obtain averaged hourly data for the model calibration. In this sense, it must be highlighted that a whole year monitoring period has been used during this work, which means a more complex analysis process, but it also provides a more accurate BES calibrated model.

After the previous analysis, the BES model will be easily calibrated in further works. This calibrated BES model will encourage the estimation and prediction of reliable energy savings for different retrofitting scenarios of the building, such as this proposed for windows replacement. To fulfil the calibration of the model, occupancy schedules and density must be analysed from monitored data in order to implement reliable inputs in the BES model.

Acknowledgements

Abstract:
The recent geopolitical conflicts in Europe highlighted the sensibility of the current energy system to the volatility of energy carrier prices. In the prospect of defining robust energy system configurations to ensure energy supply stability, it is necessary to understand which parameters modulate the system configuration. This paper presents a framework that identifies a panel of technological solutions at the district level. First, a global sensitivity analysis is performed on a mixed integer linear programming model which optimally size and operate the system. The sensitivity analysis determines the most influential parameters of the model and provides a representative sampling of the solution space. The latter is then clustered using a density-based algorithm to identify typical solutions. Finally, the framework is applied to a suburban and residential Swiss neighborhood. The main outcome of the research is the high sensitivity of the model to energy carrier prices. As a result, the sampling space separates itself into two system types. The ones based on a natural gas boiler, and the ones relying on a combination of electrical heater and heat pump. For both types, the electricity demand is either fulfilled by PV panels or by electricity imports.

Keywords:
Mixed Integer Linear Programming (MILP), global sensitivity analysis (GSA), clustering, district energy system (DES), solution space sampling

1. Introduction

1.1. Background

The energy transition presents itself as one of the main levers to mitigate global warming as the energy sector accounts for 73% of global emissions and is expected to increase over the coming decade [1]. Therefore, developing a sustainable system requires careful energy planning from policymakers. In this prospect, energy system models are essential tools for understanding and assessing the potential impact of new technologies or policies.
The built environment, which accounted for 36% of final energy consumption in 2020 [2], is viewed as a promising pathway to a sustainable energy mix. Moreover, distributed energy systems, such as those composed of interconnected energy hubs, have great potential when deployed at the district scale, increasing self-consumption, and mitigating grid congestion.

1.2. Literature review

1.2.1. Energy system modelling

Energy models play a crucial role in guiding decision-makers towards a fossil-free energy system. The decarbonization of the current system requires a profound restructuring and involves a deeper electrification [3]. Low-carbon technologies, such as solar and wind, are spreading rapidly and are expected to become the main source of electric power [4, 5]. However, those renewable energies are intermittent and decentralized, bringing new challenges such as redistribution of electricity, stabilization of the power grid, intra and inter-day storage [6]. The multiplication of energy vectors, i.e., electricity, heat, oil, waste, biomass, or even hydrogen, increases the complexity of the task to provide an optimal configuration and operation of the system. Consequently, the majority of models focus on one specific energy sector (electricity, heat, mobility, etc.) and do not account for cross-sectoral synergy [7]. Additionally, on a more general aspect, the scale of the system can vary from a single building to an entire country. Whether or not, energy subsystems are considered in the overall scale of the system, e.g., interconnected buildings to represent a district system or the regionalisation of a country-wide system.

Buildings archetypes have been widely used to define large-scale systems [8] as their emissions have doubled in the last 30 years [4]. Kotzur and al. [9] developed a bottom-up model based on residential building stock. They deployed an aggregation algorithm to define archetype buildings. Their configuration and operation, which includes the buildings' interaction, are then optimized to acquire cost-effective solutions. Stadler and al. [10] assessed the impact of model predictive control (MPC) on the Swiss building stock. Three typical buildings were defined, each having 9 variations based on their construction date. The deployment of MPC allowed the reduction of the operational expenditure (OPEX) as well as the increase of the self-consumption. This result emphasizes the importance of the interconnection and operation improvement of building energy system.

In this regard, the design and operation of interconnected distributed energy systems, such as buildings, have proven to be part of the solution to help improve sustainable development in many countries [11–14]. The distributed aspect of such systems comes from the interconnection of multiple energy sources. Those sources can be energy hubs linked by local multi-energy grids. As discussed in the review of district-scale energy systems by Allgerini and al. [15], there has been a significant improvement in the models and tools used to analyze such systems.

In their paper, Morvaj and al. [16] performed an optimization of an urban scale energy system composed of twelve buildings. For each building, an optimal design and operation have been identified and the district heating network associated was optimized to reduce greenhouse gas (GHG) emissions and the total expenditure (TOTEX). Maroufmashat and al. [17] highlighted the importance of considering multiple energy hubs in order to observe significant cost and GHG emissions reduction. Their case study showed that the implementation of distributed combined heat and power (CHP) units was limited while operating an electricity grid with low CO_2 emissions. Additionally, the operation of interconnected energy hubs can significantly increase the robustness of the power grid, e.g. mitigation of congestion and ensuring reliability.

1.2.2. Global Sensitivity Analysis

Most current models assume a perfect knowledge of the input parameters, which induces the absence of uncertainty in the model and characterizes them as deterministic [12]. However, there is some uncertainty in a number of areas, including current policy, renewable energy production, and economic trends. Therefore, specific models are developed to consider the uncertainty of input parameters: stochastic models. However, it might be complicated to transform a deterministic model into a stochastic one without major remodeling. An alternative is the application of sensitivity analysis (SA) to deterministic models as proposed in [18, 19].

The utilization of sensitivity analysis is an effective approach to evaluate the impact of input parameters on a model. There exist two main types of SA: local and global. The most common method is the local sensitivity analysis, which evaluates the sensitivity by computing partial derivatives and gradients. Even though its ease of implementation makes it popular, the sampling scheme does not scan the entire space of input parameters. This gap is filled by the global sensitivity analysis (GSA), which covers the sampling space by varying several parameters at once. In doing so, it can capture parameters interaction [20].

The review of the SA method for building energy systems performed by Tian and al. [21] emphasized the importance of choosing the right method. They concluded that the choice should be based on the following criteria: research purpose, computational cost of energy models, number of input variables, and familiarity with the methods. Another review was performed by Westermann and Evins [22], 57 studies on building design were analyzed, focusing on objective, sampling strategy, and surrogate model type. Among all studies only 16 included a SA of the model, their sampling strategies were primarily based on Latin hypercube sampling (LHS), and only 3 used an optimization model, highlighting the low implementation of SA in optimization models.

A two-stage GSA framework has been used in several studies [18, 19, 23]. Their goal is diverse, from assessing the uncertainty, and sensitivity of the system, or to explore the multidimensional design space, but the applied framework stays the same. First, a screening method filters out non-influential parameters to reduce the computational cost of further model evaluations. It is then combined with a Sobol sequence to obtain a proper sampling of the solution space for the final sensitivity analysis.

1.3. Gaps and contribution

As emphasized throughout subsection 1.2., the literature lacks an application of distributed energy systems as energy hub in large-scale energy system optimization. The role of districts as renewable energy hubs can be

central in the optimization of a carbon-neutral national energy system as the operation of energy fluxes can help considerably improve the thermo-efficiency of the system. In this prospect, the proposed configurations should represent at best the district's solution space. This paper attends to provide a framework to identify a set of optimal district configurations. The framework consists of a two-step GSA on a district-wide energy system model to explore its solution space. The latter will then be aggregated to identify typical configurations. The purpose of this paper is to contribute to the following research points:

- Identification of the most influential parameters.
- Exploration of the solution space.
- Identification of typical configurations.

2. Methodology

2.1. Global sensitivity analysis

2.1.1. Overview

In order to develop a panel of solutions for the district, it is necessary to explore the whole solution space of the model. The following methodology is inspired by the publication of Saltelli and al. [20] which assesses the state-of-the-art of GSA. A sensitivity analysis can be decomposed into four main steps:

1. Identification: k input parameters of the model are selected
2. Sampling: the input parameters space is discretized by N samples
3. Evaluation: the model outputs are computed for each sample
4. Comparison: some metrics are derived from the N outputs of the model for the k parameters

The methodology used consists of two separate SAs:

1. A screening method is performed to identify the most influential factor of the model, i.e. the parameters inducing the greatest variation of the objective function.
2. A variance-based method is used to efficiently explore the solution space of the model and quantify its sensitivity.

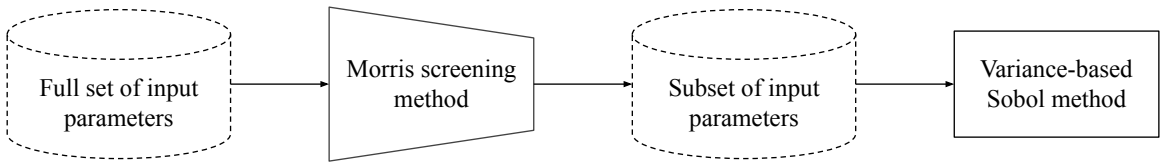

Figure 1: Scheme of the two-step GSA composed of first the Morris method as a screening and then the Sobol method is applied on the most influential parameters previously identified.

2.1.2. Morris screening

The screening method used is the Morris method, which allows to qualitatively compare the influence on the model output of a large number of parameters with a few evaluations [24]. The method discretizes the input parameters space, which is a k-dimensional hypercube, into a p-level grid, where k is the number of independent input parameters and p is a sampling parameter. Afterward, it performs a one-step-at-the-time method (OAT), i.e. it randomly modifies one input parameter by $\pm\Delta$ to generate r trajectories.
Finally, it evaluates the elementary effect of the i_{th} input parameter (EE_i) as a function of the model output $Y = f(X_1, ..., X_n)$, see Equation 1. The EE can be interpreted as a local partial derivative, thereby it represents the sensitivity of the model at a specific point w.r.t the input parameter:

$$EE_i = \frac{\partial Y}{\partial x_i} \simeq \frac{Y(X_1, X_2, \dots, X_{i-1}, X_i \pm \Delta, \dots X_k) - Y(X_1, X_2, \dots, X_k)}{\Delta} \tag{1}$$

Where Δ is defined as a function of p: $\Delta = \frac{p}{2(p-1)}$ and can be considered as the size of the discretization mesh. The total number of model evaluations amounts to $r(k+1)$, where r is suggested between 4-10 [20]. The choice of p and r has to be made jointly to ensure that the k dimensions and their interactions are correctly sampled, Saltelli proposed $p = 4$ and $r = 10$ [25] whereas Morris used $r = 4$ in [24], which seems to be the minimum usable value.

In its original work, Morris proposed the computation of the mean μ_i (Equation 2) and standard deviation σ_i (Equation 4) of the elementary effect distribution for each parameter i. However, by doing so, the positive and negative effects cancel each other out, which would falsely influence the results of the mean value. Thereby, the method has been improved by Campolongo and al. [26], by considering the absolute mean elementary effect μ_i^* (Equation 3).

$$\mu_i = \frac{1}{r} \sum_{j=1}^{r} EE_i^j \tag{2}$$

$$\mu_i^* = \frac{1}{r} \sum_{j=1}^{r} |EE_i^j| \tag{3}$$

$$\sigma_i^2 = \frac{1}{r-1} \sum_{j=1}^{r} \left(EE_i^j - \mu_i \right)^2 \tag{4}$$

Those indicators allow to compare the input parameters between each other. A small absolute mean value means a non-influential parameter. The standard deviation reflects the interaction between parameters: a high value means that the output is highly dependent on the sampling point, i.e. on the other input parameters values. Conversely, a low standard deviation indicates that the elementary effect is not subject to fluctuate with other factors variation.

The representation of the mean absolute value of the EEs and their standard deviation makes it easy to identify to which group the parameter belongs. As represented on Figure 2, one can see the different zones and the line ($x = y$) separating quadrant 1 that defines whether parameters interact together or not. The different zones can be defined as follows:

1. Non-influential parameters.
2. Influential, non-interacting parameters.
3. Influential, interacting parameters.
4. Influential parameters.

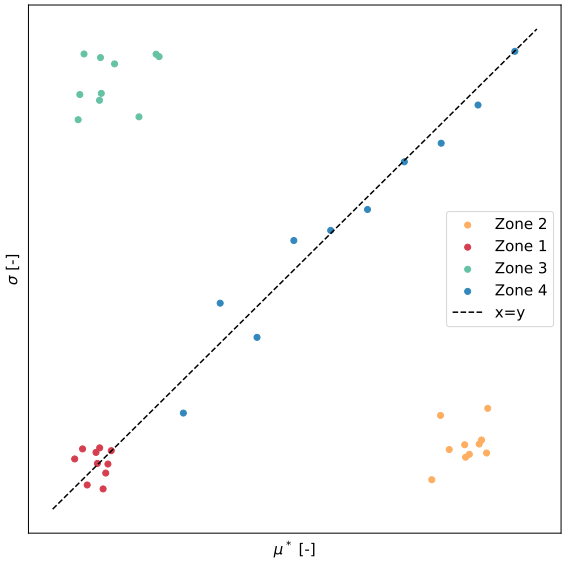

Figure 2: Identification of the typical zone on the $\mu^* - \sigma$ plane.

The comparison of μ and μ^* gives an extra insight in the monotony of the model. If the model output increases with an augmentation of the parameter, the EE will stay positive thus μ^* and μ will have a similar value. Whereas, if the EE changes sign regularly its cumulative will be lower, i.e. μ will be lower than μ^*.

2.1.3. Sobol sampling

The Sobol method is a variance-based sensitivity analysis named after the mathematician Ilya M. Sobol. The method is developed in [20, 27] and uses Sobol's recommendation on the sequencing of quasi-random numbers. However, Saltelli extended her work in [28] to reduce the error rate when computing sensitivity indices.

2.1.3.1 Sensitivity indices

The method evaluates two different sensitivity indices, the first one is the first-order sensitivity coefficient (Equation 5). It results from the ratio of the variance of the mean output, considering all parameters except the i-th, to the variance of the output. The secondary sensitivity coefficient is the total effect index, i.e. first and higher-order sensitivity coefficient (Equation 6).

Assuming: $Y = f(X_1, ..., X_n)$ is the model output, $\mathbf{X}_{\sim i}$ symbolizes all parameters but $\mathbf{X}_i$, $E_{\mathbf{X}_{\sim i}}(Y \mid X_i)$ is the mean of Y for every possible $\mathbf{X}_{\sim i}$ and finally the variance V_{X_i} is calculated for all values of X_i.

$$S_i = \frac{V_{X_i}\left(E_{\mathbf{X}_{\sim i}}(Y \mid X_i)\right)}{V(Y)} \tag{5}$$

$$S_{Ti} = \frac{E_{\mathbf{X}_{\sim i}}\left(V_{X_i}(Y \mid \mathbf{X}_{\sim i})\right)}{V(Y)} = 1 - \frac{V_{\mathbf{X}_{\sim i}}\left(E_{X_i}(Y \mid \mathbf{X}_{\sim i})\right)}{V(Y)} \tag{6}$$

The first-order coefficient only takes into account the effect of itself on the output value, but not the possible effect when considering higher-order interactions with other parameters. The total-order index evaluates the effect of a parameter considering all possible interactions with other parameters. Meaning that a parameter with a value of $S_T = 0$ can be considered as non-influential on the output Y. The total number of model evaluations is $N(k+2)$ with N being typically between 500 and 1000 and it is suggested to choose a power of two [20].

2.2. Clustering

2.2.1. Standardization and features selection

It is necessary to standardize the data when various features are used for clustering. Otherwise, the aggregation algorithm mainly takes into account the large numerical values. The chosen standardization technique is the *z-score*, see Equation 7. Each feature Y_i of the data set is standardized as follows:

$$Z_i = \frac{Y_i - \mu_i}{\sigma_i} \tag{7}$$

where μ_i is the mean and σ_i is the standard deviation of the feature Y_i. The features selected for the clustering, i.e. the district characteristics, are a mix of economic and technical attributes of the optimization result. The key performance indicators (KPI) chosen are capital and operational expenditure (CAPEX and OPEX). Installed capacity of energy conversion and storage units are included in the clustering as they are key properties of the district configuration. Regarding the exchange with the network, the total and peak energy supply and demand are considered for the natural gas (NG) and the electricity grid.

2.2.2. Aggregation techniques

Several aggregation techniques, such as K-means, DBSCAN, and HDBSCAN, performance are analyzed for this specific clustering. The K-means method is a clustering technique that minimizes the variance within clusters, which is a difficult problem to solve optimally. However, heuristic algorithms can be used to find a local optimum efficiently. To determine the appropriate number of clusters for K-means, two common techniques are the Silhouette score and the Elbow method. The Silhouette score evaluates how well each data point fits within its assigned cluster, based on the density of points within the cluster and the distance between clusters. The Elbow method involves observing the point of inflection on a plot of the sum of squared errors (SSE) as the number of clusters increases.

Another assessed method is the DBSCAN, which is based on the concept of core points. Points are defined as core points of one specific cluster when they can reach a minimum of *minPts* neighbours within a ϵ distance. Additionally, points within reach, but not satisfying the minimum neighbours criterion still belong to the cluster. However, points non-reachable from a core point are considered outliers. The choice of *minPts* and ϵ should be based on the data properties [29].

The HDBSCAN algorithm is an extension of the DBSCAN method with a hierarchical approach. The algorithm can be decomposed in a few steps to get a broad overview. First, the space is transformed based on its density. This allows to construct a minimum spanning tree used to build the cluster hierarchy. Then, the cluster tree is condensed to finally extract the clusters [30, 31].

To support the clustering task, a score is introduced to quantify the quality of the clusters. The chosen score is the density-based clustering validation (DBCV) index presented by Moulavi and al. [32]. It is based on a parameterless core distance defined by the density of objects and mutual reachability. The index ranges between -1 and 1, which represents a bad and a good score respectively.

2.3. Case study

The application of the presented framework is carried out on a suburban and residential district located in the climatic zone of Geneva, Switzerland. The energy system consists of 15 buildings, including 5 single-family houses and 10 apartment buildings [33], selected from a pool of 30 available options. Various characteristics of the buildings, such as type, year of construction, energy reference area, and height, are obtained from the cantonal and federal Official Building Registry [34,35], while the ground surface area is provided by the cantonal administration [35, 36]. The climate data, solar irradiation, and temperature are extracted from Meteonorm [37], and the characteristics of the building envelope are calculated following SIA norms 380/1 [38]. The physical information gathered on the buildings allows to define the electric and heat demands based on a 1R1C model detailed in [39]. The PV orientation is optimized based on roofs and façades information extracted from Swisstopo [40,41], while the grid specifications and electricity demand are furnished by Romande Énergie [42]. The time series are divided into 10 typical periods formed of 24 hours and 2 extreme periods of 1 hour each, resulting in a total of 242 different timesteps being considered. Various parameters are fixed during the problem definition, including unit parameters, district parameters, and energy carrier price. More information on these parameters can be found in [43].

3. Results and Discussions

3.1. Sensitivity analysis

The considered parameters for the screening step are energy conversion and storage units parameters as well as the energy carriers prices. A total of 60 parameters were considered. Following the sampling indications of Morris, 610 optimizations were required to compute the sensitivity metrics. As the result of each run is a complete system configuration and operation, a specific output value had to be identified to compare each optimization. The chosen indicator is the TOTEX, assuming an economically rational behaviour.
A good practice is to plot the absolute mean value (μ^*) and standard deviation (σ) of the EE distribution of each input parameter, Figure 3 shows such a plane for the six most influential parameters. Two parameters stand out from the rest: the supply cost of electricity and natural gas. The supply cost of electricity has a high influence on the TOTEX, high μ^*, however, its standard deviation is low, indicating that its EE is not correlated to the other input parameters. This low correlation comes from its key role in the district model. It serves to directly supply the electric demand when no installed units can fulfill it and it can also serve to supply the heat demand via HPs and electrical heaters. The retail price of NG is less influential as fewer units consider natural gas as a resource. However, it can be considered as an influential parameter as a small price of NG can help provide heat at a very low cost with a gas boiler. Note that the HP and boiler parameters are also influential with a low standard deviation, highlighting that the technologies installation is not correlated to the energy carriers prices.

Table 1 presents the Morris results of the aforementioned parameters. Comparing the absolute (μ^*) and non-absolute (μ) mean value of EE shows the monotonic correlation between TOTEX and input parameters values, e.g., an increase in electricity supply cost will always increase the TOTEX. Furthermore, the negative sign of the mean EE of the electricity feed-in tariff indicates that it contributes to the reduction of TOTEX.

Table 1: Sobol's indices, mean and absolute mean EE for retail and feed-in tariffs of energy carriers. The sensitivity of the parameters for the Morris and Sobol approaches all trend in the same direction.

	S_1	S_{Ti}	μ^*	μ
Electricity retail tariff	0.86	0.91	93k	93k
Natural gas retail tariff	0.09	0.14	33k	33k
Electricity feed-in tariff	1e-4	6e-4	0.9k	-0.9k

In order to reduce the computational time of the SA a selection of the input parameters was required. The decision to focus on the energy carrier prices was based on obtained results and similar conclusions presented in subsubsection 1.2.2..

The input parameter space is explored with 2560 samples following recommendations presented in subsubsection 1.2.2., $p = 4$, $r = 10$, and $N = 512$. The parameters variation range is $\pm 50\%$ for retail tariffs, as displayed in Figure 4, and $\pm 30\%$ for the feed-in tariff. The sensitivity indices of the Sobol can be observed in Table 1 alongside Morris μ^* values for comparison.
The Sobol results have a similar trend than the qualitative sensitivity indices from the Morris method. The electricity feed-in tariff is less influential regarding Sobol's results. Since the first-order Sobol effect and the total effect have a similar value, the interaction between energy carrier prices is mainly of additive nature, ie. S_1 and S_{Ti} are close. The retail tariff of electricity is much more influential than the NG tariff. One possible explanation is that, as mentioned before, there is a greater amount of technology using electricity compared to the NG. Therefore, a low electricity price can help to significantly reduce TOTEX, as both electricity and heat demand can be met using electricity.

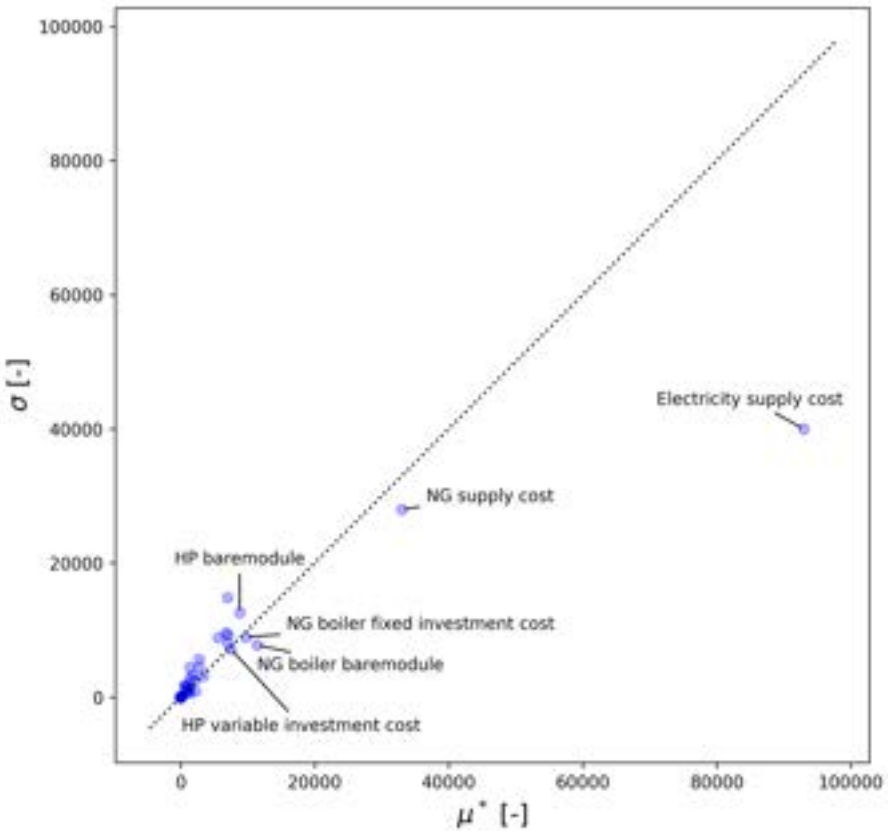

Figure 3: Morris analysis results on $\mu^* - \sigma$ plane.

3.2. Typical configurations identification

First, a Silhouette score is calculated for various numbers of clusters to identify a range of potential optimal values. The score decreases from 1 to 10 and then seems to stabilize, meaning that the optimal number of clusters is $k = 1$. Whereas, for the Elbow method the inflection occurs in the range of $k = 5 - 7$. Finally, the DBCV index is computed for the K-means clustering with k varying from 5 to 11 and the optimal number of clusters appears to be around $k = 10$ with a score of -0.54.

The DBSCAN algorithm recognizes a total of 28 clusters and obtains a DBCV index of -0.12, which is significantly better than the K-means DBCV indices. Regarding the HDBSCAN result, it obtains the best DBCV index with a value of 0.04. However, it identifies 73 clusters, which is far from the initial estimation of $k \simeq 10$.

Looking more precisely at the size distribution of the DBSCAN clusters, one can remark that beyond the tenth cluster, the size dropped abruptly. Indeed, the first ten clusters represent more than 90% of the data points, corresponding to the approximated required number of clusters. Regarding the HDBSCAN distribution, there was no sharp decrease in the cluster size. As a consequence, only data from the first ten DBSCAN clusters were considered for further calculations.

3.3. Presentation of the typical district configurations

3.3.1. Distribution of the configuration in the sampling space

Figure 4 represents with different colors the distribution of the clusters over the retail tariffs variation range. As observed in subsection 3.1., the output of the model, i.e. the district configuration, is strongly correlated to those tariffs. This relation can be observed in the figure below as the different configurations can be identified. Additionally, the sampling space naturally separates itself in half, the separation is highlighted by the amount of NG imports. Configurations 1 to 4 are based on NG and the configurations above, 5 to 10, on electricity. The NG configurations are located in the bottom right corner where the electricity tariff is high. Inversely, the electricity-based ones are in the top left region where the NG price is high. One can note that the space has fewer samples below the separation line, this is due to the data selection done in subsection 3.2..

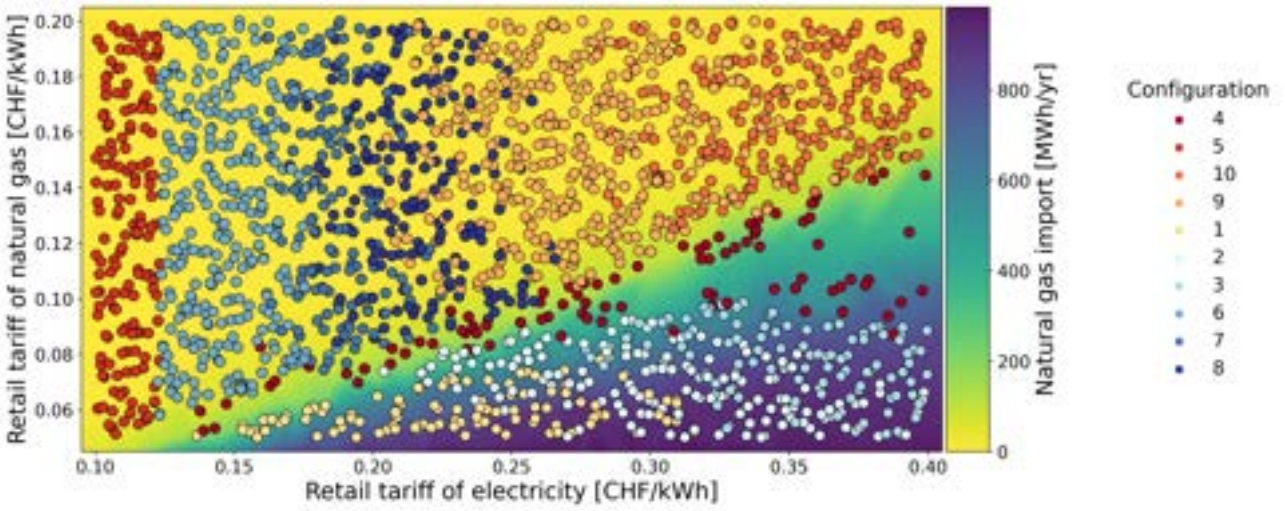

Figure 4: Typical configurations distribution in the retail tariffs space.

3.3.2. Installed units capacity

Figure 5 shows the installed units capacity for each configuration alongside their grid exchanges. The main variation between configurations is the total installed capacity, almost ranging from single to double. This discrepancy is due to the extreme period (high demands and rash environment) included in the model, as the demand is either fulfilled by imports or by an installed unit. The model installs a minimum heating capacity to supply heat in any condition. This minimum heating capacity appears in all configurations and is either composed of NG boiler or a combination of an electrical heater and HP. The additional capacity is formed by various PV capacity deployments.

Concerning the units' installed capacity, there is no positive correlation between HP and PV installation, as one would have expected from previous results discussed in subsubsection 1.2.1.. If no PV panels are installed, electricity imports increase considerably to supply the HP or the electrical heater. The HP installation triggers the deployment of water tanks to serve as a buffer. Large installation of boilers is accompanied by significant imports of NG since boilers are used as the main heat source when they are installed. The presence of HP and PV in most configurations underlines their high potential in district energy systems. Although, the electric grid is more strained with PV implementation as imports are reduced, but exports are increased, requiring a sufficient absorption capacity of the grid.

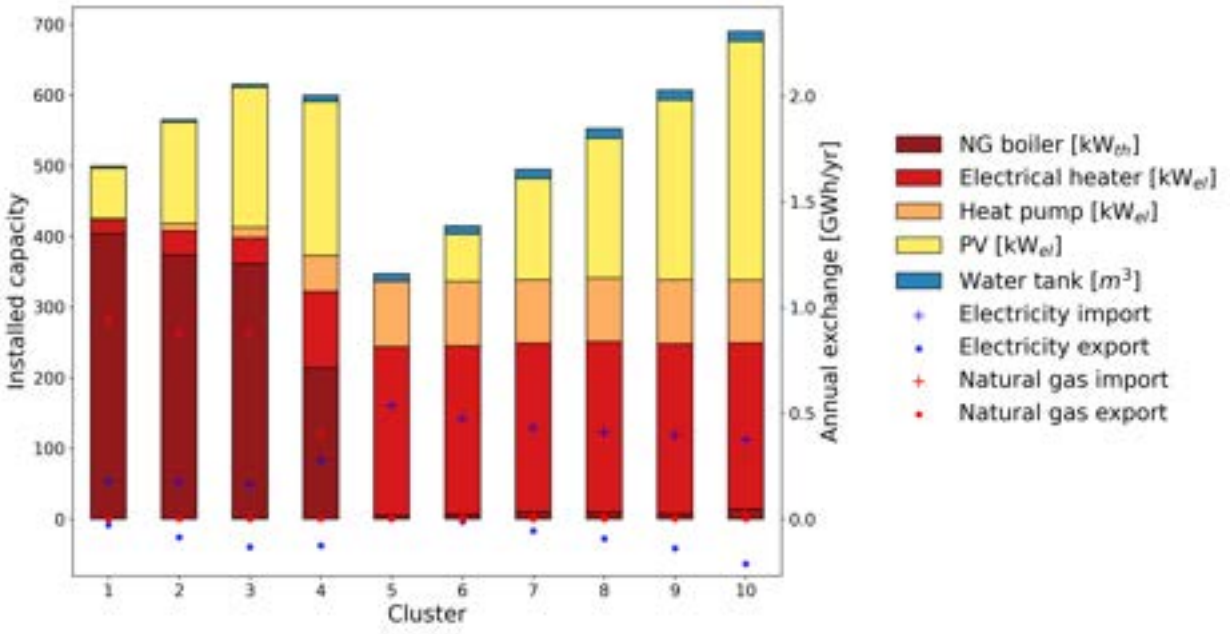

Figure 5: Identified configurations of the district and their grids exchanges.

3.3.3. Dimensionality reduction

Principal component analysis (PCA) is a dimensionality reduction technique used to facilitate the exploration of data sets. The algorithm identifies the eigenvectors of the covariance matrix. The dimensions are sorted from most to least explaining components. Usually, only the first two components are used to project the data points, as can be observed in Figure 6.

The first dimension explains 64.8% of the variance and the second 33.2%, thereby the plot illustrates 98% of the data set variance. The indicators can be regrouped into three main groups which align with the principal components, this is a direct result of having 98% of the variance explained with only 2 dimensions. The first component can be interpreted as the global warming potential (GWP) and the second as the TOTEX. The first deviates slightly from the x-axis, however, the second is perfectly aligned.

A group is positively correlated to the first dimension and contains the NG import, boiler installed capacity, and GWP. Their correlation is natural as the boiler is fueled by NG, which has a high CO_2 emission factor. Inversely, another group is negatively correlated to the first dimension. It contains the installed capacity of the heat pump and electric heater, which are low emissions technologies when coupled with a low-carbon electricity grid like the Swiss one. The electricity import is closely related to the group but helps reduce the TOTEX, negative correlation to the second dimension. This second dimension is highly correlated with the installed PV capacity, electricity export, and TOTEX. The relationship between PV capacity and electricity export stems from the high production potential of the technology in summer, which exceeds the demand. This results in a redistribution of the electricity surplus in the grid. This electricity export is sold at a low price, so the gain from the electricity buyback may not offset the operational cost of the microgrid and the PV installation cost. Note that the influence of the indicators is somewhat similar.

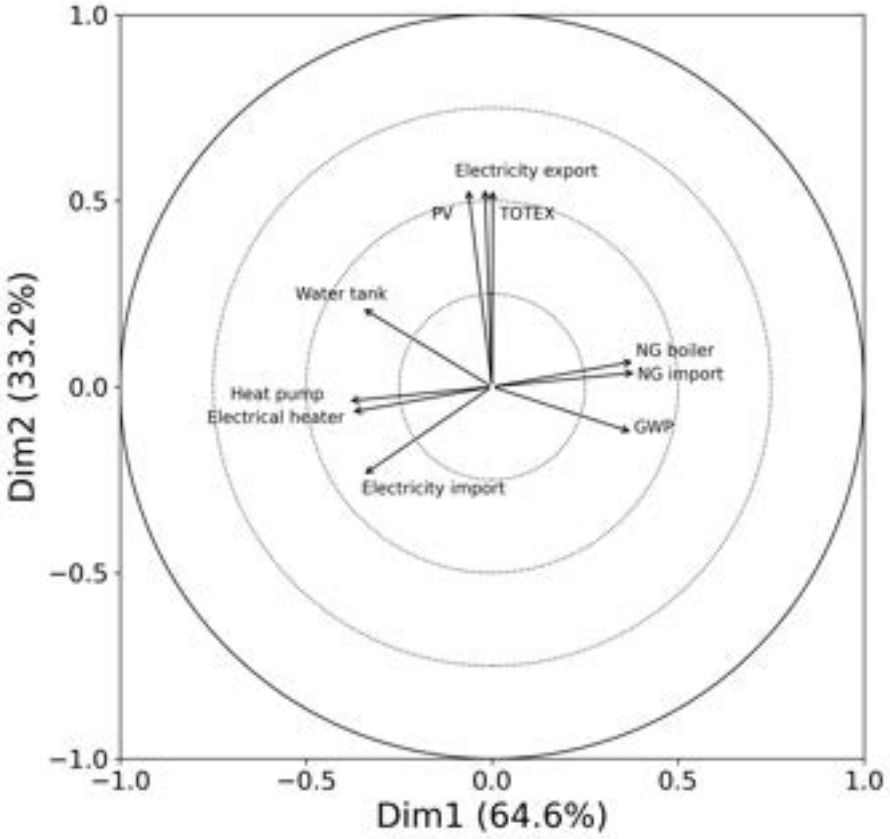

Figure 6: Variable correlation plot of the first two principal components. Indicators pointing in the same direction are correlated, those pointing in the opposite direction are inversely correlated, and those that are perpendicular are uncorrelated. The length of the arrow indicates the influence of the indicator.

4. Conclusion

The objective of this paper was to develop a framework able to identify typical district configurations. The methodology is composed of a two-fold GSA to efficiently sample the space of solutions, and a clustering step to determine typical technical solutions. The Morris method is used to screen input parameters and the sampling scheme is acquired using the Sobol method. The space of solutions obtained from the Sobol sequence was clustered using multiple algorithms. The range of optimal number of clusters was identified using two cluster validation indices and the Elbow method.

- The conclusion of the GSA emphasized the importance of the retail tariff of energy carriers in such systems.
- From 8 to 10 configurations were necessary to represent at best the solution space. The results from each technique were compared using the DBCV index. The tenth first clusters from the DBSCAN were selected as they represent 90% of the data and obtain one of the best score.
- The identified configurations can be separated into two types of systems, those based on NG and the others on electricity. Each type has a pretty basic configuration, i.e. the configurations based on NG install a boiler and the electric ones combine HP and electrical heater.
- In terms of electricity consumption, the import and export of electricity correlate negatively, respectively positively, with the installed photovoltaic capacity.

The presented results indicate that the presented framework allows to efficiently identify districts configurations. The next logical step would be to implement this framework to define a panel of configurations for district representatives of a large-scale energy system and study the impact of optimal built environment in the infrastructure.

5. Fundings

The research published in this report was carried out with the support of the Swiss Federal Office of Energy SFOE as part of the SWEET project acronym. The authors bear sole responsibility for the conclusions and the results of the presented publication.

Abstract:
Deep geothermal energy has tremendous potential for decarbonizing the heating sector. However, one common obstacle can be the mismatch between geologically attractive regions in the countryside and urban areas with a high heat demand density, which are therefore attractive for district heating systems. In the last years, an increasing number of regions consider the transport of geothermal heat into urban clusters. One example of such a region is the South German Molasse Basin in Upper Bavaria. However, such heat transport pipelines come along with massive upfront investment costs due to the required large pipe diameter and insulation thickness. While the classic concept foresees the use of water as a heat carrier in such long-distance heat transportation pipelines, CO_2 can be an attractive alternative. This study investigates the thermo-economic performance of CO_2 as a heat transport carrier for a potential long-distance heat transmission pipeline with a length of 20 km, which could connect a planned geothermal project in the South of Munich with the existing district heating network of Munich. The results of the base case scenario demonstrate that for both heat carrier options water and CO_2 rather low LCOH for the transport of the heat can be achieved. The resulting additional LCOH by the long-distance heat transport of around 0.6 c€/kWh are rather small compared to the typical overall LCOH of geothermal district heating systems. Comparing the thermo-economic performance of water and CO_2 reveals rather similar achievable LCOH, with a slight advantage for the classical concept of using water. However, this changes if the installation of a high temperature heat pump (HTHP) is considered in order to increase the thermal capacity of the heat transport system. In the case of using CO_2, the additional temperature increase takes place directly within the CO_2 stream by just installing a compressor, while in the case of the water system, a complete HTHP system needs to be installed. In combination with a higher achievable COP, the CO_2 HTHP configurations results in lower overall LCOH compared to the water system.

1. Introduction

Deep geothermal energy can play a significant role in the necessary transformation of the heating sector [1]. While there is an increasing number of geothermal projects worldwide [2], the vast majority of the worldwide potential is still untapped [3]. However, one major challenge for the utilization of geothermal energy is the common mismatch between urban areas with a high heat demand density and areas with favourable geological conditions for heat extraction. For example, promising geothermal resources in the countryside with temperatures between 80 - 110 °C can not be economically utilized without long-distance heat transport. While such resource temperatures are highly suitable for district heating supply, their temperature is too low for economic power generation by a binary cycle such as an Organic Rankine Cycle (ORC) [4].
Thus, since the local heat demand is too low in order to justify the high investment costs, without the ability to transport the heat over long distances, many promising geothermal resources would remain untapped. Molar-Cruz et al. [5] have recently studied the application potential of long-distance heat transport for geothermal energy in the Greater Area of Munich, Germany. The findings demonstrate that applying long-distance heat transportation systems can reduce the overall cost of heat supply by 15 % compared to a scenario without heat transport. Furthermore, despite the high investment costs of the transportation system, the resulting heat costs are still competitive with other heating technologies. Kavvadias and Quoilin [6] show that long-distance heat transport from conventional combined heat and power plants (CHP) can be economical and is already applied in several European countries. Furthermore, Moser and Puschnigg [7] investigated the concept of a supra-regional district heating network for a use-case area in Austria. Their results suggest that long-distance

heat transport networks between several different actors might become economical in a future non-fossil energy system and has a high potential to connect industrial waste heat and renewable energy heat sources. Thus, long-distance heat transport is a promising approach to boost the utilization of geothermal energy and the transformation of the heating sector in general.

However, due to high upfront investment and operational costs, an optimal design of the transportation system is pivotal. While the classical concept foresees the use of water as a heat carrier, CO_2 has gained increasing attention as an alternative heat carrier in both geothermal systems [8]–[10] and district heating networks (DHN) [11]. The concept of urban CO_2 district energy systems is mainly investigated for modern networks that provide both heating and cooling by heat pump systems being installed in each building. Thus, due to the low operating temperature of such systems and the corresponding CO_2 phase change, the costs of heat distribution can significantly be reduced [12].

Thus, while CO_2 is currently investigated as an energy carrier within DHN systems, its application potential for long-distance heat transport has not been evaluated in existing studies so far. The scope of this work is the evaluation of the thermo-economic potential of CO_2 as a heat carrier for a potential application case in the greater area of Munich. This area is a promising case study since the connection of the geothermal attractive region in the South of Munich with the existing DHN system of Munich is currently under discussion and within a preliminary planning phase [13]. This work investigates several technical options for the heat transport of CO_2 and compares the resulting thermo-economic performance with a conventional concept using water as a heat carrier.

2. Methodology

In the system under scrutiny, the heat is transported circulating fluid between the geothermal field and the DH (district heating) network as shown in Fig. 1.

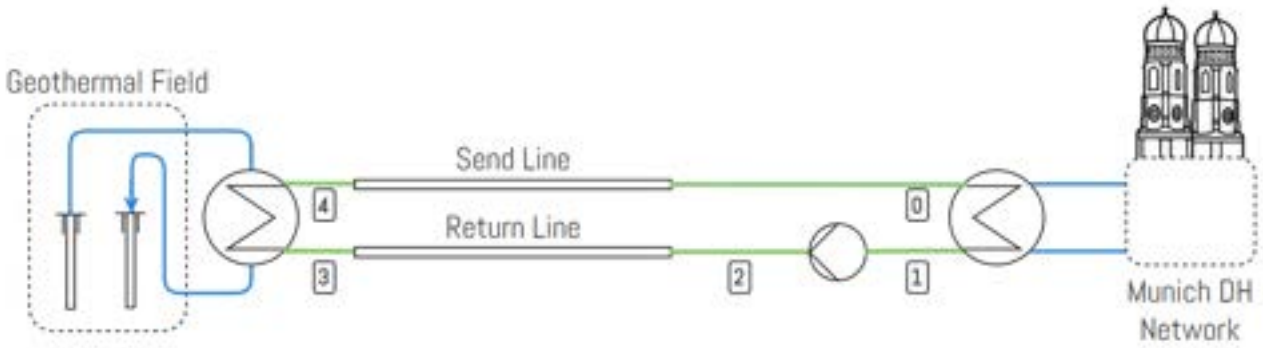

Figure 1: Base transport system scheme

2.1. Pipeline Model

The behavior of the system is highly dependent on the model of the pipelines connecting these two locations due to their length. To assess the condition of the fluid within the pipeline, pressure and enthalpy balances (1) were integrated over its length using the Runge-Kutta solver [14] implemented in Scipy [15].

$$\begin{cases} \frac{dp}{dx} = f \frac{1}{2\rho d} \left(\frac{4\dot{m}}{\pi d^2}\right)^2 \\ \frac{dh}{dx} = \frac{\Delta T}{r_{tot}\dot{m}} \end{cases} \tag{1}$$

The friction factor in (1) has been calculated using the Churchill correlation [16] while the linear thermal resistance in (1) has been defined as follows:

$$r_{tot} = r_{conv} + r_{ins},\ r_{conv} = \frac{1}{Nu\ \pi k_{fluid}},\ r_{ins} = \frac{\ln\left(1 + \frac{2s_{ins}}{d}\right)}{2\pi k_{ins}} \tag{2}$$

with:

$$Nu = 0.023 Re^{0.8} Pr^{0.3} \tag{3}$$

The formulation of the balance equations (1) implies that the kinetic and gravitational terms have been neglected in both the momentum and energy balances. The integration process used in the analysis provides a

high level of accuracy while still maintaining a reasonable computational time. However, especially for water-based systems, it is possible to achieve an acceptable level of accuracy by discretizing the duct into a few sections (less than 10).

2.2. System Model

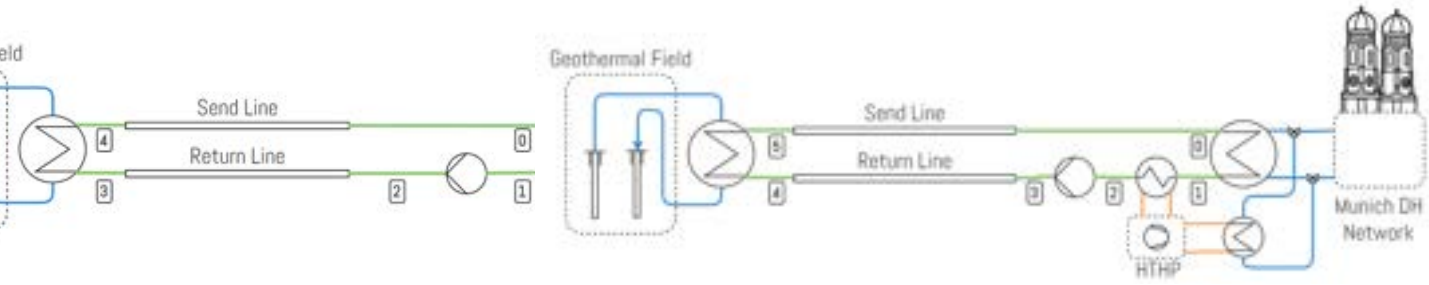
Given the high investment costs and anticipated slow transients in the pipelines, the system is expected to operate in a steady state condition, providing a constant heat flux to the Munich area DH Network throughout its lifetime. Thus, the water flow rate in the DH is evaluated based on the system's heat transport capacity rather than on the heat demand from the grid. Various configurations of the heat transfer system were analyzed for both the water-based and CO_2-based cases, as illustrated in Fig. 2 and discussed in the following section.

2.2.1. Base Case

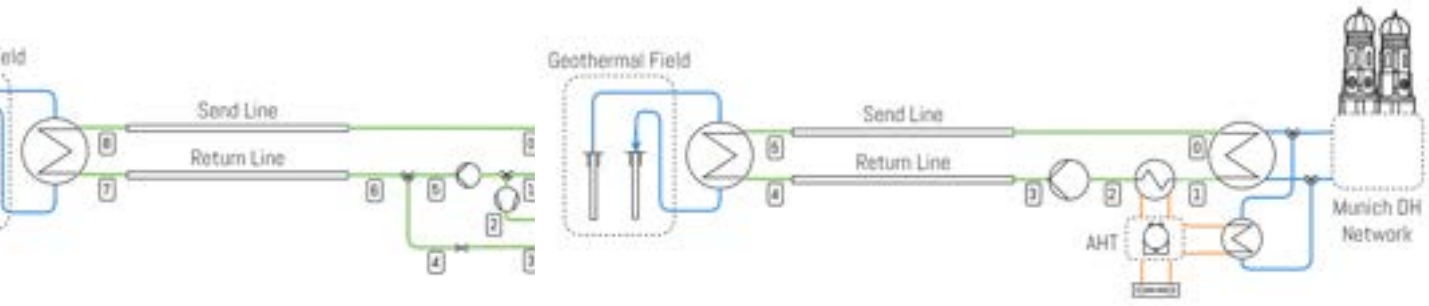
The most basic approach for long-distance heat transportation, as depicted in Fig. 2a, involves circulating the fluid via a pump placed after the DH network heat exchanger. The flow rate of the fluid is optimized to minimize the *LCOH* under specific design conditions. Additionally, for CO_2-based systems, the pipeline pressure is also optimized.

2.2.2. Heat Pump Case

The industrial requirement of fixed lowest temperature (65℃) in standard district heating networks can limit the amount of heat that can be transported for a given flow rate, as the temperature at the outlet of the DH heat exchanger cannot go below a certain value. To overcome this limitation, a heat pump can be installed after the DH heat exchanger outlet to further cool down the working fluid before redirecting it to the geothermal field, as shown in Fig. 2b.



(a) Base Case **(b)** High Temperature Heat Pump (HTHP) Case



(c) Simplified Heat Pump for CO_2-based system **(d)** Absorption Heat Transformer (AHT) Case

Figure 2: Different configuration on the DH network side of the system

This configuration not only improves the heat transfer rate but also reduces the pumping power for CO_2-based systems as CO_2 becomes less compressible at lower temperatures. Alternatively, a compression set-up can replace the heat pump in CO_2-based systems as shown in Fig. 2c, which removes the inefficiencies associated with the heat pump evaporator.

The heat pump in Fig. 2b has been modeled with a fixed exergy efficiency of 0.4, according to experimental results from literature [17], to avoid the need for complete modeling. Knowing the exergy efficiency is possible to estimate the electrical power demand as:

$$\dot{W}_{heat\ pump} = \frac{1}{\eta_{exergy}} \left(1 - \frac{T_{low}}{T_{high}}\right) \dot{Q}_{heat\ pump} = \frac{1}{0.4} \left(1 - \frac{T_{low}}{T_{high}}\right) \dot{Q}_{heat\ pump} \tag{4}$$

T_{low} and T_{high} have been evaluated considering $\Delta T_{pinch\ point} = 5$℃ in the heat pump's heat exchangers.

2.2.3. Absorption Heat Transformer Case

Heat pumps can increase power extraction from the geothermal fluid, but at the expense of increased electricity consumption. To minimize the electricity consumption, heat transformers can be used instead of heat pumps. However, the heat transformer method requires the dissipation of some of the transported heat to allow for the remaining heat to reach the desired temperature, as depicted in Fig. 2d.

The heat transformer has been modelled as a black box considering a 50% exergy efficiency [18] in analysing the various configurations. The ratio between the transmitted power and the incoming one can then be determined modifying the equation for the exergy efficiency presented in [18]:

$$\frac{\dot{Q}_{out}}{\dot{Q}_{in}} = \frac{1}{\eta_{exergy}} \frac{1 - \frac{T_{amb}}{T_{in}}}{1 - \frac{T_{amb}}{T_{out}}} \tag{5}$$

2.2.4. Heat Pump Temperature Considerations

If the output temperature from the main DH heat exchanger exceeds the requirements of the DH network, the temperature at the outlet of the heat pump can be lowered resulting in a reduction of the compression power needed (Fig. 3 should clarify this point).

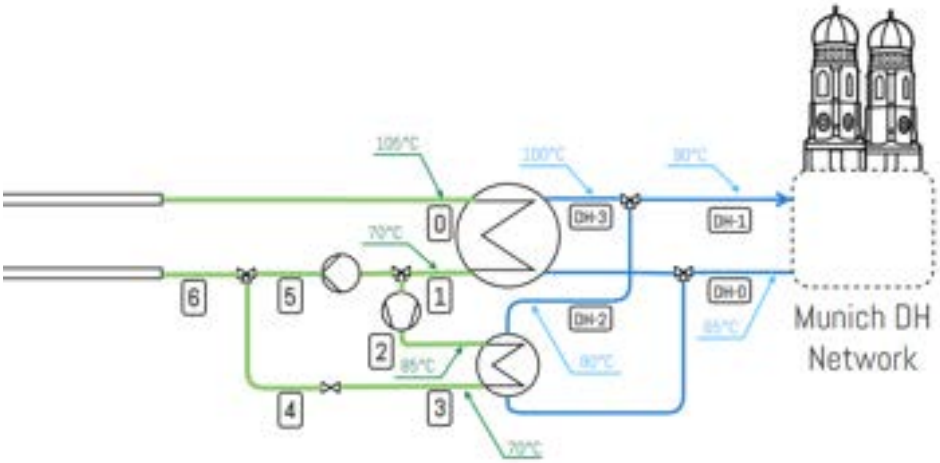


Figure 3: Example of how a lower output temperature can be set to the heat pump outlet: Temperatures of *points [DH-0]* and *[DH-1]* are fixed due to the grid design constraints (65℃ and 90℃ in this example). If temperature in *point [DH-2]* is higher than required, temperature in *point [DH-3]* can be lower to compensate

With reference to Fig. 3, temperature at *point [DH-3]* can be identified starting from an adimensional parameter defined as:

$$T_{ratio} = \frac{T_{DH3} - T_{DH0}}{T_{DH1} - T_{DH0}} \tag{6}$$

Notice that choosing T_{ratio} implies defining the ratio between the flow rate in *[DH-3]* and in *[DH-2]*:

$$\dot{m}_{DH_{ratio}} = \frac{\dot{m}_{DH3}}{\dot{m}_{DH2}} = \frac{h_{DH2} - h_{DH1}}{h_{DH1} - h_{DH3}} \approx \frac{T_{DH2} - T_{DH1}}{T_{DH1} - T_{DH3}} \tag{7}$$

Moreover, is interesting to notice that a heat pump scheme with $T_{ratio} = 0$ is equivalent to a base scheme (as defined in section 2.2.1.) in which the temperature in the DH network is controlled by letting some fluid by-pass the DH heat exchanger.

2.3. Economic Model

The levelized cost of heat (LCOH) has been evaluated to optimize the design parameter of the different schemes and to compare the different solutions. The LCOH is calculated as the minimum cost at which the heat must be sold in order to recover the investment after the lifetime of the plant, it can be derived by setting the NPV of the system to 0:

$$NPV = -C_{tot} + \sum_{t=1}^{L_e} CF_t \, (1 + i)^{-t} = 0 \tag{8}$$

Where the annual cash flow (CF_t) is:

$$CF_t = h_y \left(LCOH \dot{Q}_{DH} - \dot{W}_{pump} c_{el} \right) - C_{om} \tag{9}$$

The LCOH can then be calculated rearranging (8) and (9) assuming a constant annual cash flow:

$$LCOH = \frac{C_{tot}\beta + \dot{W}_{pump} c_{el}}{\dot{Q}_{DH}}, \quad \beta = \frac{1 + \alpha OM_{ratio}}{\alpha h_y}, \quad \alpha = \frac{1 - (1+i)^{-L_e}}{i} \tag{10}$$

The costs are evaluated using some specific correlations listed in Table 1.

Table 1: Cost correlation used in economic analysis

Component	Cost Correlation	Notes	Ref.
Overall Investment	$C_{tot} = 2C_{pipe} + \sum C_{HE} + \sum C_{other}$	*Result in [€], conversion €/$ applied if needed. Pump acquisition cost has been neglected. C_{other} represents the cost of additional components such as the heat pump or the CO_2 compressor*	-
Yearly Maintenance	$C_{om} = OM_{ratio} C_{tot}$	*5% OM_{ratio} considered*	-
Pipeline	$C_{pipe} = \left(0.6492\, d^{0.9779} + C_{ins}\right) L$	*Result in [$], pipe diameter in [m]*	[6]
Pipe Insulation	$C_{ins} = c_{ins}\left(\pi s_{ins}\left(d + s_{ins}\right)\right)$	*Result in [$/m], c_{ins} in [$/m^3]. It depends on the insulation material (see [6])*	[6]
Heat Exchangers	$C_{HE} = 49.45 UA_{HE}^{0.7544}$	*Result in [$], Correlation for CO_2, UA_{HE} in [W/K], it is the product of the HE area and heat transfer coefficient*	[19]
Heat Pump	$C_{heat\ pump} = 0.33667 \dot{W}_{heat\ pump}$	*Result in [M€], $\dot{W}_{heat\ pump}$ in [MW], Correlation for $\dot{W}_{heat\ pump}$ up to 10MW, Only the heat pump acquisition cost has been considered.*	[20]
Heat Transformer	$C_{heat\ transformer} = 375 \dot{Q}_{in}$	*Result in [€], $\dot{Q}_{in}$ in [kW], correlation valid for $\dot{Q}_{in} \approx$10MW, correlation for absorption heat pumps used following the approach of [21]. 375 is the mean of the range (300-450) presented in [22]*	[22].

2.3.1. Remarks on the LCOH calculation

Following the approach defined in [6], the LCOH calculated in 10 refers only to the process of transporting the heat. In order to identify the real cost of heat for DH users, heat production costs (well drilling, reservoir circulation pump, etc.) must be taken into account:

$$LCOH_{tot} = \frac{(C_{tot} + C_{prod})\beta + (\dot{W}_{pump} + \dot{W}_{pump_{prod}}) c_{el}}{\dot{Q}_{DH}} \tag{11}$$

In order to avoid the need for a complete economic evaluation of the production site, it is tempting to simplify the overall LCOH calculation considering a fixed price for the produced heat using values retrieved from literature:

$$LCOH_{tot} = \frac{C_{tot}\beta + \dot{W}_{pump} c_{el} + \dot{Q}_{geo} c_{heat_{prod}}}{\dot{Q}_{DH}} \tag{12}$$

It is important to consider that using equation (12) may lead to distorted results. The reason for this is that more complex system schemes, such as those described in sections 2.2.2. or 2.2.3., are chosen because they have a lower temperature in the return line and thus a higher heat extraction rate ($\dot{Q}geo$) *for the same number of wells and reservoir pumping power.* However, due to the fixed value for $c_{heat_{prod}}$ in equation (12), this behavior cannot be accurately modeled. To address this issue, the most straightforward solution is to evaluate the overall production cost of different systems using a fixed design extraction power:

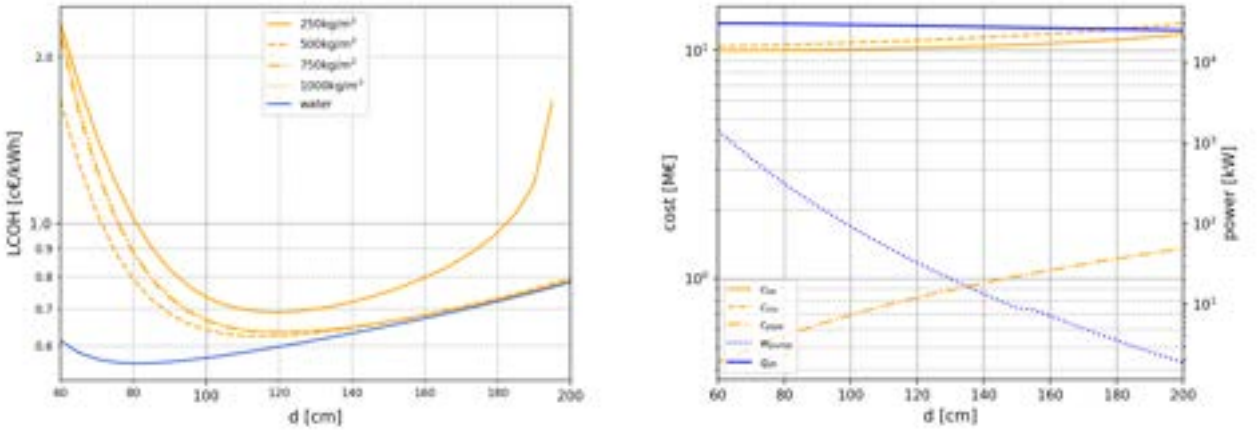
$$LCOH_{tot} = \frac{C_{tot}\beta + \dot{W}_{pump} c_{el} + C_{heat_{prod}}}{\dot{Q}_{DH}}, \quad C_{heat_{prod}} = \dot{Q}_{geo_{DESIGN}} c_{heat_{prod}} \tag{13}$$

3. Results

This section presents the results for the four different investigated technological concepts visualized in Fig.2.

3.1. Base case

Fig.4a displays the achievable LCOH for both water and CO_2 considering different pipe diameters. The results indicate that both heat carriers have a certain optimal pipe diameter, which corresponds to the optimal trade-off between investment and operational costs. For CO_2, the optimal pipe diameter is at around 130 cm, while it is at around 85 cm for water. While the deviation between both heat carries is rather small (0.1 c€/kWh), no clear advantages for using CO_2 as heat carrier in this standard scenario can be seen. The figure also shows the effect of the minimum CO_2 density in the system, showing an optimum in the LCOH for $\rho_{min} = 500 kg/m^3$.



(a) LCOH with diameter

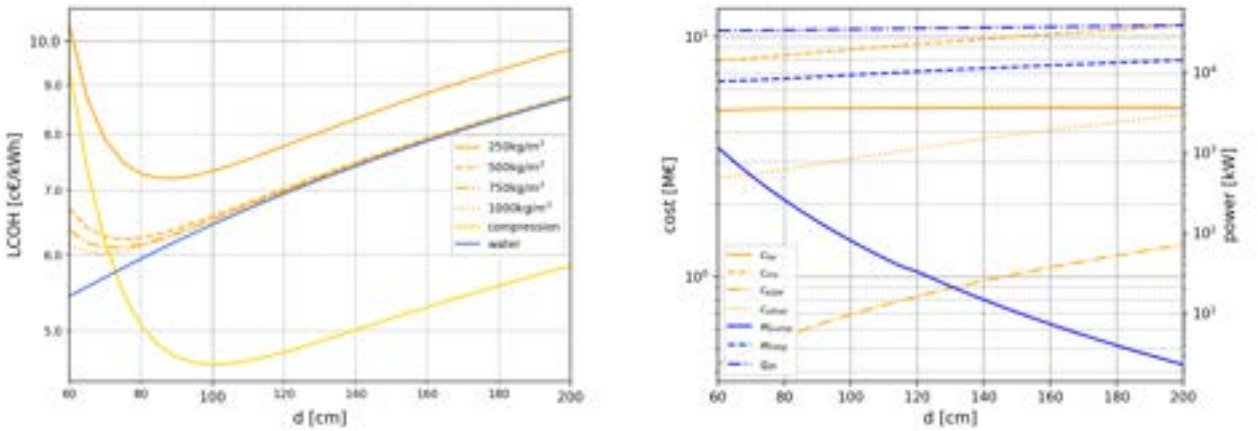
(b) Cost Composition for CO_2 with $\rho = 450[kg/m^3]$

Figure 4: Achievable LCOH for water and CO_2 considering different densities for the CO_2

The findings presented in Fig. 4a can be understood by analyzing the information provided in Figure 4b. Heat exchangers and pipeline installation are the biggest contributors to the capital investment, costing around 10 M€ and 1 M€, respectively. The cost of the heat exchangers can be explained considering that the system is required to transport a substantial amount of power with a limited temperature difference (ΔT) between the geothermal water (115℃) and the district heating network (90℃). As a result, the two heat exchangers can only have a limited logarithmic mean temperature difference (LMTD), 12.5℃ in the best case scenario, this increase the required UA and the heat exchanger cost. Increasing the pipeline diameter results in some additional heat loss to the environment because of the increase in surface area. These losses are negligible if compared with the overall power transported by the system, but make the UA requirements even more demanding.

3.2. HTHP case

Do to the high investment cost required for the acquisition of the heat exchangers the installation of an heat pump can be useful for increasing the available ΔT and allowing the installation of smaller heat exchangers.



(a) LCOH with diameter

(b) Cost Composition for CO_2 with $\rho = 700[kg/m^3]$

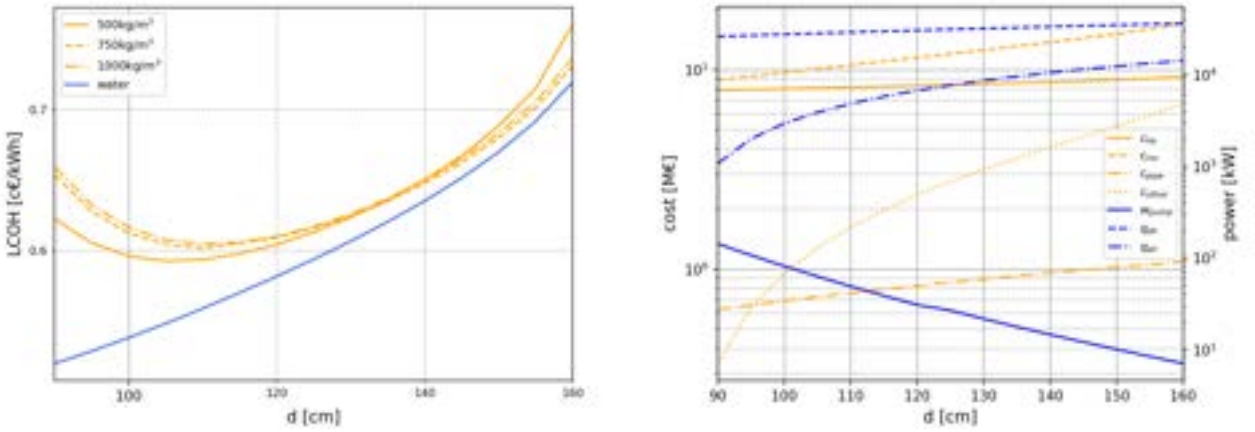
Figure 5: Achievable LCOH for water and CO_2 for the HTHP (High Temperature Heat Pump) case

In Fig. 5, it is apparent that the LCOH has substantially increased when compared to the baseline scenario, despite a decrease in the cost of heat exchangers to 4M€. This is mainly due to the increased in electrical power consumption. The high cost of electricity (the average price for Bavaria in 2022 was 22.5 cents per kilowatt-hour [23], which is more than 30 times higher than the LCOH for the baseline scenario) makes it unprofitable to extract heat from the fluid using electrical power, even with a high COP. It is critical to note that this is true for the LCOH shown in Figure 5 which only considers the cost of the transport system, ignoring the cost of heat production, depending on the cost of heat production this effect can change dramatically.

Another interesting finding shown in Fig. 5 is that the CO_2 scheme the compression system replacing the heat pump (Fig. 2c) due to its simplicity and higher COP, is capable of performing better than the water-based system in the considered scenario. Especially against the background of high heat demand periods during the winter, the additional installation of a CO_2 compressor can be favourable from an operator's perspective, since it allows to supply of additional heat without the need for additional drilling.

3.3. AHT case

An absorption heat transformer can be considered as a solution of increasing the ΔT without using additional electrical power. In fact, as can be see from Fig. 6, the LCOH has decreased for both water and CO_2.



(a) LCOH with diameter **(b)** Cost Composition for CO_2 with $\rho = 450[kg/m^3]$

Figure 6: Achievable LCOH for water and CO_2 for the AHT (Absorption Heat Transformer) case

Fig. 6b, shows that the cost of the heat exchangers has decreased to 8M€. The power provided by the AHT in the optimal condition for CO_2 (d=110cm) if 4MW which is only about 10% of the overall heat transported by the network, this shows that the real advantage of installing an AHT it to increase the available ΔT in order to allow the installation of smaller heat exchangers.

4. Conclusion

The results of this work provide valuable insights into both the achievable LCOH of long-distance heat transport from geothermal sources in general and the thermo-economic comparison of water and CO_2 as potential heat carrier fluids. First, the results of the base case scenario (cf. Fig 4a) demonstrate that for both heat carrier options rather low LCOH for the transport of the heat can be achieved. The resulting additional LCHO by the long-distance heat transport of around 0.6 c€/kWh is rather small compared to the typical overall LCOH of geothermal district heating systems [24]. Considering that long-distance heat transport enables the utilization of geological attractive regions in the countryside with lower project-specific LCOH, installing the long-distance heat transport system might result in an overall lower LCOH of the whole geothermal heating system. Therefore, the findings of this work support the general conclusions by the work of Molar-Cruz et al. [5] on the theoretical advantages of geothermal heating systems with long-distance heat transport as well as the economic feasibility of the projects currently in the planning stage in the Greater Area of Munich, Germany [13].
Comparing the thermo-economic performance of water and CO_2 shows rather similar achievable LCOH, with a slight advantage for the classical concept of using water. While CO_2 reveals a lower pressure drop within the piping system, this advantage is overcompensated by the fact that the pressure increase for CO_2 is taking place at a lower density than for water, resulting in a higher power demand. Furthermore, considering the potential integration of an HTHP increases the LCOH significantly, mainly due to the currently rather high electricity prices. Nonetheless, the considered LCOH only address the installation and operation of the transportation system and the HTHP installation. However, installing an HTHP lowers also the LCOH of the geothermal project itself

(which are rather high especially caused by the drilling cost [25]) due to a higher utilization and it reduces the need for installing and/or integrating further alternative heat sources. Thus, while the installation of an HTHP might be useful from a thermo-economic perspective, it needs to be assessed in a broader system study considering also other available potential heat sources and technologies. Regarding the potential application of an HTHP into the long-distance heat transport system, the results of this work highlight the potential advantage of CO_2 as a heat carrier (cf. Fig. 5). In the case of using CO_2, the additional temperature increase takes place directly within the CO_2 stream by just installing a compressor, while in the case of the water system, a complete HTHP system needs to be installed. Thus, the usage of CO_2 allows significantly lower investment costs as well as higher COPs.
Concerning the thermo-economic comparison of water and CO_2 for the considered use case with a rather high required DH supply temperature, CO_2 results in comparable LCOH as water, but has no further positive impact on the economic performance despite in case of an additional HTHP system for increasing the thermodynamic capacity of the heat transport system. Furthermore, the future trends towards lower DH supply temperatures as well as the use of CO_2 as a heat carrier in geothermal systems (cf. [9] might result in a thermo-economic favourability of CO_2 as a heat carrier for long-distance heat transport and might be evaluated in future studies.

Abstract:

Nowadays, the energy sharing of RES production within Renewable Energy Communities (REC) is promoting the diffusion of a more decentralized energy system, where dispersed renewable generation can be locally self-consumed by REC members. The maximization of self-consumption through the matching between generation and demand is thus fundamental to ensure higher economic and environmental benefits for residential end-users joining REC configurations. However residential electricity demand and the corresponding load profile are generally influenced by end-users' behavior. In fact, even if most of the household appliances can be assumed as fixed loads, the usage of some appliances depends basically on the residents' habits. The engagement of customers in changing their energy consumption patterns is then challenging to promote flexibility in electricity demand to further increase the benefits of adopting and joining renewable energy communities. In this view, a MILP approach is proposed to model end-users' flexibility for investigating how the changing in consumption habits can potentially improve the energy sharing by maximizing the match between RES production and demand. User's discomfort is evaluated consequently as the distance between the desired or usual consumption pattern and the optimized one. An Italian multifamily residential building case study, where end-users adopt a collective self-consumption scheme, is considered to highlight energy and economic results assuming different level of end-users' flexibility. Finally, a comparison between the maximization of energy sharing and the minimization of discomfort rate is pointed out through weighted sum method to identify solutions with different relevance of the end-users' flexibility.

Demand Management, MILP, Energy Community, Residential buildings.

1. Introduction

Energy Communities (ECs) in Italy are a relatively new concept that has emerged as a response to the challenges posed by climate change and the need for a more sustainable energy future [1]. In fact, these communities aim to promote the use of clean and sustainable energy, reduce greenhouse gas emissions, and foster local economic development contrasting energy poverty [2]. For these reasons, in a EC, public and private entities as well as citizens and households jointly and collectively own and manage renewable energy resources (RES) to locally increase self-consumption [3]. Hence, ECs are based on the idea that energy production should be decentralized and democratized, with people taking an active role in shaping their energy future and in driving the energy transition towards a more sustainable energy system.

Since the main goal of an EC is to increase the match between the local RES based production with the local electricity demand, battery energy storage systems (BESSs) are assuming a relavant role. Storage systems are in fact assets for decoupling the timing of energy production from its consumption. Thus, the use of this system has the advantage of leaving the end-user free to keep its own consumption habits, while overproduction can be stored and released when needed. However, one of the possible critical aspect in adopting BESS is still its profitability without incentives [4–6].

A different and complementary approach can be instead considered by promoting the cooperation between people (e.g. households) and the energy system (i.e. the EC). In particular, to increase self-consumption and self-sufficiency, changes in consumption habits may be proposed to end-users to modify the timing at which these consumptions occur [7]. This lead to the adoption of demand management where, through a simulation approach, the optimal usage of some electric appliances in the households can be identified and suggested to end-users for adapting their habits to a more sustainable and profitable behaviour. Consequently, also the BESS sizing could benefits on the adoption of demand management due to lower expected RES overproduction.

In this view, the work presented by [8] gives a wider overview on the different approaches adopted to model the demand management in the residential sector. Some of them are based on linear programming (LP) and mixed integer linear programming (MILP) for deploying load-shifting and then minimize the energy bills for end-users. For instance, a MILP smart home energy management model has been presented in [9] to arrange the operation of the household appliances for minimazing costs by considering time-varying pricing model to control the system. In particular, electrically controllable appliances are shifted to reduce electricity bought from the grid by harnessing RES production and storage usage. Similarly, a home energy management strategy to minimize the customer's billing is presented in [10], where different components and appliances are modeled by MILP. Shiftable loads are modeled again as components with a fixed operational time window that can be arranged to reduce the electricity bought from the grid.

According to these examples, a MILP modeling approach is proposed in this work to exploit the benefits due to load shifting in residential sector, but considering the perspective of an energy community (see Figure 1). In this case, the self-consumption of RES-based production is maximized by suggesting different end-users' habits, so that the aggregated load demand can more efficiently match the RES production. Results are compared with ones achievable by using a different approach based on the integration of an energy storage system to figure out also potential interoperability with demand management. Additionally, end-users' discomfort is also modelled to take into account the end-users' acceptability of the demand management. In fact, costumers perception on flexibility tools is still controversial [11]. Then, multi-objective optimization is also proposed to investigate how different willingness to participate in demand management can influence the benefits.

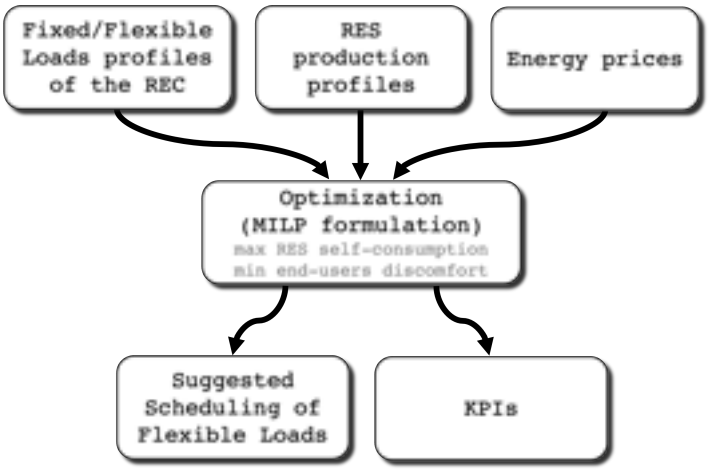

Figure 1: Scheme of the proposed MILP approach

2. Problem formulation

A Mixed Integer Linear Programming (MILP) formulation is proposed here to model the demand management of electric appliances used by residential end-users joining a collective self-consumption configuration. Consequently, equations and constraints representing this energy system are linear or alternatively should be linearized. In particular, two different kind of equations can be considered for describing the energy exchanges within an energy community, the interaction of the collective self-consumption with the grid and the management of the electricity demand: energy balance equations and constitutive equations representing the energy behaviours of the different assets. Binary (i.e., integer) variables are also introduced to describe the on/off status of the components and appliances and to consider their operational limits. A detailed description of this general approach can be found in [12].

The time horizon of the simulation is discretized by subdividing it in N_i intervals with length Δt equal to 5 minutes in this particular application for fully exploiting the potentiality of the demand management in residential end-users.

2.1. Modeling Demand Management

Demand management of the consumption aims at modify the end-users' habits in using electric appliances to meet specific goals of the energy community. As already pointed out, in this particular case, the objective is to increase the self-consumption of the RES production to maximize energy sharing and improve the economic benefits. Hence, end-users can actively participate by shifting the energy consumption for all those appliance that are programmable by definition as, for instance, washing machines and dishwashers [8]. These appliances, in fact, have a fixed duty-cycle whose start can be anticipated or deferred with respect to the end-users'

usual habits. As a consequence, assuming a daily time horizon discretized on N_i time intervals, the duty-cycle of an end-user's appliance can potentially be started at any time intervals.

This condition can be modelled by a squared matrix where each columns represents the load pattern (or load profile) of the *a*-th programmable appliance by assuming a different starting time interval for the duty-cycle. Practically, the first column is the usual load pattern, while the other columns are obtained by cyclic permutation of the first one, as follows:

$$\mathbf{P}_{j,a} = \begin{bmatrix} p_{j,a,1} & p_{j,a,N_i} & p_{j,a,N_i-1} & \cdots & p_{j,a,2} \\ p_{j,a.2} & p_{j,a,1} & p_{j,a,N_i} & \cdots & p_{j,a,3} \\ p_{j,a,3} & p_{j,a,2} & p_{j,a,1} & \cdots & p_{j,a,4} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ p_{j,a,N_i} & p_{j,a,N_i-1} & p_{j,a,N_i-2} & \cdots & p_{j,a,1} \end{bmatrix} \tag{1}$$

where $P_{j,a} \in \mathbb{R}^{N_i x N_i}$ and $p_{j,a,i}$ is the consumption of the *a*-th programmable appliances in a given *i*-th time interval for the *j*-th end-user. Clearly, an appliance can only adopt one load profile from the matrix *P*, while the other must be ignored. For this reason, N_i additional binary variables have to be introduced, one for each columns, so that:

$$\sum_{i=1}^{N_i} \delta_{j,a,i} = 1 \tag{2}$$

where $\delta_{j,a,i}$ is equal to 0 if the *i*-th consumption pattern (i.e. the *i*-th column) is not selected and equal to 1 if the corresponding *i*-th consumption pattern is chosen. Hence, equation 2 ensures that only a load profile can be selected, while the others are not considered. As a consequence, this representation introduces flexibility in the usage of electric appliances to be considered in the demand management purpose.

2.2. Energy storage

A battery electric storage system (BESS) is also considered as an essential element to further introduce flexibility in the management of an energy community [13]. Even if its integration can be complementary to the demand management, because of BESS basically introduce flexibility by potentially leaving consumption habits unchanged, its operation need to be modelled as well to exploit the interaction with demand management. The BESS formulation adopted here is based on the one already introduced in [14], where the BESS is studied considering passive sign convention. Under this assumption, the electric power input to the BESS has positive sign (during charge), viceversa the output one (during discharge) has negative sign. As a consequence, the State Of Charge (*SOC*) of the battery (i.e. its energy conten) in a given time interval is defined; as follows:

$$SOC(t_{i+1}) = \eta_{sd} SOC(t_i) + \left(\eta_c P_{b,c}(t_i) - \frac{P_{b,d}(t_i)}{\eta_d} \right) \Delta t \tag{3}$$

where η_{sd} is the self-discharge efficiency, η_c is the charge efficiency, η_d is the discharge efficiency and $P_{b,c}$ and $P_{b,d}$ are the battery power respectively during charge and discharge. However, electric power during charge and discharge are typically limited, so further constraints need to be introduced, as follows:

$$0 \leq P_{st,c} \leq \delta_c \frac{SOC_{max}}{T_c} \tag{4}$$

$$0 \leq P_{st,d} \leq \delta_d \frac{SOC_{max}}{T_d} \tag{5}$$

$$0 \leq \delta_c + \delta_d \leq 1 \tag{6}$$

where SOC_{max} is the storage capacity of the battery, T_c and T_d are the minimum charge and discharge time, while Equation 6 is a operational constraint where δ_c and δ_d are binary variables that compel charge and discharge powers to be different from zero only one at a time.

2.3. Energy balance of the community with demand management

As already depicted in Section 2.4., an energy community is a scheme where local RES production, energy storage systems and the end-users interact each other to increase local self-consumption. In this context, where residential end-users jointly acting as renewables self-consumers, if demand management is also introduced for some of the appliances, the energy consumption for each end-users can be divided in two different main categories: fixed load and a flexible one. The corresponding energy balance for the community can be then defined in each time interval, as follows:

$$P_{PV}(t_i) + P_p(t_i) + P_{b,d}(t_i) = P_s(t_i) + P_{b,c}(t_i) + \sum_{j=1}^{N_u} U_{fix,j}(t_i) + \sum_{j=1}^{N_u} \sum_{a=1}^{N_a} U_{flex,j,a}(t_i) \tag{7}$$

where P_{PV} is the RES production from PV, P_p is the electricity bought from the grid, $P_{b,d}$ is the electric power supplied by the battery, $P_{b,c}$ is the electric power consumed by the battery, $U_{fix,j}$ is the overall fixed load of the j-th end-whikle $U_{flex,j,a}$ is the flexible load of the a-th programmable appliance owned by the corresponding j-th end-user. Then, the left hand side of Equation 7 represents the *sources* for the energy community, while the right hand side identifies the *loads*, where P_s has the role of representing power injected and sold to the grid.

However, according to the modelling of demand management proposed in Section 2.1., each flexible load can be represented by N_i possible load patterns where only one of them is not actually zeroed. As a consequence, each flexible load introduced in Equation 7 can be also represented as follows:

$$\mathbf{U}_{flex,j,a} = \sum_{i=1}^{N_i} \delta_{j,a,i} \mathbf{p}_{j,a}^{(i)} \tag{8}$$

where $\mathbf{p}_{j,a}^{(i)}$ is the i-th column of the matrix $\mathbf{P}_{a,j}$, while $\mathbf{U}_{flex,j,a}$ is the vector describing the load profile for the a-th programmable appliance of the j-th end-user. Of course, Equation 2 ensures that only one load patterns will be selected during the search of the optimal solution.

Additionally, limitations owning to the contractually committed power have to be considered for each end-user. In fact, demand management shifts the flexible loads and consequently power demand can exceed the available power for a residential end-user which is usually equal to 3 kW in most of the Italian domestic costumers [15]. This can be avoided by introducing for each j-th end-user and in each i-th time interval a further constraints, as follows:

$$U_{fix,j}(t_i) + \sum_{a=1}^{N_a} U_{flex,j,a}(t_i) \leq P_c \tag{9}$$

where P_c is the contractually committed power for domestic costumers.

2.4. Objective functions

In this paper, according to the recent Italian rules [16], a multi-family building is considered where a PV plant is used to supply the energy demand of the residential end-users jointly acting as renewables self-consumers. In this context, the energy demand of the some electric appliances are supposed to be schedable to increase and maximize the self-consumption of the RES production. This goal is equivalent to reduce or minimize the electricity produced by the PV and injected into the grid, so the objective function is evaluated, as follows:

$$OF_1 = min \sum_{i=1}^{N_i} P_s(t_i) \Delta t \tag{10}$$

where P_s represents the electric power sold to the grid. However, the management of some of the electric appliances according to this policy, may be potentially in contrast with the users' habits. For this reason a measure of the end-users' discomfort in adopting demand management is also introduced. This is represented by a sort of weighted distance between the scheduled path demand of the shiftable loads (e.g. the one suggested by solving equation 10) and the end-user usual consumption habits. Consequently, an alternative objective function has been introduced to minimize this user's discomfort, as follows:

$$OF_2 = min \sum_{j=1}^{N_u} \sum_{a=1}^{N_a} \left[\sum_{i=1}^{N_i/2} i \cdot \delta_{j,a,i} + \sum_{(N_i/2)+1}^{N_i} (N_i - i + 2) \cdot \delta_{j,a,i} \right] \tag{11}$$

In this objective function, the coefficients i and $(N_i - i + 2)$ are introduced to weight differently each consumption patterns represented by a column of the matrix **P**. In particular, the consumption patterns far from the usual habit (i.e. the first column of **P**) are more penalised with respect to the closest one. In fact, for instance, if the 10th column was selected as consumption pattern, its weight (i.e. 10) would be higher than the one obtainable by the 3rd column (i.e. 3). In this way, the objective function naturally force the solution to be close to usual habits of the end-users. Additionally, weights are symmetric with respect to the center of the matrix, since each column of **P** is generated by a cyclic permutation of the usual consumption pattern of a given appliance. Hence, for example, the second and the last column of **P** have of course the same weight, because they represent two patterns symmetrically close to the end-user's habit.

Clearly, equation 11 states that minimum discomfort has to be reached (i.e., end-users do not change their consumption habits) and practically this in contrast to equation 10. For this reason, also a multi-objective approach have been also explored. In particular, since the formulation proposed here is MILP based, a weighted sum method [17] is adopted to combine the two objective functions, as follows:

$$MOF = min[\alpha OF_1^* + (1 - \alpha) OF_2^*] \tag{12}$$

where $0 \leq \alpha \leq 1$, while OF_1^* and OF_2^* are the normalized objective functions. Different weight α in Equation 12 givea the possibility to explore solutions where demand management is less compelling, consumption patterns are closer to end-users' habits and discomfort is reduced.

3. Key Performance Indicators

KPIs are used here to investigate the performances of the proposed demand management within an energy community on yearly basis, considering scenarios with different sizes of the active assets (i.e. PV and BESS). In particular, these reference scenarios are designed by supposing no demand management, because the considered use cases should investigate the role of the demand management in existing configuration of the collective self-consumption scheme. Three groups of KPIs were considered: energy, economic, environmental and discomfort.

3.1. Energy KPI

The energy impact of the demand management in a multi-family residential building has been evaluated considering two different indicators: the self-consumption (*SC*) and the self-sufficiency (*SS*). The *SC* identifies the self-consumed PV production compared to the yearly PV production, while the *SS* identifies the self-consumed PV production compared to the yearly electricity demand of the building, as follows [18]:

$$SC = \frac{E_{sh}}{E_{PV}} = \frac{\sum\limits_{year} P_{sh}(t_i) \cdot \Delta t}{\sum\limits_{year} P_{PV}(t_i) \cdot \Delta t} \tag{13}$$

$$SS = \frac{E_{sh}}{E_L} = \frac{\sum\limits_{year} P_{sh}(t_i) \cdot \Delta t}{\sum\limits_{year} U_e(t_i) \cdot \Delta t} \tag{14}$$

where U_e is the aggregated yearly electricity load profile including fix and flexible loads, while $P_{sh}(t_i)$ and E_{sh} represent the self-consumed PV production within the energy community also named shared energy and calculated, as follows:

$$P_{sh}(t_i) = min[(P_{PV}(t_i) + P_{b,d}(t_i)), (U_e(t_i) - P_{b,c}(t_i))] \tag{15}$$

3.2. Economic KPI

The economic impact of the demand management in an energy community has been evaluated only in terms of cost savings for the end-users. In fact, as already pointed out, demand management is supposed to be

adopted in existing scenarios of energy communities. Hence, economic feasibility and profitability of investing in the active assets of the community is not considered here, so economic indicators evaluating the return of investment are not included in this work.

In this light, the indicator named Percentage Cost Reduction (*PCR*) [19] is used to compare the yearly costs of the electricity bills YC_{dm} obtained by the energy community adopting demand management with the ones YC_{ref} where demand management is not adopted. Practically, *PCR* is calculated as follows:

$$PCR = \left[1 - \frac{YC_{dm}}{YC_{ref}}\right] 100. \tag{16}$$

Both yearly costs are calculated considering the per unit cost for the electricity bought from the grid E_L and the economic benefits and incentives offered to energy communities by the current Italian regulatory framework, as follows:

$$YC = E_L C_p - E_{PV} C_s - E_{sh} C_{sh}. \tag{17}$$

Specifically, the PV production injected into the grid E_{PV} is economically valued at the wholesale market price, while the shared energy E_{sh} benefits of an incentive. The former, considering 2019 as reference year, is assumed fixed at approximatively 50€/MWh [20], while the latter is equal to around 110€/MWh and the electricity retail price is assumed instead equal to 200€/MWh on average [19].

3.3. Environmental KPI

Environmental KPI measure instead how demand management influences the reduction in the primary energy consumption or, alternatively, in CO_2 emissions in an energy community. The carbon saving is in fact calculated by comparing the carbon emissions with and without demand management, as follows:

$$\Delta CO_2 = \left[1 - \frac{CO_{2,dm}}{CO_{2,ref}} \cdot 100\right] = \left[1 - \frac{E_{p,dm} \cdot EF_e}{E_{p,ref} \cdot EF_e}\right] \cdot 100 \tag{18}$$

where EF_e represents the national CO_2 emission factor for the electricity bought from the grid [21], while $E_{p,dm}$ and $E_{p,ref}$ are the yearly electricity demand of the building not fulfilled by RES production when DM is adopted and not implemented, respectively.

3.4. Discomfort KPI

Finally, also a further KPI is introduced to measure how demand management changes the usual habits of end-users and contemporarily create discomfort. This can be basically measured by comparing the suggested optimal path demand (gained by solving Equation 10) with the end-user's habits. Since each of the programmable appliances considered in this study have a specific duty-cycle, this comparison is equivalent to measure the distance between two duty-cycles with different starting time or, in other words, this distance is the difference of two starting time, as follows:

$$Dis = \sum_{d=1}^{N_d} \sum_{j=1}^{N_u} \sum_{a=1}^{N_a} \frac{1}{N_j} \mid t_{j,a}^{us} - t_{j,a}^{op} \mid \tag{19}$$

where $t_{j,a}^{us}$ and $t_{j,a}^{op}$ are the usual and optimal starting time of the duty-cycle for the j-th user and its programmable appliance a, while N_d is the number of the reference days adopted to represent a whole year. Clearly, $t_{j,a}^{op}$ is get from the solution obtained by solving Equation 10.

4. Case study description

A multifamily residential building of 40 apartments, located in the North-West part of Italy, was selected as reference use case in this study. In fact, this building typology is the most representative according to the current Italian building stock [19, 22]. The electricity demand of each apartment was estimated considering an open-source simulator developed by the CADEMA research group of the Politecnico di Torino [23]. The open-source simulator creates the daily load profiles of the main electric appliances for an aggregate of households. Then, different load profiles were generated for a whole day according to the season, the day of the week (i.e. weekdays and weekend days) and the energetic labels of the appliances with a time-resolution of 5 minutes.

In particular, the simulated load profile of each appliances are based on statistical data obtained from past load measurement campaign in National research project, so the generated patterns can be assumed as related

to end-users' habits. The appliances considered in the simulator are vacuum cleaner, dishwasher, washing machine, tumble drier, audio-video devices (tv, hifi stereo,...) and other electronic devices (laptop, personal computers) and lighting. Among the others, dishwashers and washing-machines were assumed as the ones suitable for the application of demand management due to their ability to be programmed [8]. Figure 2 shows on the left an example of the resulting aggregated electricity demand estimated for the residential building (including both fix and flexible loads of each end-users) with a focus (on the right) for a given end-users where fix demand (blue line) and the consumption of programmable appliances (red and yellow lines) are highlighted. Hence, loads that can be rescheduled have a duty cycle that can be anticipated or delayed with respect to the habits depicted in Figure 2 (right side).

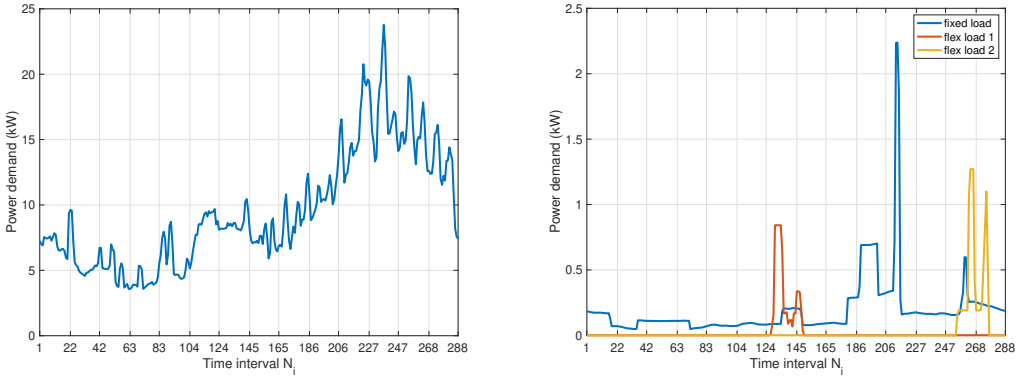

Figure 2: Load profiles of the case study: aggregated demand (left), consumption of a single end-user with fixed and flexible demand (right)

On the other hand, PV production was estimated by adopting the PVGIS database [24] to take into account the effect of the solar beam at the considered location of the case studies. Specifically, PV size was estimated a priori by adopting the sizing criteria proposed in [14] but assuming no demand management. In this light, the PV size is selected on energy basis according to the simultaneous maximization of the self-consumption (*SS*) and self-sufficiency (*SC*) for the energy community, so that the chosen PV size ensures the lowest distance with respect to the Utopia point in the $SC - SS$ plane. The maximum PV size was also limited to 70kW$_p$ due to the available roof surface of the residential building being studied [19]. Of course, since the open-source simulator is on a daily basis, also PV production was estimated on the same timeframe. However, to limit computational effort in simulating the proposed model, reference days were then identified to represent a whole year. In particular, two days (i.e., a weekday and a weekend day) for each seasons have been considered.

The resulting PV size were then considered to identify a reference configuration for the case study where the energy community exploits the RES production for increasing local self-consumption but without demand or BESS management. This reference scenario is firstly compared with one where the demand management is adopted to evaluate its impact without BESS. Later, other scenarios assuming the same PV size, but parametrically increasing BESS size without demand management, were compared to the reference configuration. In this way, demand management is also compared with a different approach based on the BESS management as described in Section 2.2..

5. Results

The assessment of demand management in an energy community with a collective self-consumption configuration is presented in this section. The use-case considered is a residential multi-family building with 40 flats located in the North-West of Italy [19]. According to the sizing approach proposed in Section 4. the installed PV capacity for maximizing both *SS* and *SC* is equal to 40 kW$_p$. Starting from this reference configuration (i.e., Scenario 0) without demand management (DM), the scenarios being studied are summarized in Table 1.

Table 1: PV and BESS size in different Scenarios

Scenario	0	1	2	3	4
PV	✓	✓	✓	✓	✓
BESS (kWh)	-	-	15	30	30
DM	-	✓	-	-	✓

In particular, Scenario 1 highlights the impact of the demand management, while Scenarios 2 and 3 points out the impact of BESS management with increasing BESS sizes. Scenario 4 has been further included to exploit also potential interaction between two different flexibility approach within the energy community. The main BESS characteristics considered in the simulations are also reported in Table 2. In this case, a round-trip efficiency of approximately 90% is assumed, the rated fully charging and discharging time are equal to 3 hours, while self-discharge effect is substantially neglected.

Table 2: BESS characteristics assumed in the simulations [5].

η_c	η_d	η_{sd}	T_c (h)	T_d (h)
0.95	0.95	1	3	3

Table 3 shows the KPIs obtained by the different Scenarios. It can be noticed that demand management in Scenario 1 has a positive impact from the economic, energy and environmental point of view. In fact, the shift of energy consumption for the programmable appliances can improve the match of the demand with the PV production. In other words, the aggregated demand of the flexible loads should mainly occur during PV production, as depicted in Figure 3, leading end-users to more virtuous behaviours for the energy community perspective. Consequently, self-consumption and self-sufficiency can be enhanced up to 12.7% and 5.7%, respectively, while energy cost and CO_2 emission can be reduced by 4.6% and 9.1%.

Clearly, the positive economic impact can also contribute in increasing cash-flows and, consequently, in making more profitable the PV investment for the community.

Table 3: KPIs obtained for different Scenarios

Scenario	0	1	2	3	4
SC (%)	83.2	95.9	91.7	96.3	99.4
SS (%)	37.2	42.9	41.0	43.0	44.4
PCR (%)	-	4.6	3.1	4.9	5.8
E_{sh} (MWh/y)	34.7	42.9	38.2	40.1	41.4
ΔCO_2 (%)	-	9.1	6.1	9.3	11.5
Dis	0	91.5	0	0	94.8

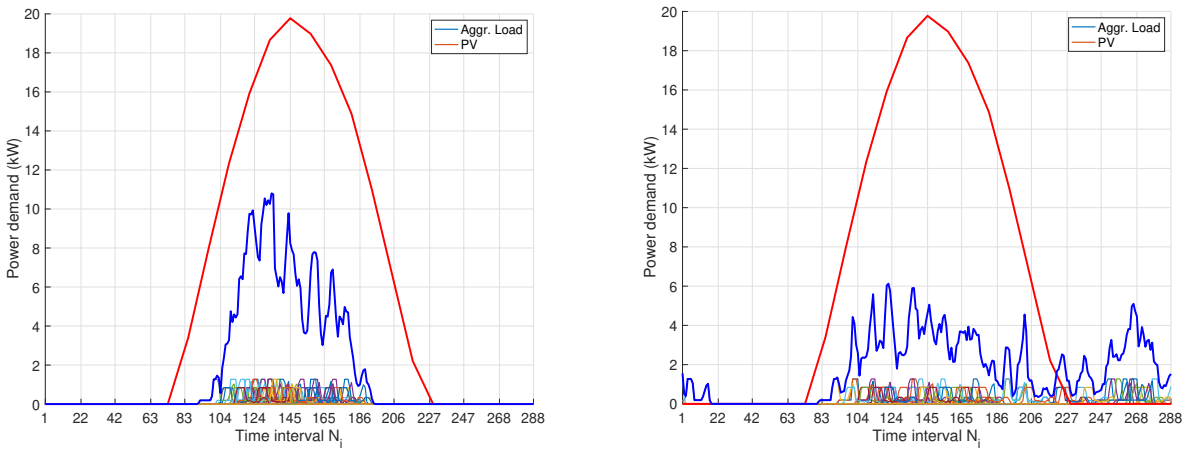

Figure 3: Aggregated load of all the programmable appliances in Scenario 1 with (left) and without (right) demand management during a spring day.

The resulting net load is then significantly close to zero during daytime, so that RES production is mainly self-consumed within the community and not injected into the grid as reported in Figure 4. Furthermore, demand management can also reduce the net load during the afternoon and evening hours, still due to load shifting effects. However, discomfort inevitably increases, since end-users' habits should be changed.

Similar benefits can be gained in Scenario 3 by optimally managing BESS to increase self-consumption, as noticed in Table 3 and Figure 4. In fact, even without demand management, the adoption of BESS with a rated capacity of 30 kWh can contribute to reach high levels of *SC* and *SS* close to 96% and 43% respectively, while cost and emission savings can be close to 4.9% and 9.3%. Nevertheless, this approach needs of the installation of a costly asset (i.e. electrochemical battery) while the end-users' behaviour is not involved at all. Additionally, BESS needs to be replaced once its cycle life is reached, making not yet totally profitable its usage in residential applications without the adoption of incentives [4, 25].

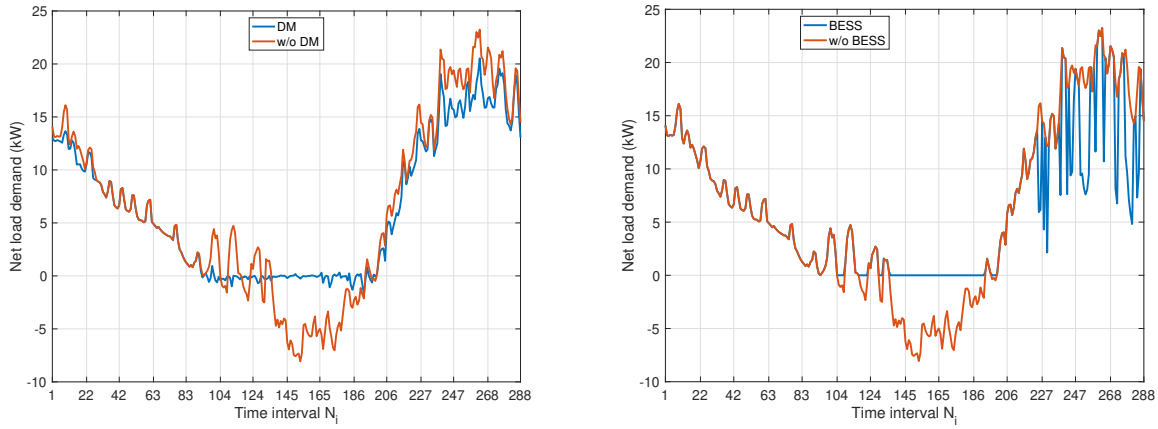

Figure 4: Net load of the energy community during a summer day for: Scenario 1 with (blue curve) and without (red curve) demand management on the left; Scenario 3 with (blue curve) and without (red curve) BESS management on the right.

However, when the interaction of the two different flexibility approaches is considered (i.e., Scenario 4), all the KPIs benefit of the demand management. In this case, a fully self-consumption of PV production is almost reached, while cost and emissions savings can be close to 6% and 11.5%, respectively. Specifically, the demand management allows a lower battery usage while ensuring a longer technical lifetime, postponing the need of investment for its replacement. Furthermore, demand management contributes in contrasting the injection of PV overproduction, as pointed out by the net load shown in Figure 5, while BESS benefits of a lower

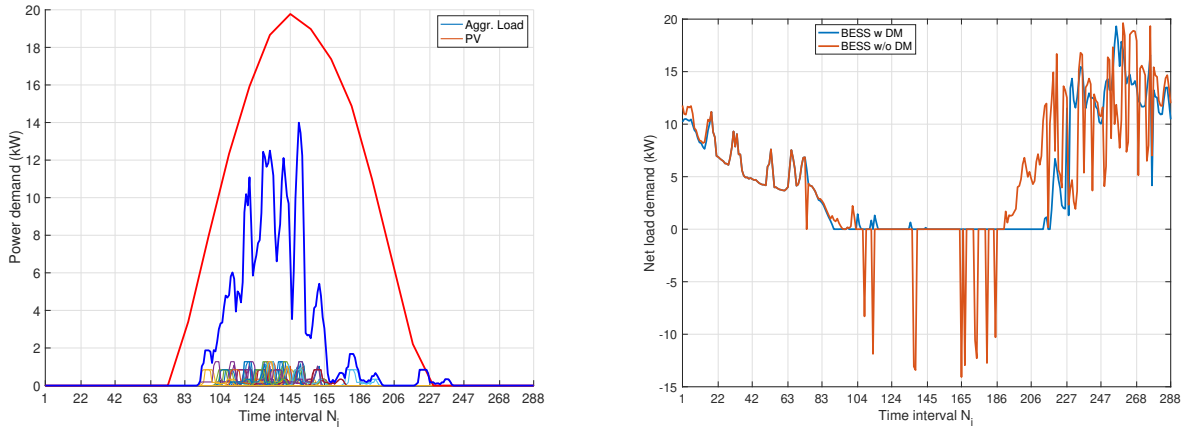

Figure 5: Scenario 4: aggregated load of the programmable appliances with and without demand management during a spring day; net load of the energy community during spring with and without demand management.

Finally, multi-objective simulations have been also explored to evaluate the impact of different end-users' availability in changing their habits for following or adopting demand management. As already observed, different end-users adaptability can be obtained by considering different weights α in Equation 12. In fact, a lower α represents a decreasing willingness to participate in demand management and vice versa. Table 4 shows the results of the multi-objective simulation for Scenario 1 considering different weights. As expected, the greater is α the better the economic, environmental and energy KPIs, while the higher the discomfort. Correspondingly,

the net load of Figure 6 has more negative values (i.e., reduced self-consumption) when OF_2 (i.e., the discomfort) is weighting more than the OF_1 (i.e., the self-sufficiency). These results suggest that some trade-off solutions can be achieved where end-users' acceptance or availability in following demand management is not fully agreed. Nevertheless, positive results can be still obtained and then end-users acceptability can be thus promoted to increase the willingness to participate in flexibility [7].

Table 4: KPIs obtained for Scenario 1 considering different weight in multi-objective simulation

α	0.75	0.5	0.25
SC (%)	95.8	92.4	88.6
SS (%)	42.8	41.3	39.6
PCR (%)	4.5	3.3	1.9
E_{sh} (MWh/y)	39.9	38.5	36.9
ΔCO_2 (%)	8.9	6.5	3.8
Dis	38.9	19.7	7.1

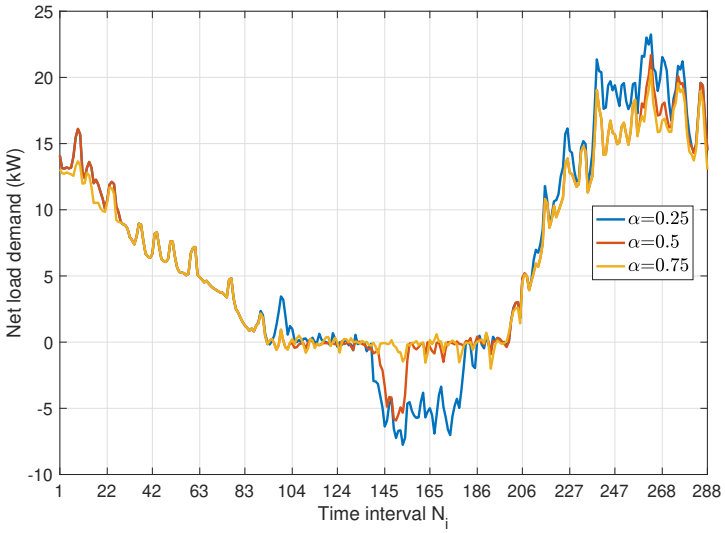

Figure 6: Scenario 1: aggregated load of the programmable appliances with and without demand management during a spring day; net load of the energy community during spring with and without demand management.

6. Conclusion

The energy communities represent a great opportunity to increase self-consumption of RES based production, fostering more sustainable energy ssystems with lower operational costs capable to contrast energy poverty. In this context, flexibility is assuming a relevant role for reaching these goals, because it can improve the match between consumption and production. Classically, storage systems are considered for decoupling the timing of energy production from the demand, so that overproduction can be stored and released when needed, leaving the costumers habits unchanged. In this work, instead, a complementary approach based on demand management was considered, by promoting changes in consumption habits that may be proposed to end-users. In particular, a Mixed Integer Linear Programming formulation is proposed here to model the demand management of electric appliances used by residential end-users joining an energy community under the Italian regulatory framework. An Italian residential multi-family building with PV is assumed for exploiting the economic and environmental benefits of the flexibility. Discomfort was also evaluated to highlights how demand management impacts the households habits.

The results figured out how demand management can effectively increase local self-consumption with a corresponding reduction in terms of energy costs and CO_2 emissions up to 4.6% and 9.1%, respectively. Similar results could be potentially obtained by using electric storage systems, but investment and operational cost increase as well, making stil less profitable this solution. Interoperability between battery and demand management can instead be supported, because storage units can be potentially undersized or alternatively less stressed, while energy, environmental and economic KPIs are improved. Of course, discomfort is being pe-

nalized, then multi-objective simulation has been also introduced to evaluate how KPIs are influenced by a different willingness to participate in demand management. Results show that potential trade-off solutions can be still found, even thought benefits are reduced. In this case, future work will be further developed to investigate how to economically enhance end-users availability according to their rate of flexibility.

Abstract:
Thermal management systems of electrified vehicles especially heavy-duty trucks face multiple competing goals such as minimum energy consumption, minimum battery degradation and highest passenger comfort. The design process of a suitable thermal management system addressing these goals requires a holistic approach including the various cross couplings occurring in real world operation. Therefore, a physics-based modular full-vehicle model is introduced. The model includes an electrified drive-train, passenger cabin and thermal management system. The mechanical and electrical drive-train components, including the battery, motor and power electronics are thermally connected with each other and the cabin using various cooling circuits. A reversible heat pump and several control units are used to adjust the specific thermal requirements leading to complex interconnections and cross couplings. We estimate the performance of a heavy-duty truck on typical long-distance trips including stops based on legal regulations used for fast charging and overnight charging. While charging overnight, conservation air conditioning of the cabin is performed as efficiently as possible. For this operation, we present different strategies for battery thermal conditioning. Operating strategies for the full vehicle, especially the thermal systems in a summer and a winter scenario are proposed. Simulations of a typical deployment scenario are performed to explore the effects of different operating and control strategies for thermal management. Our virtual deployment scenarios include easy to modify driving cycles, driving time regulations, charge stops and climatic boundary conditions. For evaluation purposes we present an energy-flow-diagram for the full vehicle. Based on the simulation results we recommend thermal system operating strategies in a full-vehicle context for heavy-duty truck long distance trips and charging.

1. Introduction

In order to fulfill Paris goals for reducing CO_2 emissions in the transport sector, electrically powered trucks are needed. Both, battery-electric or fuel-cell trucks show promise for flexible transport of goods [1]. Some recent investigations discuss opportunities and challenges for fuel-cell trucks [2, 3]. An overview of current long-haul heavy-duty fuel-cell trucks is given by Pardhi et al. [4]. While it is believed that both, battery-electric and fuel-cell technologies will be used to power future heavy-duty trucks [5]. In this research we only focus on battery-electric heavy-duty trucks.

The transformation from internal combustion engines to electrically powered vehicles has occurred rapidly for passenger cars, as observed in car registration statistics of different countries [6]. Although electrical powered trucks became available in recent years [5, 7], the adoption of heavy-duty vehicles has been slow compared to light-duty vehicles [8]. Several reasons for the slower transition can be identified. First, heavy-duty trucks are typically required to cover longer distances than light-duty vehicles, while carrying large amounts of cargo. Therefore, the battery systems suitable for a heavy-duty truck must be much larger compared to that of a light-duty vehicle. Second there is a lack of fast charging stations, especially *MW*-Chargers [9], for trucks along the main transport routes resulting in longer stop times compared to conventionally powered vehicles. Third, electric trucks are still much more expensive than conventional trucks [10] and their diesel engines are already optimized on efficiency [2].

Several investigations found in the literature motivate the current study. Verbruggen et al. [11] performed simulations for powertrain design of a battery-electric heavy-duty truck. Nykvist and Ollson [12] performed an analysis on the feasibility of battery electric heavy-duty trucks and in doing so considered fast-charging and range in their investigation. Several authors investigated thermal behavior of large battery packs suited for trucks, e.g. [13]. Furthermore, the influence of thermal encapsulation of truck batteries was investigated. Energy savings for overnight parking are highlighted [14].

Our study focuses on the choice of operating strategies for the thermal management system of the whole truck during driving and charging, which has not been addressed in the literature. To analyze the effects of different operating strategies on energy consumption, battery degradation and thermal comfort, we model the full vehicle in order to take into account cross couplings. As an extension to the previously published studies we propose to employ a detailed physics-based model to investigate battery-electric trucks. With our approach a detailed analysis of the entire vehicle and its subsystems is possible. Furthermore, we describe the degradation of the battery, which allows us to predict the overall lifetime of the truck. Our model also allows different vehicle configurations to be tested. Furthermore, sensitivity analysis for certain parameters can be performed and parameters can be optimized easily.

Our physics-based vehicle model (see figure 2.) accounts for all the main components of a battery-electric heavy-duty truck with a special focus on the details of the thermal systems. The truck uses a state-of-the art Li-Ion battery system designed for performing long-distance trips with full payload. Our system contains NMC-Pouch cells [12]. Other manufacturers plan to use LFP cells [15]. In the future, solid state batteries may also be used for heavy duty trucks [16]. Electric and mechanical components such as motors, power electronics and gears produce waste heat [17]. Our model accounts for this waste heat and also includes battery degradation, which increases significantly at operating temperatures that are either too high or too low [18, 19]. During fast-charging battery waste heat can be very high [20]. Additionally, there is a need for cabin air conditioning and a fresh air supply.

As a result of these points, there is a need for a multi-function thermal management system. Because a long driving range is a main requirement for heavy-duty trucks, the thermal management should be as efficient as possible [21]. Different operating strategies can be applied [22] to optimize energy consumption. Also, battery degradation in the context of a full truck and different environments and operating conditions can be investigated because of the implemented degradation model [18].

We employed test scenarios with challenging conditions for the analysis of the whole system of a battery-electric heavy-duty truck. Operating strategies are compared in terms of battery degradation and energy consumption. Long-distance trips are the most challenging deployment scenario for battery-electric vehicles [23] and therefore, we focus especially on these long-distance trips. There is a need for large battery capacities and rapid charging [5] to minimize break times. In a parameter study, the effects of different boundary conditions as well as operating strategies on the aforementioned energy consumption, battery degradation and thermal comfort are investigated. The boundary conditions include harsh climatic conditions such as very high or low temperatures that are challenging [14, 24], due to the increased energy demands for thermal management. Furthermore, the driving cycle could be challenging, especially for hilly terrain. Due to the large weight of a typical battery-electric truck, which can weigh as much as 42 metric tons [24], high rolling resistances and grade resistances occur. For downhill driving, significant recuperation is possible, which can reduce energy consumption but results in higher loads for the mechanic and electric components and more waste heat. Simulations of the battery-electric truck on different trips using different operating strategies are conducted and investigated. The effects of the different operating strategies on the behavior of the system are analyzed in detail.

2. Description of the Modular Full Vehicle Model

For our investigations we use a modular multi-scale vehicle model implemented in Modelica modelling language using models from the TIL suites [25]. Due to its modular structure, the model can be configured for different types of vehicles such as busses, heavy-duty trucks or passenger cars. An earlier version of the model was presented by Steeb et al. [26]. They combined the vehicle model with a high-dimensional battery model and investigated thermal hotspots in automotive batteries.

A block diagram of the vehicle model used in this study is shown in figure 1. The model in general can be structured into mechanical, electrical and thermal sub-models. Furthermore, the model includes boundary conditions and control units for several models.

The boundary conditions (described in details in section 3.) include climate data and a drive cycle. We set the ambient temperature,ambient humidity and solar radiation as climate conditions. These affect the driving resistance and, importantly, act as the boundary conditions for all thermal models, having particular influence on the cabin, cooling circuit, and the reversible heat pump (RHP).

The drive cycle provides time-based calculated data for the vehicle's velocity and slope. We took distance-based data and re-calculated those for use in a time-based calculation. The time-based format fits well into the overall solution process of the formulated system of equations. For example, time-based driver rest stops can be set easily. Also, for heavy-duty trucks, the payload can be varied, and a time-based format enables the payload to be modified during a multi-stage trip. Furthermore, the drive cycle can set a charging request if ignition is activated. A driver model compares target speed with actual speed. Target speed is set as a boundary condition by the drive cycle. The driver is designed as a controller calculating brake or acceleration

pedal position. Data for slope and payload are processed in the driving resistance.

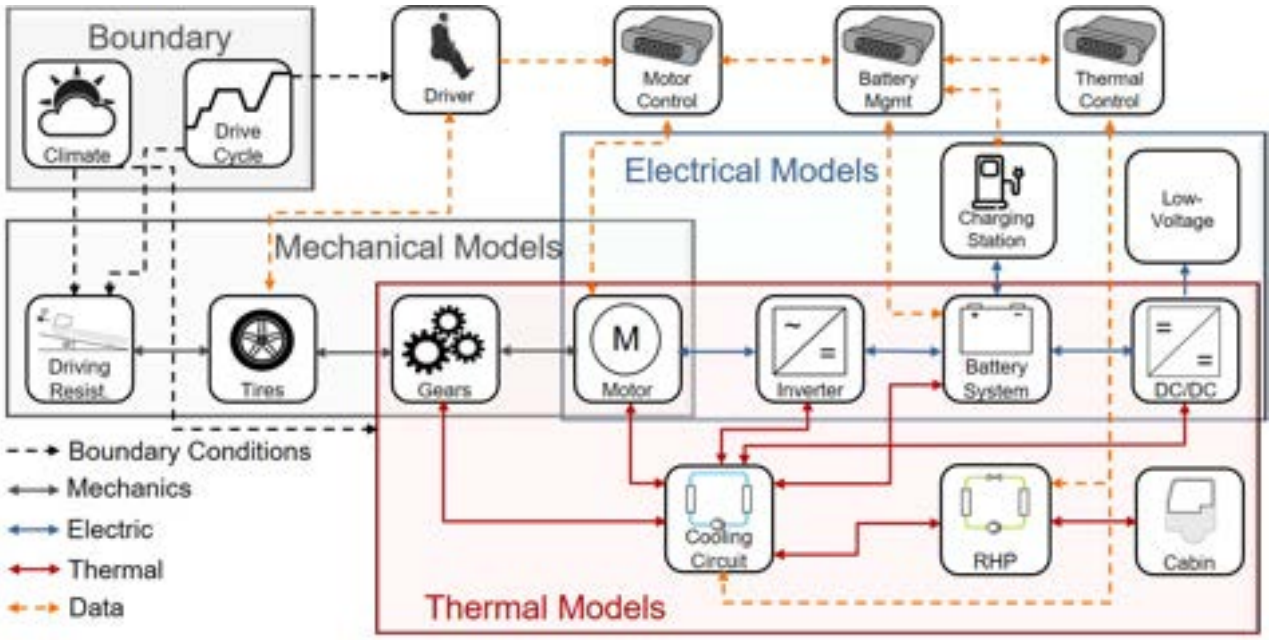

Figure 1: Model of a full vehicle including balance rooms for flow variables (mechanical and electrical power, heat), data connection , and boundary conditions, adapted from [26].

2.1. Models of Mechanical Drive-train and Force Components

The mechanic part includes models for driving resistance, tires, gears and an electric motor describing the driving dynamics of a configured vehicle. The driving resistance model includes replaceable parameter sets for drag coefficient c_w, frontal area A_{front}, weight $m_{vehicle}$ and rolling friction coefficient μ_{roll}. These values are summarized in Table 1. Traction force is calculated by summing roll, air, grade and acceleration resistance:

$$F_{Traction} = F_{Roll} + F_{Air} + F_{Grade} + F_{Acceleration} \tag{1}$$

Rolling resistance F_{Roll} and grade resistance F_{Grade} mainly depend on the vehicle mass $m_{vehicle}$ and rolling friction coefficient μ_{roll}. Air resistance F_{Air} is influenced by the frontal area A_{front} and drag coefficient c_w. The driving resistance model receives slope and the additional vehicle weight due to payload from the driving cycle model.

Table 1: Vehicle parameters used in all scenarios.

Vehicle total mass	Frontal area	Drag coefficient	Rolling friction coefficient
42 t	9.25 m^2	0.5	0.0055

The tires convert torque from gears into translational movements $F_{Traction}$ of the vehicle on the street (driving resistance model). The tire model also takes into account braking force and the tire inertia. Vehicle velocity and distance are calculated. Data are shared into a data-bus system. The gears model mechanically connects the tires and electrical motor. It operates at a constant efficiency and conserves inertia. Constant efficiency means that the incoming power is divided into a mechanical fraction, which is passed to the drive train, and heat. A thermal model is included in the gear model and accounts for waste heat rejected to the cooling circuit.

The electric motor is modeled with a fixed efficiency as well. The model includes replaceable data sets for motor characteristics such as torque data or inertia. The motor torque set-point is provided by the motor control unit. That translates the brake or acceleration pedal positions into motor torque. Constraints are taken into account including battery management data such as minimum recuperation temperature, maximum charging or discharging power, and motor limits. The motor provides mechanical power P_{mech} to the tires and calculates thermal losses P_{loss}.

2.2. Models of Electrical Components

The motor model acts as an interface to the mechanical and electrical models. The needed electric power P_{el} is calculated as the sum of P_{mech} and P_{loss}. While the motor operates at a constant voltage the electric

current depends on P_{el}. An inverter model provides electric power at a constant voltage level. It also operates at a constant efficiency. The inverter model is electrically connected to the battery system including a high voltage network. Furthermore, the DCDC-Converter enables a connection to a low voltage network. The low voltage network provides power for energy consumers such as ignition or infotainment. A charging station model is included. The charging can be activated by the station itself for time-based charging, or requested by the drive cycle. Charging power is controlled by the battery management. We implemented state-of-the-art charge maps that provide feasible charging powers depending on the actual battery temperature and its state of charge (SoC). Furthermore, a derating of charging power for high battery temperatures is applied.

The Li-Ion battery system is the key component of a battery-electric vehicle (BEV) and, therefore is modeled with many details [22, 26]. The battery system consists of a cooling plate, a thermal interface material and of a typical pouch cell with a nominal capacity C_N, as well as current arresters. On the battery system level, we model one representative battery cell and scale current, voltage and heat exchange up to system level. The battery system is designed for an on-board supply voltage of $800\,V$ and has a battery capacity of $725 kWh$. The representative single battery cell is modeled with a 2-dimensional (length and height) discretized model using thermally and electrically connected battery bundles. A battery bundle represents a single discretized part of a battery cell including the same behavior and equations for the adjusted cell volume, mass and capacity [27]. Each battery bundle includes an equivalent circuit model for electric modeling and calculating irreversible ($\dot{Q}_{irrev}$) and reversible ($\dot{Q}_{rev}$) heat production [28]:

$$\dot{Q}_{irrev} = R_i \cdot I^2 \tag{2}$$

$$\dot{Q}_{rev} = I \cdot T \cdot \frac{\partial U_{OCV}(T, SoC)}{\partial T} \tag{3}$$

The internal resistance $R_i(SoC, T)$ depends on temperature T and SoC. Irreversible heat production grows quadratic with higher currents, while the internal resistance typically decreases with higher temperatures. Reversible heat can be positive or negative. For high currents, its effect is small compared to $\dot{Q}_{irrev}$.

For State of Health (SoH) calculations, a semi-empirical battery degradation model based on the investigations of Wang et al. [18] was implemented. The SoH depends linearly on Ah-throughput $Ah_{Throughput}$, exponentially on the C-Rate, defined as $c\text{-}Rate = I/C_N$, and an Arrhenius-Term is used to describe the temperature dependence. Since the model is valid for a wide temperature and C-Rate range, it is capable of capturing the temperature and C-Rate coupling. Therefore, optimal thermal operating points for a given electric stress can be derived from the model. For moderate C-Rates, the optimum temperature of $25^\circ C$ results in the lowest degradation rate while higher and lower temperatures cause the degradation rate to increase rapidly. Other degradation dependencies like depth of discharge or SoC are neglected, which is a reasonable assumption due to the almost stationary use-case-scenarios of heavy-duty trucks. As outlined by [29], the chosen model seems to be the most suitable for the considered application. The model is valid for a wide temperature and C-Rate range. It is capable to describe the coupling of temperature and C-Rate. Optimal thermal operating points for given electric stress can be identified with an equation for ΔSoH depending on T, C-Rate and fitting parameters $a-e$:

$$\Delta SoH = (a \cdot T^2 + b \cdot T + c) \cdot \exp(d \cdot T + e) \cdot C-rate \cdot Ah_{Throughput} \tag{4}$$

2.3. Models of Thermal Components

As described previously, models of the gears, motor inverter and DCDC-Converter use thermal sub-models. The thermal sub-models contain the waste heat production as well as thermal capacitors and resistors describing the geometry and thermal behavior. Motor, gears and inverter thermally interact with the environment and the liquid cooling circuit. Similarly, battery cooling is connected to the cooling circuit. We use a cooling plate model for calculating convective and conductive heat transfer from liquid to the battery cells.

The cooling circuit model (see Figure 2; liquid) includes the interface to the ambient air that flows through the front-end heat exchanger of the truck. A fan is used to increase the air flow rate across this heat exchanger. Each of the two liquid loops are equipped with an air-liquid heat exchanger that is used for heat rejection to the ambient. A low temperature loop is designed for battery cooling. A high temperature liquid loop is used for cooling of motor, gears and inverter. Both cooling circuits use liquid pumps and for certain use cases, connections of the circuits are possible (e.g. battery heating).

Figure 2 depicts a piping and instrumentation diagram of the reversible heat pump with continuous lines marking the activated cooling mode. A third heat exchanger on the air path located in the front-end of the vehicle is used as an evaporator or gascooler/condenser in the reversible heat pump. It is designed as a two-stage R744-refrigeration cycle with switchable operation modes enabling heating or cooling of the battery and cabin. The refrigerant flows through the compressor and enters at a high pressure level in the *Gascooler*, which is bypassed on the air side. Next the refrigerant flows through the open *Valve 1*. Gascooling takes place in the

Front-End HX (heat exchanger) and the *Internal HX*. After that the refrigerant mass flow is divided to provide battery and cabin cooling. In the battery path refrigerant flows through *Valve 3* and is expanded in *Valve 4*. The R744 is evaporated in the *Battery HX* cooling the liquid coolant used for battery cooling. After that the refrigerant flows through *Valve 7* and *Valve 8*. For cabin cooling the refrigerant is expanded in *Valve 5* and flows through *Valve 6* and into the Evaporator, conditioning the fresh air for cabin cooling. Both refrigerant flows get mixed and enter the *Accumulator* and the the low pressure side of the *Internal HX*. Both, the RHP

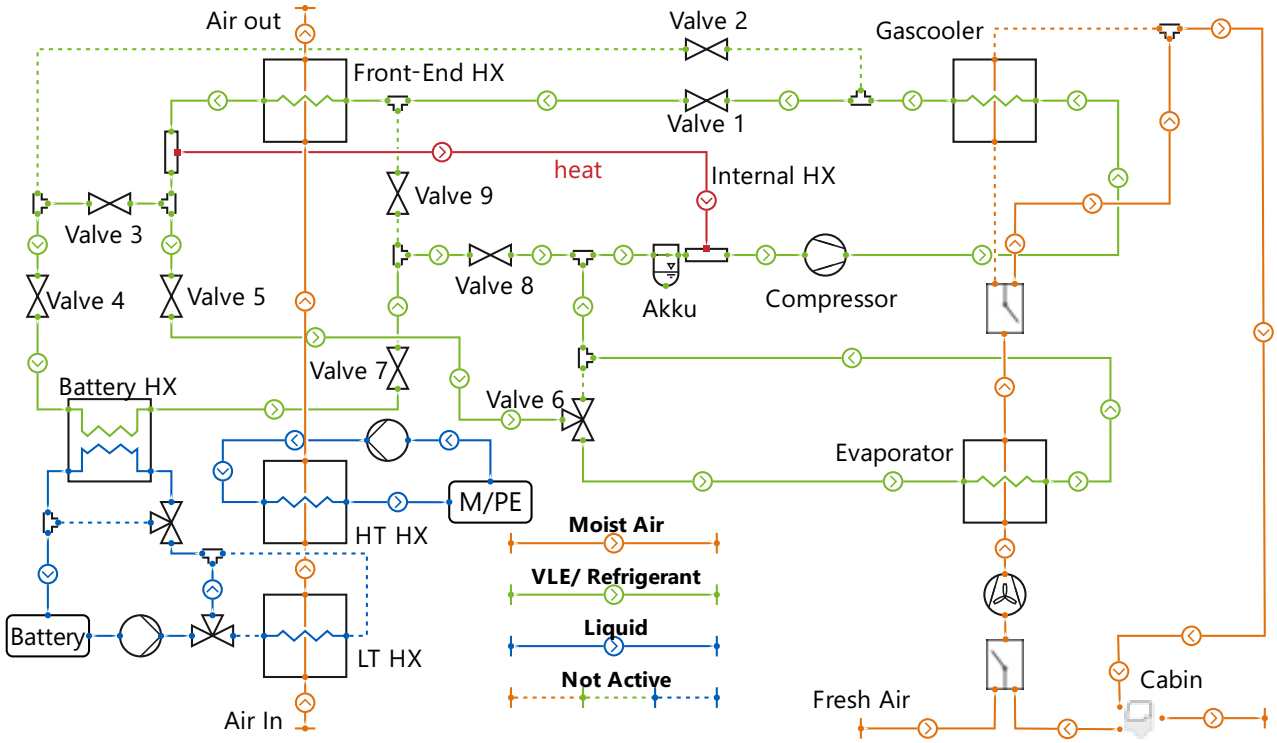

Figure 2: Piping and Instrumentation Diagram with TIL components of a reversible heat pump for cooling and heating of battery and cabin and the simplified cooling circuits including cooling of electric motor (M) and power electronics (PE). The case of the battery and cabin cooling is displayed.

and cooling circuit exchange data with a thermal control unit that specifies setpoint temperatures depending on the actual state of the vehicle and its subsystems. We use sets of PI-controllers for implementing different control strategies.

As described previously, the reversible heat pump is used for conditioning the vehicle cabin. The cabin interacts with the boundary conditions: Ambient temperature and humidity, solar radiation and driving speed. For simplicity, we always set $22°C$ as our target temperature for cabin air.

3. Deployment Scenarios and boundary conditions

We present two typical driving cycles each paired with two climatic conditions resulting in challenging deployment scenarios for a heavy-duty truck. These scenarios are used to investigate the effects of different operating strategies on the defined performance metrics. The applied operating strategies are discussed in the next section. The first drive cycle represents a typical long-distance day-trip for a truck in Germany and is depicted in Fig. 3. Starting in Hanover, the truck travels the 632 km distance to Munich in about 8 hours and 10 minutes excluding stops. The truck starts the drive cycle with half an hour of pre-conditioning followed directly by four and a half hours of mostly full-speed *Autobahn*-Driving. Due to regulations, a break of 45 minutes is required after that time. This break is also used for fast charging. Fast charging during the stop is required to cover the remaining driving distance for the day. For our analysis, the route is driven in a summer scenario with an outside temperature of $35°C$ and a high solar radiation affecting the truck's cabin.

Second, we investigate a two-day long distance trip. The two-day cycle is designed as a simplified driving cycle according to the maximum allowed driver's steering time in European Union regulations [31]. The whole trip runs for 1530 km on a flat terrain. Such a trip could be seen as a trans national European drive from Lithuania to Belgium. The velocity profile including pre-conditioning and rest (and charge) breaks can be seen in Figure 4. The tour starts with 3 hours of pre-conditioning, followed by two consecutive four and a half hour driving periods at $85\frac{km}{h}$ interrupted by a 45 minute resting and charging break. The night break is 11 hours and then

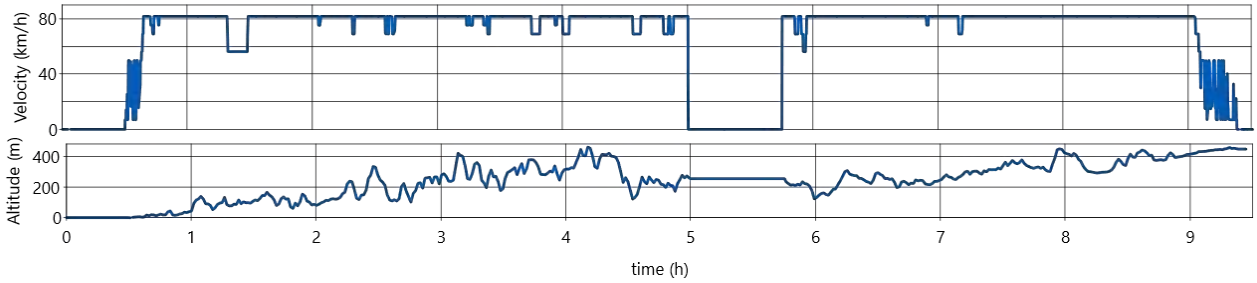

Figure 3: Hanover-Munich long-distance day-trip: Velocity and Altitude profile with rest and fast charging break, adapted from [30].

the same procedure will be driven the second day. During the short breaks fast charging will be performed. Slow charging is performed during the night break. During all charging breaks, cabin air conditioning must be provided.

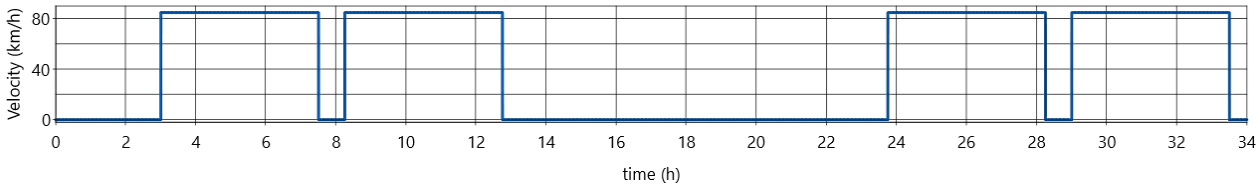

Figure 4: Velocity profile for a two-day long distance trip without altitude changes, including two fast charging brakes and one overnight brake.

4. Operating Strategies

An operating strategy is needed to handle competing goals pertaining to thermal management in the vehicle's operation. Those goals include:

- Minimum battery degradation
- Best thermal comfort for the driver
- Minimum energy consumption and maximum driving range

These goals are constrained by the following additional conditions: Safe operation of all vehicle components and systems, especially the battery and reaching suitable charging times. Most of these goals are in competition at various points of operation and must therefore be prioritized. Battery degradation can be reduced by maintaining optimum battery temperature and operating at low C-Rates. Maintaining suitable battery temperature, increasing energy consumption reduces driving range. If the reversible heat pump is working, a strategy for cooling or heating priority between the cabin and battery is necessary.

Two operation strategies for the summer scenario Hanover-Munich trip are suggested. One strategy prioritizes **minimum energy consumption**. The other strategy prioritizes **minimum battery degradation**. For safety reasons, thermal comfort of the driver is always prioritized and the best possible comfort is provided. For the **minimum battery degradation** strategy, the thermal system tries to cool the battery as much as possible to quickly reach and maintain the degradation-minimizing temperature. This is especially important during and after fast charging. For minimum energy consumption strategy, less intense battery cooling is performed at a more optimal operating point of the RHP and the target temperature for battery cooling is set higher than the degradation-minimizing temperature to save energy in thermal management.

Two operation strategies for fast charging during the two-day long-distance trip are suggested. We distinguish between a 45 minute daytime charging break that satisfies legal requirements, and lengthening the day-time charging breaks by 15 minutes resulting in a total of 30 minutes longer trip time. Minimum charging time competes with minimum battery degradation, which is expected to be higher when higher charging power is used.

In winter scenario we investigate the influence of battery pre-conditioning based on the two-day long distance trip. We compare different target temperatures for battery heating by the reversible heat pump during an hour of pre-conditioning before driving on a flat terrain for 9 hours including a fast-charging brake of 45 minutes.

The winter scenario also includes fast charging breaks but due to lower ambient temperatures battery cooling is easier. During overnight charging a constant heating and fresh air supply for cabin are required. For overnight charging, we study an eight hour night-time break for charging. The truck arrives with a nearly empty battery (SoC = 10%) and charges with a constant charging power (P_{charge} = 75 kW). We distinguish three thermal management operating strategies for RHP operation (see figure 2) during overnight charging. Our first strategy uses battery waste heat as the heat source for RHP, forming a water-air heat pump. Due to the relatively high temperature level and capacity of the battery a very high heating efficiency is expected. The second strategy utilises ambient air as heat source forming a typical air-air heat pump. Finally, the third strategy uses an electric heater. It is used as a benchmark for comparison of the electrical energy consumption and possible savings.

5. Results

To analyze cross couplings in the complex system that is the full truck model, we use a energy-flow diagram on the top level. Figure 5 shows the flow rates of the three main process variables: Mechanical and electrical power as well as heat flow rates. The diagram shows a summer case at an ambient temperature of 35°C and the Hanover-Munich route. The current and average consumption of electrical energy an other simulation parameters are depicted, cf. Fig 5. At the moment of the operational snapshot in Figure 5 the truck is climbing

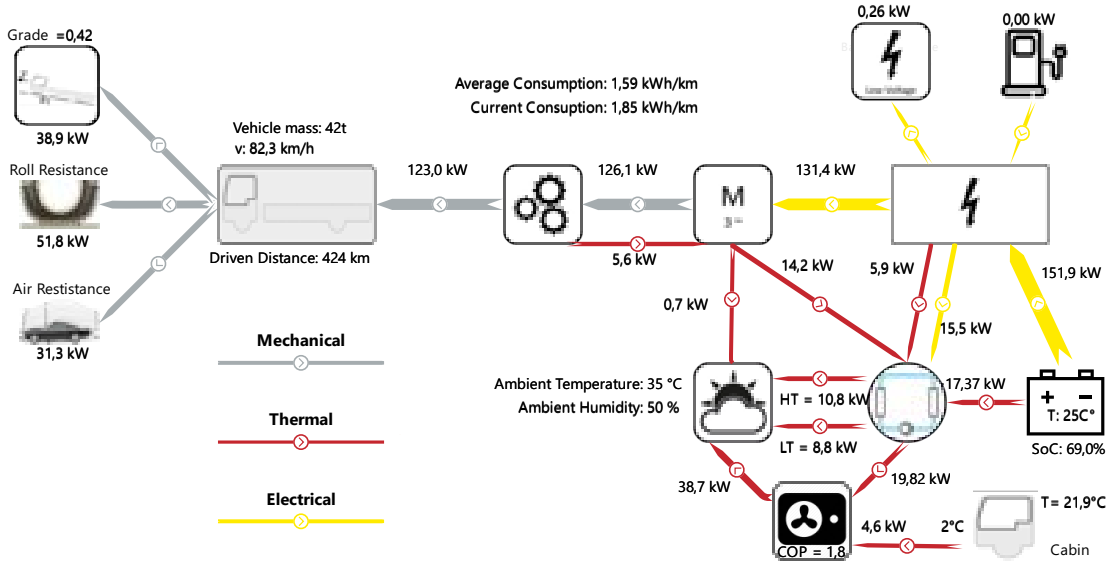

Figure 5: Energy flow diagram showing the mechanical, electrical and thermal power flows and additional information about the vehicle state an hour after fast charging in the Hanover-Munich cycle.

a slight grade. Efficiencies of sub models (e.g. gears) can be observed from the different powers displayed at each side of the component. Thermal and mechanical inertia of the components are included. The battery rejects 17.37 kW of heat to the cooling system. Heat is released to the cooling cycle and a small portion directly to the environment by the LT-Cooler and partly to RHP. Cabin cooling is also performed through RHP on a lower temperature level.

5.1. Model Plausibility Check

We checked the plausibility of our heavy-duty truck model by comparing it to test data available for the *Volvo FH Electric* [10], which is a battery-electric truck of the same class as the one that was modelled. The real world test of the Volvo truck resulted in an average energy consumption of 1.1 $\frac{kWh}{km}$ for a 338 km route with a diverse topography in Southern Germany [10]. We took the same route and chose a summer scenario with an ambient temperature of 28°C to investigate the modelled truck. Cabin cooling is performed to keep the cabin at 22°C. Our simulation resulted in an average energy consumption of 1.33 $\frac{kWh}{km}$. The 21% difference in the results can possibly be attributed to differences in the energy consumption for air conditioning, the truck's weight or slightly different roll and air resistances.

5.2. Influence of Thermal Management Operation Strategy for Summer Scenario

In Figure 6, the comparison of battery degradation, represented as the change in SoH and battery temperature for the Hanover-Munich trip in summer is shown for both operation strategies (see section 4.). The degradation is reduced by 40% when applying the **minimum battery degradation** operating strategy compared to the

minimum energy consumption strategy. On the other hand, at the beginning of fast charging at a time of 5 hours, 2.3% percent of SoC or 9 kWh of energy is saved for **minimum energy consumption** operating strategy.

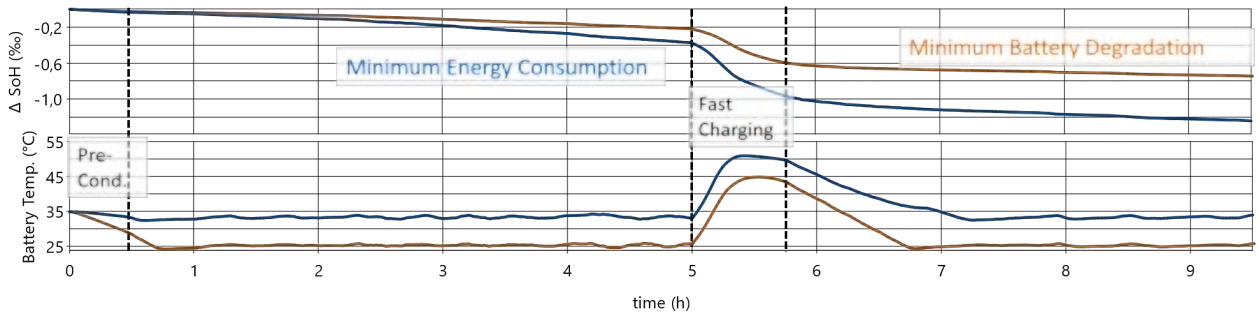

Figure 6: SoH degradation and battery temperature for a Hanover-Munich long distance day trip on challenging topology and two operation strategies: **minimum battery degradation** (orange) and **minimum energy consumption** (blue). Battery degradation is reduced by 40% using the **minimum battery degradation** operating strategy.

This investigation underlines the trade-off between energy consumption for thermal conditioning of batteries and battery degradation. Because only small energy savings are achieved with the **minimum energy consumption** strategy compared to the driving energy but large difference in battery degradation is observed using the **minimum battery degradation** strategy. Preference should be given to battery cooling to limit degradation.

5.3. Influence of Fast Charging Strategies on Long Distance Trips

We investigate the influence of fast charging on battery degradation incorporated in a long distance trip (see Figure 4.To do this we lenghtend the charging break from 45 minutes to 60 minutes and reduced the associated charging power by 25%. Figure 7 illustrates the differences in battery degradation for the two fast charging times over the whole two day trip.

First, this investigation shows the enormous influence of fast charging operation on battery life, which can be seen by comparing the blue and orange curves in Fig. 7. It can be seen that battery degradation during charging is significantly higher than while driving. This results from the larger currents that occur during fast charging compared to the discharging currents drawn from the battery while driving. Also the battery is facing those higher currents at higher temperature levels which is another crucial factor for the degradation.

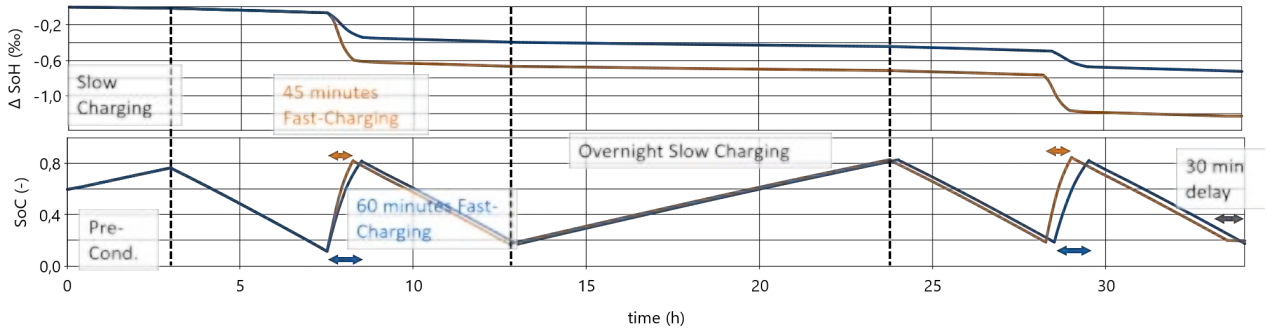

Figure 7: SoH degradation and SoC over a two-day long distance trip with two operating strategies for daily fast charging: 45 minute charging breaks (orange), extended 1 hour charging breaks (blue). Significant reductions (42%) in battery degradation are seen for longer charging breaks.

Second, Fig. 7 shows the effect of lengthening charging breaks by 15 minutes and at the same time reducing charging power on battery degradation. By extending the break time by 15 minutes, resulting in an additional 30 minutes beeing needed for the two-day trip, the battery degradation can be reduced by 42%. Further elaboration is recommended to analyze the economical trade-off between battery degradation and depreciation and delivery time. The preliminary discussed goals of fast charging time and battery degradation conflict strongly.

The results of this investigation enable us to approximate the total battery lifetime expectancy. Driving the two-

day long distance trip, the battery looses 0.07% of its state of health when taking 60 minute charging breaks. By extrapolating the result down to a SoH of 80%, a battery lifetime of 287 drive cycles or 437.000 *km* is approximated. Considering the result for the same drive cycle but using 45 minutes charging breaks a lifetime range of only 245.000 *km* can be achieved. This result confirms that battery change could be necessary during the lifetime of the truck, particularly if fast charging is performed regularly. A separate depreciation of the battery and other components is suggested, and battery degradation should be considered in logistics operation strategies.

5.4. Influence of Terrain on Battery Degradation

To asses the influence of terrain, we compare the Hanover-Munich trip (Fig. 6) to the long distance trip (Fig. 7) for total trip battery degradation. Although the long-distance trip is more than 2.42 times longer than the Hanover-Munich trip, the battery degradation is similar. This directly translates to a higher degradation per unit distance driven for the Hanover-Munich cycle. The effect can be explained by the challenging terrain of the Hanover-Munich cycle that results in much higher discharging C-Rates for hill climbing and recuperation when going downhill. When combined, these effects lead to a higher total number of battery charging and discharging cycles.

5.5. Influence of Battery Aging on Long-Distance Feasibility

To assess the impact of battery aging, we compare previous results for the Hanover-Munich trip for the summer scenario with the same conditions and an already degraded battery. Figure 8 shows a comparison of SoCs against the driving time for a new battery and a degraded battery with a SoH of 0.9. Due to the degradation, not only is the total battery capacity decreased, but the internal resistances are also increased, resulting in more irreversible heat production during charging and discharging. This puts an additional load on the cooling system. The truck reaches the fast charging stop with an SoC of 0.09 instead of 0.19 for a new battery. More intense fast charging needs to be performed, or the charging break needs to be extended, if the truck is required to cover the remaining drive cycle without another stop.

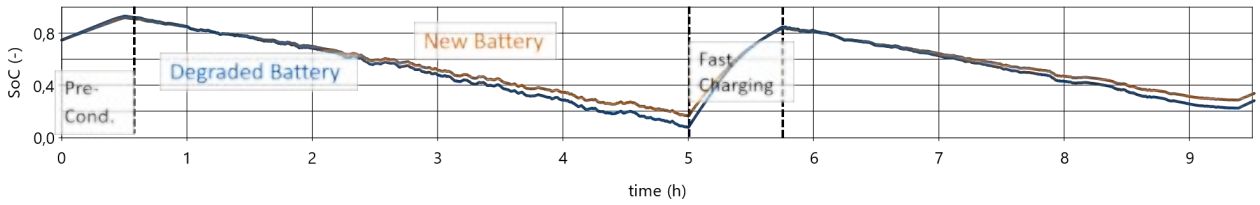

Figure 8: SoC over Hanover-Munich long distance day trip compared for new (orange) and degraded (SoH = 0.9, blue) battery. Less driving range and more intense fast charging result, for the degraded battery.

Our investigations indicate that the loss of battery capacity due to degradation should be taken into account when choosing an appropriate size of battery system for the given operational and range requirements of the vehicle. This again highlights the importance of appropriate thermal management operation strategies to reduce battery degradation.

5.6. Influence of Pre-Conditioning in Winter Scenario

For a one-day long distance trip we compare the influence of pre-heating in a winter scenario at $-5°C$ ambient temperature. After pre-conditioning the battery is heated using waste heat from the motor and electronics as well as its own produced heat.

From figure 9 it can be observed that in a winter scenario battery heating in the pre-conditioning phase can reduce battery degradation significantly. A battery heated to $10°C$ instead of $0°C$ through pre-conditioning reduces battery degradation caused in the first hours of the driving cycle by 33%. Pre-heating the battery up to $20°C$ (which takes more than one hour) does not reduce battery degradation much further. It is demonstrated that operating at low battery temperatures results in accelerated degradation. Battery heating before driving is strongly recommended in winter scenarios. A heat pump is suggested for this purpose to improve energy efficiency.

5.7. Overnight Charging in Winter Scenario

The energy consumption of the three different operation strategies for thermal management for an overnight cabin heating and simultaneous battery charging are displayed in table 2.

The results show, that a heat pump can reduce energy consumption for cabin heating significantly. For 8 hours of overnight cabin heating at an ambient temperature level of $-5°C$, 11.1 kWh of energy are saved using an air-air heat pump instead of an electric heater. Futher saving can be realized by employing the RHP

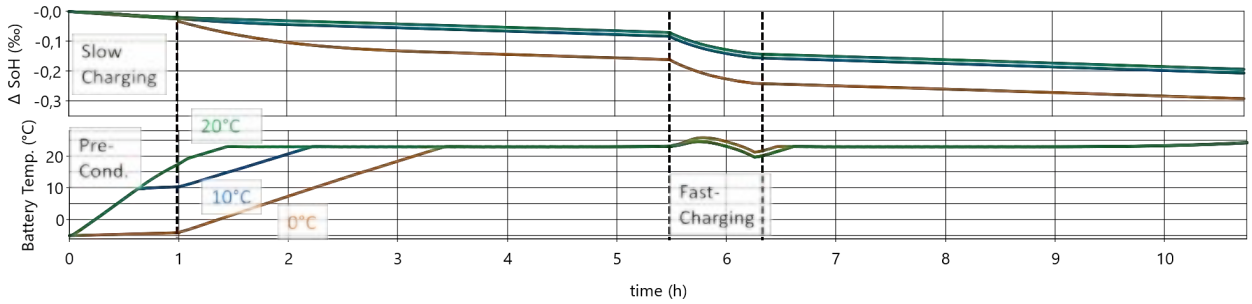

Figure 9: Influence of battery pre-conditioning (with RHP) before driving in a winter scenario with an ambient temperature of -5°*C*. Comparison on battery degradation and battery temperature. Target temperatures for battery heating while pre-conditioning is active: 0°*C* (orange), 10°*C* (blue), 20°*C* (green).

Table 2: Electric energy consumption of different cabin conservation air conditioning thermal management strategies (see section 4.) during overnight charging in winter scenarios.

Water-Air Heat Pump	Air-Air Heat Pump	Electric Heater
2 kWh	3.9 kWh	15 kWh

(see figure 2) as an water-air heat pump during overnight charging. The electrical energy consumption could be halved again for this operation strategy. When using the water-air heat pump only the *battery HX* and *gascooler* transfer heat. During overnight slow-charging the battery waste heat is efficiently used as RHP heat source. Depending on the chosen charging speed, the current SoC, the SoH of the battery and the ambient temperature the waste heat approximately covers the required heat for RHP. If the predicted demand of heat to keep the cabin temperatured exceeds the amount of available waste heat of the battery, that is produced while charging the battery, the battery could also be used as a thermal capacity. Therefore, battery operating temperature could be increased during the last hours of operation before overnight break in order to have a higher temperature level of the RHP heat source. After that battery temperature could slowly be decreased overnight using battery as heat source for RHP.

6. Conclusions and Outlook

In our study, we demonstrated that a physics-based full-vehicle model of a battery-electric truck is suitable to accurately predict the consumption of electrical energy in a benchmark scenario. Using the full-vehicle model, the effect of fast charging on the state-of-health of the battery was explored using real-world deployment scenarios. It was found that fast charging stops have an important impact on the achievable life time of a battery electric truck.

Our study also compared different operating strategies for summer and winter scenarios. Fast-charging breaks along with legally required minimum break time leads to accelerated battery degradation. A slight extension of charging times and associated lower charging currents lead to significantly less battery degradation and thus much less depreciation on the battery (truck). Prioritizing minimum battery degradation over minimum energy consumption as thermal management operating strategy leads to significant reduction in battery degradation.

Furthermore, our investigations showed how a challenging hilly terrain influences battery degradation due to high discharge currents while driving uphill and high charging currents for recuperating while driving downhill. In this context we exemplary contrasted the remaining capacity when reaching predefined charging stops of a pristine and a degraded battery to evaluate the long-distance feasibility over lifetime. The results showed that especially for long-haul trucks the battery size should be designed anticipating degradation due to aging. For the investigated winter scenario we showed the positive effect of pre-heating the battery before driving. Pre-heating lowers degradation significantly. For battery and cabin heating a heat pump is recommended due to energy efficiency. For overnight heating operation the heat pump is used as well. Battery waste heat while slow charging can be used as a heat source for an efficient heat pump.

Looking to the future, solid state batteries are a promising development in battery technology. It is predicted that they will require a higher temperature level for operation [16]. For long distances and driving times of heavy-duty trucks, as well as route planning and pre-conditioning times, solid-state batteries are especially suitable for trucks. Adjusted thermal management systems are needed with solid state batteries. There is a special need for heating technologies and battery pre-conditioning. Due to its modular structure, our model is well suited for such investigations in the future.

Acknowledgments

As this work was funded under grants AUTO-GEN (01IS20086B) and PHYMOS (19I20022I), the authors would like to thank the German Federal Ministry of Education and Research and the German Federal Ministry of Economic Affairs and Climate Action for their financial support.

Abstract:
Finding new alternatives to current energy systems is a need to develop disruptive solutions. In this case, a complete new approach the Sodium as energy resource is described. Tradicionally, Sodium has been considered a risky element even if it were proposed as coolant in many applications, as nuclear or solar thermal plants. Such applications has been concerned by the explosive reaction of alkali as Na with water. In this communication, we analysed the altenative of profiting of such highly exothermic reaction for an energy use. Previuosly , we analised the utilization of sodium as propellant, and next steps presented in this paper shows the proposal of a sodium-water based heater to feed heating and cooling networks. A tentative configuration for the design of such heater, and the heat exchangers to adapt heated water temperatures will be presented. We present the conceptual design of a 13.5 MW district heating plant for a $\Delta T = 10^oC$ heating water from 60 to 70 ^{o}C, consuming 1 kg/s Sodium, reaching an efficiency of 95%, comparable with existing boilers..

Keywords:
Sodium-Water reaction, District Heating

1. Introduction

The energy sector is facing the need of a systemic transformation to reduce as much as possible the carbon dioxide content in the atmosphere, increasing the circularity of all the energy and industrial processes , as well as fulfilling the global energy demand. Current tendencies to improve the sustainaiblity of the energy system into the framework of the energy transition are based on the massive deployment of renewable primary energy sorces, the implementation of high capacity storage systems to manage intermitent generation of such sources. In addition, some authors consider nuclear energy [1] to support that high penetration of renewables to achieve zero-emissions targets. Additionally, even if fossil resources are expected to be axhausted at any time in the future, they would be able to contribute to decarbonise the energy system during such energy transition by the utilization of carbon captire and sequestration (CCS) technologies [2], as well as hydrocarbon pyrolysis [3].

Solutions for a decarbonised energy transition my be provided for electric and themal energy uses, either for industry or for heating/cooling application. Current solutions based on batteries, hydrogen or incremental developments of emerging, existing technologies, may have some limitations to provide a suitable scheme that would allow to comply with the maximun environmental targets. This could be specially critical for a complex system as it is the energy system itself, that should increase significatively its integration into circular processes coupling with other sectors. To increase the chance to achieve the required environmental targets seems necessay to analyze disruptive alternatives that can be added to the options that are currently available to increase the technological options to implement a sustainable energy system. Oxygen oxidation has generally been used as the fundamental form of enthalpy or chemical energy release, giving rise to combustion reactions. Another option is the use of water as an oxidizing element. One of the possibilities is the use of the sodium-water reaction, which responds to the exothermic balance expressed in 1:

$$Na + H_2O \longrightarrow NaOH + \frac{1}{2}H_2 \qquad \Delta H_0 = -141\frac{kJ}{mol_{Na}} = -6.13\frac{MJ}{kg_{Na}} \tag{1}$$

This reaction, when it occurs in excess of water, is followed by the dissolution of sodium hydroxide in water, which is also exothermic, and can offer, in the case of developing the reaction in a closed vessel, a practical heat generation of the order of 188 kJ/mol_{Na}(8.174MJ/kg_{Na}), The hydrogen produced recombines with oxygen that may be present in the reaction environment with an extra heat production, so that the total energy release

obtained in a total oxidation of Na to NaOH with water and oxygen and a subsequent dissolution of NaOH in water reaches 326.6 kJ/mol_{Na}(14.21MJ/kg_{Na}). In the case of developing an application that takes advantage of this energy, the final product would be a solution of solid hydroxide in water, which can be extracted in liquid form and continuously.

We have previously evaluated experimentally the sodium-water reaction in excess of water [5], qualifying its performance of sodium as candidate fuel for rocket propellant. Such works was one of the fist attempt to convert the inhetent risk associated to the use of sodium as coolant due to its high reactivity with water [6], to a potential valid decarbonised fuel. In this communication we analyse the application of such reaction to one of the most important sectors for the decarbonization of our Society. The residential sector accounts for a significant amount of CO_2 emissions due to the utilization of fossil fuels for climatization and heated water demand.

2. Sodium water reaction closed fuel cycle

The utilization of sodium as main fuel, combined with and oxydising agent as water, has as one of its primary source the common salt (NaCl). The extraction of sodium from sodium chloride, energy is needed according with the following electrochemical potential:

$$Na^+ + Cl^- \longrightarrow Na + \frac{1}{2}Cl_2 \qquad E_0 = -4,07V \tag{2}$$

The energy that is needed, for instance, in form of electricity may be calculated by electrolytic conversion with the following semi-reactions:

$$Cathode : Na^+ + e^- \longrightarrow Na \qquad E_0 = -2,71V \tag{3}$$

$$Anode : 2Cl^- \longrightarrow Cl_2 + 2e^- \qquad E_0 = -1.36V \tag{4}$$

The reaction enthalpy may be evaluated fromn the Gibbs energy of the reaction, which is calculated from the Faraday constant (F=96485 C/mol), and taking into account that one electron is needed for the formation of one Na molecule (23 g/mol) as:

$$\Delta G_0 = -n_e F E_0 = -96485 \cdot 4.07 \frac{J}{mol_{Na}} = 392.6 \frac{kJ}{mol_{Na}} = 17 \frac{MJ}{kg_{Na}} \tag{5}$$

The total enthalpy or enegy requirements for the dissociation of sodium clodride has to add the energy to heat it up to the fusion temperature and meld the compound, according to:

$$\Delta H = \Delta G_0 + C_{p,NaCl} \cdot (T_{f,NaCl} - T_a) + h_{fg,NaCl} = 17 + 1.9 + 0.32 \frac{MJ}{kg_{Na}} \approx 19.2 \frac{MJ}{kg_{Na}} \tag{6}$$

This number may be compared with the total amount of energy that is produced by the sodium water reaction (equation 1), what gives an overall potencial energy efficiency of the conversion of primary energy into heat of 73 % in the case of extracting Na from sodium chloride. Obviously, this figure is the maximum thermodynamic efficiency, that will be reduced by the losses of the electrochemical arrangement for Na synthesis, as well as the heat efficiency of the sodium-water reactor.

The utilization os NaCl as input raw material for the generation of the sodium reactant may be replaced by the recovery of sodium from the sodium hidroxide product of the raction. In this case, the redox reactions are:

$$Na^+ + OH^- \longrightarrow Na + \frac{1}{2}H_2O + \frac{1}{4}O_2 \qquad E_0 = -3,11V \tag{7}$$

In this case, the amount of electrons (n_e) involves in the redox semireaction is 4, leading to a minimum potential energy demand of 8.2 MJ/kg_{NaOH}, that is a net energy demand for the recovery of sodium of 14 MJ/kg_{Na}. The efficiency of the NaOH/Na cycling depends only on its irreversibilities and the efficiency of the electrochemical and heat management equipment.

The energy needed to run both sodium synthesis processes is intended to be provided by low-carbon electricity, as wind, solar FV or nuclear.

3. Sustainability of the Sodium Water Reaction

One of the most important aspects related to the utilization of any energy source is the evaliation of its sustainability, what includes concepts as environmental impact, resources availability and circularity. The evaluation of the alternative of the sodium-water reaction, as a possible alternative to combustion in the context of the decarbonization of the energy system, can be analyzed based on sustainability criteria, and the comprison with the use of fossil resources today and some other alternatives. Among these generic characteristics for the evaluation of an energy source are:

- Greenhouse gases emissions related to its use as energy source.
- Circularity potential.
- Abundance and availability of primary resources.
- Energy density.

3.1. Environmental impact and circularity

The decarbonization of the energy system requires the development and implementation use of technologies with zero or very low emissions of greenhouse gases, such as methane or carbon dioxide, and to a lesser extent, water vapor or other triatomic molecules. As described, the sodium-water reaction has as its final product sodium hydroxide (NaOH) dissolved in water. Being a set of reactions that are not related to carbon chemistry, there is no recombination with oxygen to form CO or CO_2. It can be said that it is a high exergy thermal power generation without greenhouse gas emissions, which is compatible with applications in which fossil fuels such as natural gas are difficult to replace.

Regarding the potential for circularization, the result of the reaction is a solution of Na(OH) with water, which can be reintroduced into the reactor, increasing the hydroxide concentration. From a certain concentration after some recirculation cycles, after making the last thermal exchange, if it is allowed to cool in a open deposit, the NaOH crystallizes and precipitates [9]. The maximun concentration that may be reached depends on the process temperature, as seen in the NaOH/water system shown in figure 1. For instance, if operating at 25 ºC, NaOH concentration should not exceed 50 %.

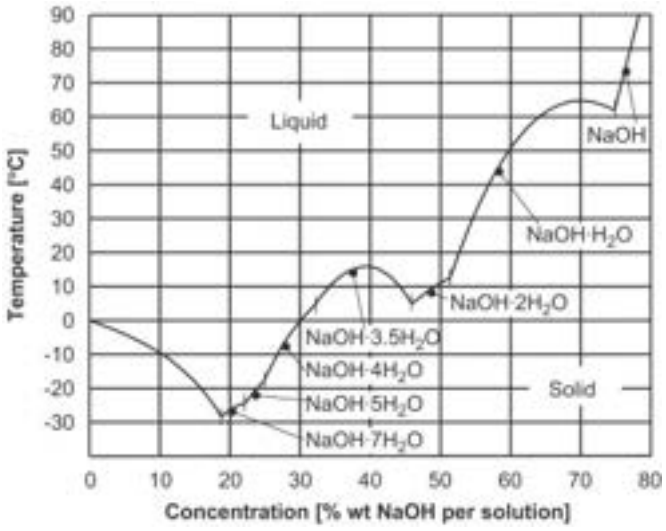

Figure 1: The NaOH–H2O system. Stability ranges of the different hydrates and the respective solidification lines [11]

3.2. Abundance of the primary source

Sodium is the sicth element in abundance accounting for 2.83 % of the Earth‘s crust [7]. That means that is far from being considered a risk from the geo-political point of view, being widely available. A list of the most abundant elements are listed in table 1. Sodiun is very reactive and it is not found as a single element. The most common sodium compound is sodium chloride. This very soluble salt has been leached into the oceans over the lifetime of the planet. Salt beds can be found where ancient seas have evaporated. It is also found in many minerals including cryolite, zeolite and sodalite.

The high availability of sodium compounds implies to fulfill one of the most important constraints for the sustainability of energy sources, that is the possibility to grant access to the resource to everyone.

Table 1: Element abundance on Earth [8]

Element	atomic number	% by weight
oxigen	8	46.60
silicon	14	27.72
aluminium	13	8.12
iron	25	5.00
calcium	20	3.63
sodium	11	2.83

3.3. Energy density

The development and application of the sodium water reaction convert sodium in an enegy vector, thjat could be compared with the rest of the vectors and storage techonology available. Suche comparison may be done in terms of energy density. The energy density of sodium has been evaluated as 14.2 MJ/kg_{Na} by mass or 13.8 GJ/m_3 by volumem in the case of adding the heat of the sodium-water reaction and the hydrogen oxidation, what is expected in excess of water. A comparison with other energy carriers is depicted in the table 2. All of the energy carriers that are considered now are based on liquid or gaseous substances. Sodium is a solid substance, what reduces energy lost during storage, enabling its use for long term storage.

From the point of view of the energy density, sodium is comparable in terms of volumetric capacity with other carriers as compressed natural gas, ammonia and liquid hydrogen. In any case, either compressed natural gas or different forms of hydrogen storage alternatives requires the implementation of criogenics or dedicated compression systems. Its performance is lower respect to liquid fuels, specially interms of energy per mass. Sodium as solid energy carrier is comparable with ammonia.

From this comparison, it can be assessed that sodium has energetic properties that are comparable with other energy vectors that are proposed as key for the implementation of a decarbonised energy system.

Table 2: Energy density of several energy carriers [10]

Carrier	Energy per mass (MJ/kg)	% Energy per volume (GJ/m^3)
Hydrogen (liquid)	143	10.1
Hydrogen compressed (700 bar)	143	5.6
Hydrogen at STP	143	0.0107
Natural gas (liquid)	53.6	22.2
Natural gas (250 bar)	53.6	9
Natural gas at STP	53.6	0.036
Methane at STP	55.6	0.0378
Gasoline	46.4	34.2
Diesel	45.4	34.6
Ammonia	18.6	11.5
Sodium	**14.2**	**13.8**

STP stands for Standard Temperature and Pressure (25 ºC, 1 bar)

4. Application to District Heating

I has been shown how the highly exothermic sodium-water reaction has certain potential to be integrated into the enegy system. Nevertheless, the reaction evolution should be controlled, as it has been done with combustion, to convert a reasonable reaction heat into a useful sevice. At this respect, district heating and cooling are one of the most important potential applications. Currently, the residential sector is the responsable of a very significant part of current CO_2 emissions in many countries, in many case above 50 % [4].

4.1. Process description

A full process that has been designed for the implementation of a district heating and cooling installation based on the sodium-water reaction is depicted in figure 2. The process is composed of the following functional circuits:

- Water feeding system (WFS).
- Sodium feeding system (SFS).

- Sodium-water reactor (SWR).
- Heat exchange to District Heating (HDH)
- Reactor outflow treatment system (ROTS).
- Air Purge System (APS).

The water feeding system (WFS) pumps water to the sodium water reactor. A pump controls the inflow of fresh running water to the process, that is mixed with pure water rejected by the osmotic separator of the reactor outflow treatment system (ROTS). The sodium feeding system (SFS) preheat sodium up to its liquid state (98 ºC) from the sodium inflow at room temperatura. It is composed by a preheater that melts sodium according to the inlet rate set up for the reactor. We have assumed in our design a sodium consumption of 1 kg/s as described in table 3. Such massflow is contolled by the reaction rate and volume of the sodium-water reactor (SWR). The basic parametes for the control of such reaction may be established by the experimental work already done for the characterization of the reaction in a fixed volume [5] and depicted in figure 3. Oor experimental work shows as the energy that is generated in the reactor is proportional to the amount of sodium that is present in the reaction chamber, with a low impact of the excess of water, or addicional material, as in this case is the remaining sodium hidroxide. As we intend to avoid water vaporization, the reactor should be pressurized.

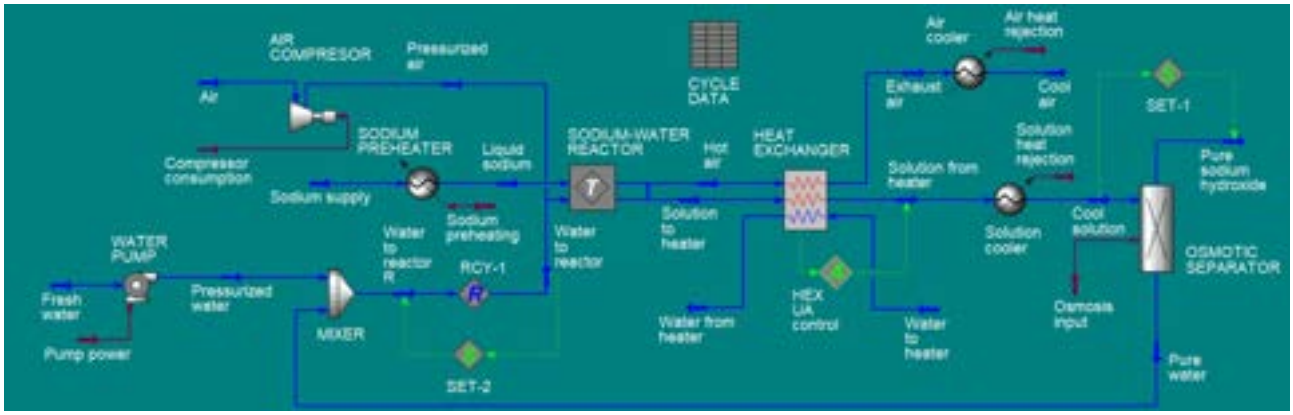

Figure 2: Process for the DHC application of the sodium-water reactor boiler including an osmotic separator for Na(OH)

The continuous reaction product stream passed to one leg of a heat exchanger of the HDH system to transfer the useful heat to the district heating loop. The service hear exchanger has an additional input from the air purge system (APS), which main purpose is to clean up the reactor stream from residual hydrogen that could remain in the reactor product stream. The air stream contributes to the total amount of heat transferred to the district loop, increasing efficiency.

The reactor outlet stream from the heat exchanger, composed by a sodium hydroxide solution in water is treated in the ROTS system to extract to extract pure Na (OH) and and water to be recirculated and mixed with running fresh water. The core of the reactor outflow treatment system is an osmotic separator that extract sodium hydroxide. Such separators are operating at low temperature [13] that is achieved by a cooler downstream the HDH. As an alternative, depending on the concentration of the solution, it can be solidified by lowering temperature. To improve the energy efficiency of the ROTS system, it i spossible to regenerate heat in the solution cooler exchanging energy between the pure water stream and the solution from the DHD. Such temperature reduction in the solution from water may happen with concentrations higher than 30 %. Such concentration may be achieved by the reduction of the pressure to enhance water vaporization of the mixture. For low concentration of Na(OH), the product stream can feed directly an electrolytis section to recover Na in case of the integration of a sodium recovery section. In that case, the facility will decouple electricity consumption from heat generation for the district heating, using sodium as storage.

4.2. Process data estimation

A conceptual analysis of the process that is proposed for the application of the sodium-water reaction to district heating (DH), that may be extended to dostrict cooling (DC) adapting the set-points of the control variables (mainly temperatures), has been modelled with UniSim R491 Suite [12]. From the previous discussion, we have analysed the substitution of the ROTS for a solution storage, that will increase the content of Na(OH) during operation. The simplified conceptuak process is depicted in fiigure 4 The size of the facility has been set to the processing of 1 kg/s of sodium, what is considered representative for a full scale district heating.

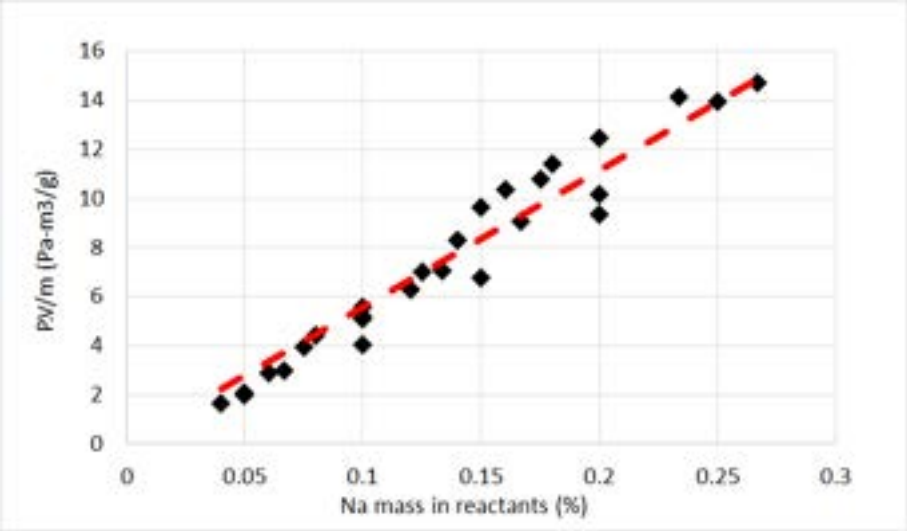

Figure 3: Normalised energy generation vs. Na in excess of water. [5]

Such sodium consumption corresponds to a heat plant of 13.5 MW. In this first analysys we have designed the service heat exchanger for district heating $\Delta T = 10^{o}C$ heating water from, 60 to 70 ^{o}C. In the case of the the application to district cooling, that may require higher temperatures, for instance, to drive absorption chillers, such service temperature may be upgraded by certain change in the set-points, as pressure and outlet temperature, of the reactor.

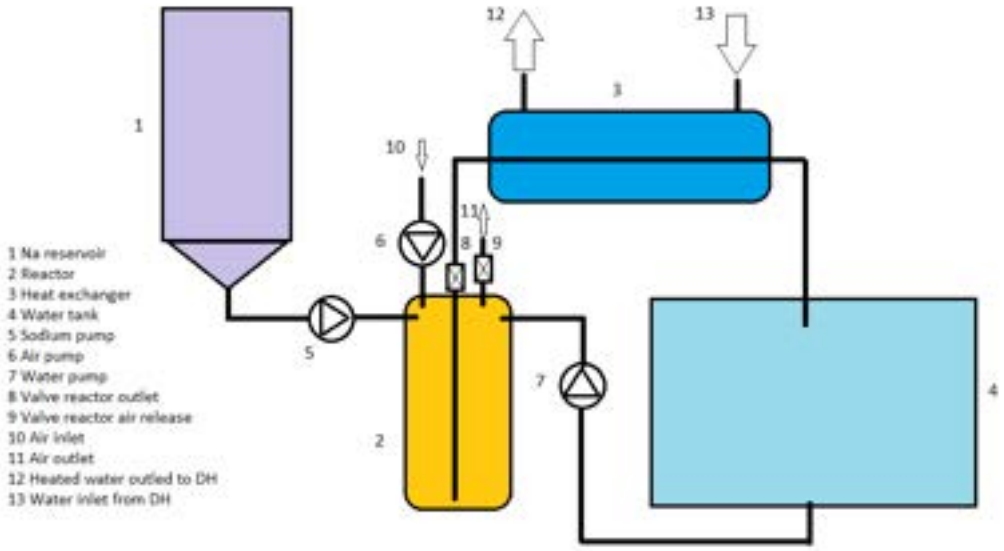

Figure 4: Conceptual design of a simplified process with Na(OH) solution recirculation

Pressure is one of the main parameters to avoid water vaporization from the reactor. The pressure into the reactor and the product and reactant loops will depend on the temperature that is intented to reach. In this case, we have fixed a pressure of 10 bar, providing a balanced between losses by water vaporization, compressor consumption and material requirements. For 10 bar, the outlet tempetature from the reactor has been set at 140 ºC, adjusting the reactants mass flow (water and sodium) to control the heat that is produced in the mixture. Water excess defined as the ratio of total water to the reactor respect to the stechiometric water of the reaction is 62. Water inyection allows the control of the temperature into the reactor preventing overheating.

The total efficiency of the facility is defined from the heat power to the district heating (Q_{DH}), the total heating value of the complete oxidation of sodium (including hydrogen combustion, HV_{tot}) and the auxiliary electric consumption (compressor, pumps,) (P_{aux}):

$$\eta = \frac{Q_{DH}}{HV_{tot} + P_{aux}} = \frac{14093kW}{14206kW + 551kW} = 0.95 \quad (8)$$

The mass balance of the facility is descibed in table 3, with the temperature and pressure of each main stream. The main process data for the facility are sumarised in table 4.

Table 3: Main process mass balance datasheet

Stream	massflow (kg/s)	T (^{o}C)	P (bar)
Fresh water	0,8	15	1
Pure water from ROTS	50.1	80	10
Aire	1. 513	15	1

Water pump	0.95	$8.2 \cdot 10^{-4}$
Heaters	6035	0.52
Heat power to DH (Q_{DH})	13540	-
Thermal losses APS	245.3	0.02

5. Conclusions

There is a need for disrupting technologies that could deiversify the available tools to tackle the enormeous challenge of the global climatic crisis. There is a general consensus about the need to shift from a fossil-based society to a more sustainable system that could be more integrated into the natural mass and energy balance of the Earth, reducing as much as possible the impact of the current human activity. That transformation should find alternatives to carry out succesfully such deep systemic changes. Some technologies are on the table. In paricular renewable based primary sources as wind and solar are having every year a more important role. Nevertheless, additional technologies are needed to complement and be added to those sources to solve some of theur limitations as management capacity, inttermitency and storage.

The utilization of sodium as energy vector has been scarcely developed. In this communication we have described how sodium may be considered as an energy vector, with storage capacity and potential of application to end users. In this case, we introduce a district heating (that may be extended to cooling) facility that provides heated water with a reasonable efficiency (95 %), comparable with existing boilers, with storage capacity if a sodium electrolytic section is added. In that case, a circular operation Na-Na(OH) will have a potential efficiency very similar with other Power-to-Heat or Power-to-Power storage technologies, as thermal storage, Carnot batteries [15] and better than electrolitic hydrogen (electrolyser-fuel cell combination, Power-to-Heat) [14]. Heat pumps offers as well a good solution to impove efficiency of district heating solutions depending on the ΔT that they should provide, with Coefficients of Performance (COP) between 3 and 5, but must add as well Power-to-Power energy storage to integrate energy management cost.

The description of the facility includes a definition of the process with its functional blocks, as well as the mass and energy balance, to process 1 kg/s of sodium, estimating the water excess that should be needed to keep the temperature and pressure conditions to reasonable thermal losses and auxiliary energy consumption.

Further work will apply a complete parametric analysys of the facility design to optimize efficiency and describe more in detail the facility to operate to use surplus renewable electricity production for heating delivery, adding management and storage capacity to decarbonised electric grid, and coupling electric and thermal networks. A lot of work should be done to evaluate the application of this technology to low/medium temperature applications as district heating, as well as high temperature application including thermal conversion to power.

Acknowledgments

This work does not received any funding, but it has been developed thanks to the effort of staff involved in the PhD program of sustainable energy, nuclear and renewable of the UPM, for the PhD thesis of Juan Guerrero Padrón.

Nomenclature

n_e: Electrons involved in the redox reaction.

E_0: Standard electrochemical potential (V)

G_0: Gibbs energy in standard conditions (MJ/kg)

$h_{fg,NaCl}$: Latent heat of NaCl

Q_{DH}: Heat power to the district heating (kW)

HV_{SWR}: Heating value of the reaction (kW)

Q_{aux}: Auxiliary heating power in the process (kW)

P_{aux}: Electric power consumption in the process. (kW)

WFS: Water feed system

SFS: Sodium feed system

SWR: Sodium-water reactor

HDH: Heat exchange to District Heating System

ROTS: Reactor outflow treatment system

APS: Air Purge System

Abstract:

This article describes thermal flexibility of building methods at a district level considering different level of details of building models, illustrated by a case study in a newly built district in Grenoble. Heat represents a huge part of final consumption (81% for the residential sector, 60% for the industry), so district heat networks represents a major action lever towards energy transition. In previous work, a mix thermal and electric architecture has been designed and described at district level. This architecture has been upgraded to simulate the thermal building flexibility and integrate model-predictive controllers. Therefore, this upgrade considers a tool for co-simulation between an optimization problem modeler and several simulation models (an electric model and a set of models for the thermal simulation). On the optimization side, we considered one to eight buildings to be flexible in the district, and assess the impact of its flexibility on the system. A refinement of their flexibility potential is one difficult key aspect of this study, considering a complex multi-vector MILP model. The calibration process has been developed in order to identify the optimization model of this flexible equivalent building. On the simulation side, the simulation models are divided into: the production, the heat network, the heat distribution at building level and the building.

Keywords:

Thermal Flexibility, Multi-vector energy, district scale, Co-simulation, MPC.

1. Introduction

In a context of climate change, research in the efficient energy management field have greatly improved.

Complexity in the energy network have raised by including more and more renewable energies at a local scale [1], a deeper coupling between different energy vectors [2] and a multiplicity of storage system [3]. Aiming a reduction of the carbon emission, building, especially residential building, represent a massive impact as a third of the global energy consumption and a quarter of the carbon emissions [4]. To tackle this factual state according to the energy context, researchers are currently studying a new approach considering the building as a flexible element in energy systems.

2. State of the art

Considering its thermal inertia, building can be a flexibility tool in the same way as Electrical Vehicles in the control strategy at district scale. Its impact grew by considering coupling network such as thermal-electrical coupling. In order to integrate flexibility of buildings, solutions such as cosimulation ([5], [7], [8]) or aggregation ([6], [8], [11], [12]) have been explored. The main issue is the complexity of the model that can be:

- Physical model, with different levels of complexity ([5], [6], [7], [10], [11], [12])
- Data-based model driven from physical simulation ([8], [9])

Considering the aggregated approach, despite solid results and processes, it seems lacking some level of fineness in the study of flexibility of each building at district scale. On the cosimulation side, a classic control is applied which have proven its robustness but is not perfectly adapted to flexibility.

Thus, in this article, we propose to study the impact of thermal flexibility of building at district scale, with an individual approach for building simulation. We enhance a cosimulation process including Model Predictive Control (MPC) [13] in the loop in order to take benefit from the flexibility approach.

First, we present the main tool and method included in the cosimulation approach carried by the cosimulation engine PEGASE. Then, we present the theoretical aspects of the multi-vector cosimulation via the thermal models, the electrical models and the Mixed Integer Linear Programing (MILP) model used to determine the

optimised control strategy. Finally, we present a use case based on a real district Cambridge in which we study the impact of thermal flexibility from none to ten building.

3. Tools and methods

In this section, we present the methods and tools used in our work.

This work focuses on the management of district energy systems providing electricity and heat (Domestic Hot Water DHW and Space Heating SH) through a coupling between electric and heat network including renewable energy and storage.

3.1. Multi-Energy Networks Case Study

To illustrate our approach, we use a district-scale multi-energy network case study presented in previous works ([13], [14], [15]). This case study is inspired from the Cambridge district, based in Grenoble: it takes into account the electric, space heating (SH) and domestic hot water (DHW) needs of the buildings, and the objective is to satisfy them is an optimal way using a combination of renewable energy sources, storage and district heat network and the power distribution grid. Table 1 recalls some of the energy systems considered. A more detailed description of the case study can be found especially in [15].

Table 1. List of the energy system considered in this work.

Production	Storage	Loads
Photovoltaic panels	Battery	Electric loads from building
Cogeneration	Thermal Energy Storage	Heat loads
Heat pumps	Fuel cells	DHW consumption
Solar panels	Electric Vehicles	
Gas Boiler		

In the current work, we especially study the impact of thermal flexibility at building level on the energy management at district level.

3.2. Co-simulation and Model-Predictive Control Approach

In order to account for the dynamic behaviour and complex control of such a multi-energy coupled system, we use a co-simulation and model-predictive control (MPC) approach. More precisely, we use the PEGASE tool [15] to couple an optimisation model with several dynamic simulation models it controls. Thanks to the cosimulation process, a complex multi-vector system at district scale can be scattered into several subsystems, for which specific software are chosen.

Figure 2 shows the overall process and presents the main components involved:

- A model of the electric distribution network (“Electric Model”), including photovoltaic (PV) production and electricity storage
- Three thermal models, for the District Heating production systems (“DHN Model”, standing for District Heating Network model), for the buildings (“Building Model”) and for the internal heat distribution in the building (“HDC Model”, standing for Heat Distribution Circuit).
- An optimisation model, based on the Mixed Integer Linear Programming (MILP) formalism (“MILP Problem Solver”)

All dynamic simulation models are encapsulated using the standard Functional Mock-up Interface. To perform the MPC process, the MILP problem is solved recursively with a rolling horizon, using a commercially available MILP solver (see [15] for details).

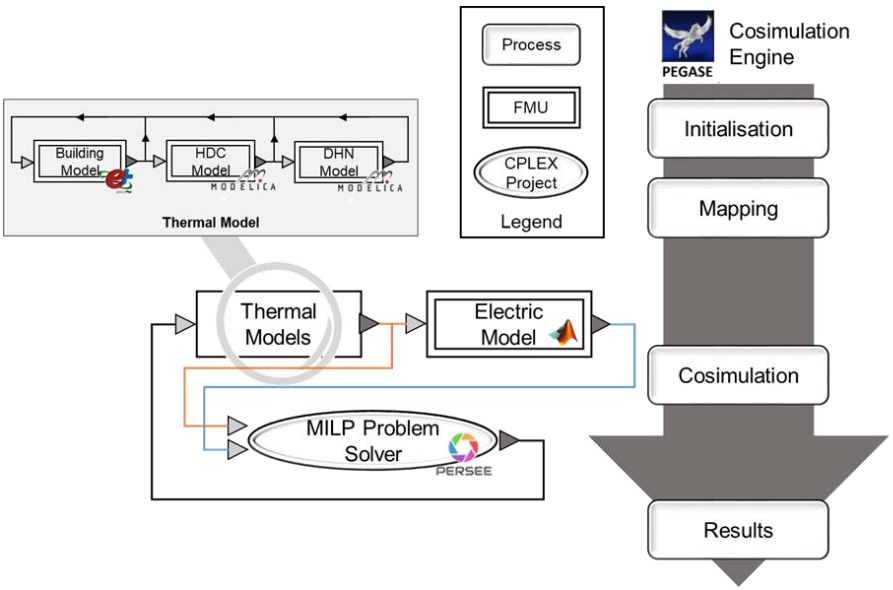

Figure 1. General principles of co-simulation driven multi-vector energy management. (Source: Authors)

3.3. Dynamic simulation models

This section describes more in details the dynamic simulation models used in the case study. It should be noted that these models are designed in a rather generic way, with parameters adapted to the case study. Also, the use of the co-simulation approach and FMI standard enables using the most adapted software to design each of them.

3.3.1. District-scale electric distribution network

This model is presented more in details in [14]. The electric network is scattered into subsystems such as:

- Building electric load using precalculated timeseries
- PV plants using solar irradiation and exterior temperature timeseries in order to provide their electricity production at each time step
- Electrical storage considering an electrochemical model and an inverter model
- Electrical grid consisting of a power balance of all components.

This model is implement using Matlab-Simulink [16] with a library of specific models dedicated to electric smart grid simulation.

3.3.2. District-scale heat production systems

Figure 2 from Rava et al. [14] describes the thermal model included into this work. This model is composed of four different type of energy systems:

- Controllable generators (P_i) such as cogeneration or heat pump
- Non-controllable generators (R_j) such as solar thermal field
- Storages (S_k) such as heat storage
- Load-tracking generator (LT) such as a gas boiler

In this model, the boundary conditions are the global heat set point imposed to generators by the controller (Q_{DHN}), and the inlet temperature (Tr_{DHN}) on the inlet side and the outlet temperature (Td_{DHN}). We consider a constant flow rate ($\dot{m}_{DHN}$)

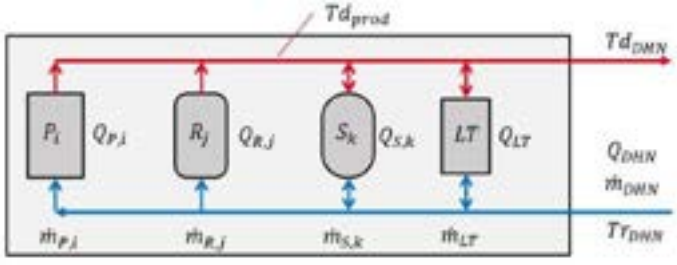

Figure 2. Schematic representation of the model of the thermal network production plant. (Source [14])

This model is implemented using Modelica [17], an object-oriented simulation tool that can simulate a various kind of thermo-dynamics simulation.

3.3.3. Buildings

Dynamic models are developed to represent several buildings of the district. Each building is considered as one thermal node. Given the footprint, the number of levels, the number of apartments and a global window area ratio of a building:

- The thermal zone is extruded from the footprint up to the total height of the building (3m by level)
- External surfaces are composed of layers with respect of typical thermal resistance values for French
- Building (typology LC24 in the PROFEEL project methodology)
    - Vertical surface : 5.3m².K/W;
    - Floor : 4.6m².K/W;
    - Ceiling : 6.5m².K/W;
- A global double glazing window is considered on each external surface with respect to the window ratio of the external surface;
- The 2012 French Thermal Regulation internal gains scenario, calculated according to the number of person in the building, is considered to reproduce the presence of inhabitants and their occupations;
- The air of the building is renewed considering air infiltration (1.2m3/h/m² @4Pa) and mechanical ventilation (0.3Vol/h).

Building simulations are carried out with the EnergyPlus software. EnergyPlus [17] is a validated and physicsbased Building Energy Simulation (BES) program used worldwide by researches, engineers and architects, and is developed by US Department of Energy. EnergyPlus building models are exported as FMUs using the energyplus-fmus export tool, considering the heat supplied by heat emitters as input, and the air, operative and ambient temperature as outputs.

3.3.4. Heat Distribution Circuit (HDC)

Since previous work [20] illustrated the impact of the thermal inertia of heat distribution circuits on flexible building control strategies, we included a detailed heat distribution circuit for each building in our simulation. Figure 3 represents the model of the secondary heat loop for each building.

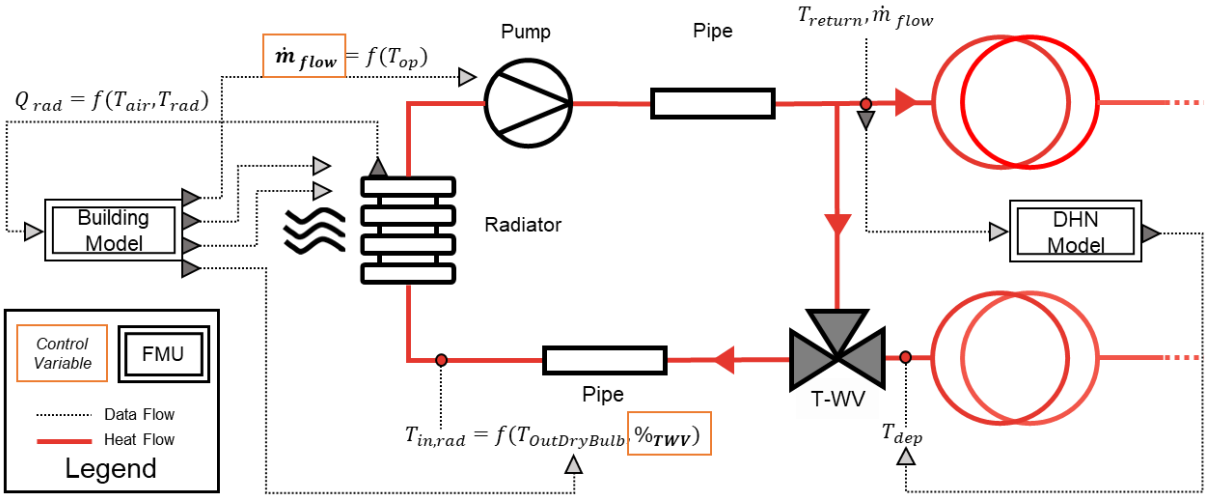

Figure 3. Schematic representation of the Heat Distribution Circuit model and its interaction with other models. (Source: Authors)

The model simulates the inertia of the distribution circuit and controls the building model temperature. It is composed of:

- A radiator providing heat to the thermal zone of the corresponding building (Q_{rad})
- A pump providing the proper flow rate (m_{flow}) to ensure the set point temperature
- A three-way valve (T_WV) used in order to control the input temperature of the radiator ($T_{in,rad}$) according to a heating law based on the outdoor temperature ($T_{OutDryBuld}$).
- Two pipes (after the valve and before the return loop) which simulate the inertia of the distribution circuit.

In addition, it takes into account the meta-control coming from the MILP model. Thus, a maximal value of heat is set to limit the heat provided to the building model according to the control strategy determine by the MILP model on the horizon.

3.4. Optimisation models for Model-Predictive Control

A Mixed Integer Linear Programming (MILP) model is used to compute an optimised strategy of control considering the overall multi-vector system. The MILP model is built using the in-house Persee software [20], which provides building blocks for multi-energy systems similarly to other tools, e.g. OmegAlpes [21].

3.4.1. MILP model for the Multi-energy networks

Figure 4 gives an overview of the MILP model of a multi-vector system based on previous work [15, 16].

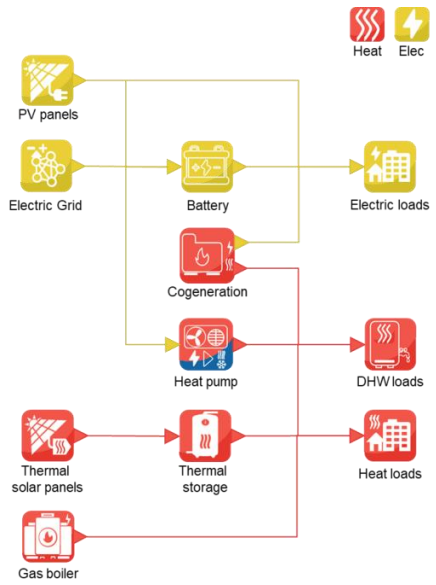

Figure 4. Design of an example of a complex multi-vector optimisation model at district scale. (Source: Authors)

The specificities of PERSEE enable the multi-vector modeling with complex system, including renewable energies. Using the model depicted by Figure 4 as an example, there are two energy vector:

- **Heat vector**
  - Production side
    - Thermal solar panels models: imposed thermal power injection into the system between min and max forecast time series
    - Gas boiler model: Thermal production from fuel gas into thermal
  - Storage side
    - Thermal storage: Storage model as a water tank considering energy power ○ Consumption side
    - Heat needs: imposed heat extraction from a pre-existing heat profile
    - DHW needs: imposed DHW extraction from a pre-existing DHW profile
- **Electric vector**
  - Production side
    - PV panels: imposed electrical power injection into the system, between min and max forecast time series
    - National electrical grid: computed flow injection or extraction to real or fictive grid
  - Storage side
    - Electro-chemical storage: batteries tank model with power map limitation
  - Consumption side
    - Electrical needs: imposed electric extraction from a pre-existing electric need profile
- **Coupling elements**
  - Heat pump: heat pump model consuming electricity to produce Heat and possible Cold
  - Cogeneration: thermal production from 3 input flows with optional electrical cogeneration

3.4.2. Flexible MILP model for flexible buildings

Figure 5 represents the building flexible MILP model implemented in PERSEE from previous work by Aoun et al. [22].

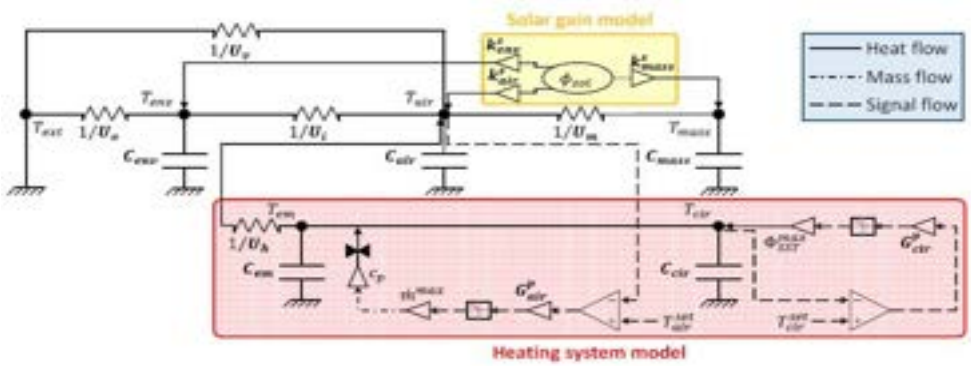

Figure 5. RC Model from which the building flexible MILP Model is inspired. (Source [24]) This model consists in the set of constraints and objective as follow (1):

$$min(dt^h.\sum_{t\in T}[c_T.\Phi_t + \Phi^{max}.c^{mean}.\Delta T_t + \lambda^{losses}.\Phi^{max}.c^{mean}.(T_t^{cir} - T_t^{air})])$$

$$\begin{cases} C^{air}.\frac{dT^{air}}{dt^s} = U_{air}^{ext}.(T_t^{ext} - T_t^{air}) + U_{air}^{env}.(T_t^{env} - T_t^{air}) + U_{air}^{mas}.(T_t^{mas} - T_t^{air}) + U_{air}^{em}.(T_t^{em} - T_t^{air}) + K_{air}.I_t^{sol} \\ C^{env}.\frac{dT^{env}}{dt^s} = U_{env}^{ext}.(T_t^{ext}(t) - T_t^{env}) + U_{air}^{env}.(T_t^{air} - T_t^{env}) + K_{env}.I_t^{sol} \\ C^{mas}.\frac{dT^{mas}}{dt^s} = U_{air}^{mass}.\left(T_t^{air} - T_t^{mas}(t)\right) + K_{mass}.I_t^{sol} \\ C^{em}.\frac{dT^{em}}{dt^s} = U_{air}^{em}.\left(T_t^{air} - T_t^{em}(t)\right) + \Psi_t \\ C^{cir}.\frac{dT^{cir}}{dt^s} = \eta^{cir}.\Phi_t - \Psi_t \\ \Psi_t \le m^{max}.cp.(T_t^{em}(t) - T_t^{cir}) \end{cases} \quad (1)$$

In this model, two distinct parts are considered:

- The building part where the air (T_{air} for the air temperature, C_{air} for the air capacity and K_{air} for the air solar gain factor), the building envelope (T_{env}, C_{env} and K_{env}), and the thermal mass of the building (T_{mas}, C_{mas} and K_{mas}) are modelled. The interactions between those thermal nodes and with the outdoor are taken into account with the thermal inductances (exterior/air (U_{air}^{ext}), envelope/air (U_{air}^{env}), mass/air (U_{air}^{mas})).
- The HDC part where the circuit (T_{cir} for the inlet circuit temperature, C_{cir} for the circuit capacity) and the emitter (T_{em} and C_{em}) are modelled, considering their interaction with the air via the emitter (U_{air}^{em}).

Φ_t represents the boundary condition with the heat transferred by the primary loop of the HDN and Ψ_t represents the heat transfer between the emitter and the circuit.

3.5. Calibration of the MILP model for Flexible buildings

Calibration of building model is a complex process. In this work, the MILP model needs to be calibrated to have similar thermal inertia as its EnergyPlus twin.

Figure 6 depicts the process of calibration applied on this study.

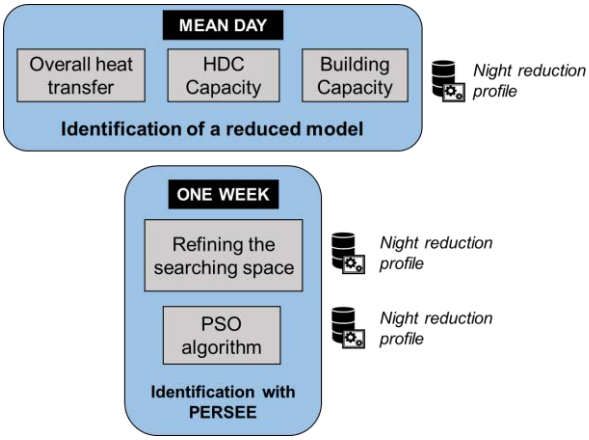

Figure 6. Process for calibration of optimization building model for flexibility (Source: Authors)

This calibration consists in two phases with two options for the second phase.

3.5.1. Phase one: initial parameters estimation

Figure 7 depicts the reduced model used in the phase one of calibration

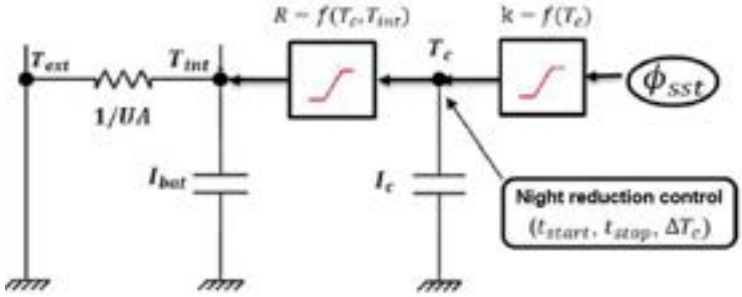

Figure 7. Reduced model used in the first phase of calibration process (Source: CEA)

This phase consists in the identification of the thermal parameter of the building considering this reduced model using a heat profile with night reduction as an input:

- The overall heat transfer coefficient of the building: determined in the night period following an empiric relation between this heat transfer coefficient and the difference between the indoor temperature and the outdoor temperature.

$$QHeat = UA.\,(Tindoor - Toutdoor) \tag{2}$$

- The total building capacity: determined using an empiric relation between the morning peak ($Q_{morning}$ when the setpoint passes from the night to the day mode) and the descending phase of the evening peak ($Q_{down,ve}$ when the setpoint temperature passes from the day to the night mode) and night and day setpoint temperatures (respectively T_{night} and T_{day}).

$$C_{building} = \frac{Q_{morning} - Q_{down,eve}}{T_{day} - T_{night}} \tag{3}$$

- The heat distribution circuit (HDC) capacity: determined by using an empiric linear relation with the descending phase of the evening peak.

$$C_{HDC} = \frac{Q_{down,eve}}{15} \tag{4}$$

- The solar coefficient aperture: determined by evaluating the total energy gain of the building during the solar period. Then, solar gain are obtained by subtracting the total energy the emitter heat and the internal gain from energy plus simulation.

$$K_{Building} = \frac{\mathrm{UA.(Tindoor - Toutdoor) - Q_{int} - Q_{heat}}}{\mathrm{Irr}} \tag{5}$$

The parameter of the reduced model are then used in order to give a first-phase value (FPV) for each parameter of the PERSEE building model. The table 2 details their relation:

Table 2. List of the energy system considered in this work.

Persee parameter	Relation with reduced model parameters
C^{air}, C^{env}, C^{mas}	$\frac{C_{building}}{3}$
C^{cir}, C^{em}	$\frac{C_{HDC}}{2}$
U_{air}^{ext}, U_{air}^{env}, U_{env}^{ext}, U_{air}^{mas}	$\eta_{Uxxx} * \mathrm{UA}$
K^{air}, K^{env}, K^{mas}	$\eta_K^{xxx} * \mathrm{K_{building}}$
U_{air}^{em}	$(\frac{\Phi_{heat}^{nom}}{\Delta T_{nom}})^{1.33}$ and $\Delta T_{nom} = \frac{\mathrm{T}_{out,nom}^{em} + \mathrm{T}_{out,nom}^{em}}{2} - T_{setpoint}^{air}$

η_{Uxxx} and η_K^{xxx} are extrapolating from the Building 2022 parameter in Table 2 of [24].

3.5.2. Phase two: refined parameter estimation

In order to refine the estimation of parameters, we use a Particle-Swarm Optimisation (PSO [23]) algorithm to identify the parameters using the MILP model for calibration. For a calibration assessment purpose, we choose a specific indicator, based on the root-mean-square error (RMSE) between observed and measured air temperature profiles and observed and measured heat profiles:

$$RMSE = \frac{rmse_{heat} + rmse_{temp}}{2}$$

$$rmse_{heat} = \frac{t_f}{\Delta t}\sqrt{\sum_{0}^{t_f} \frac{(\hat{\Phi}_{heat} - \Phi_{heat})^2}{max(\hat{\Phi}_{heat} - \Phi_{heat})}}$$

$$rmse_{temp} = \frac{t_f}{\Delta t}\sqrt{\sum_{0}^{t_f} \frac{(\hat{T}_{air} - T_{air})^2}{max(\hat{T}_{air} - T_{air})}}$$

The calibration with the MILP model in the loop consist in two steps. Figure 8 details the first step.

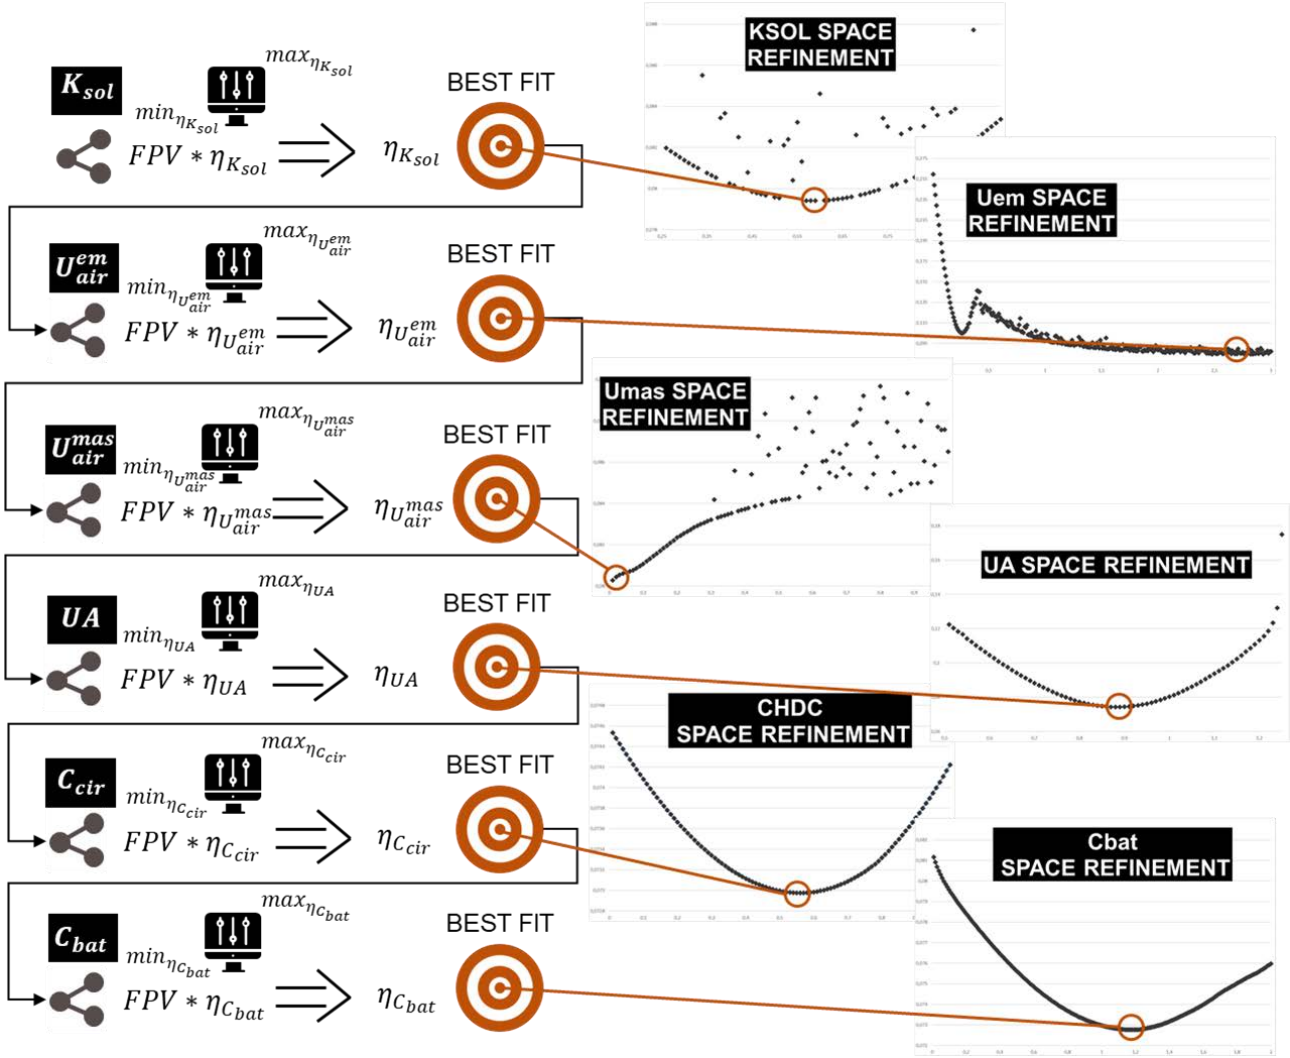

Figure 8. Heuristic method for refining the search step (Source: Authors)

At this stage, we aim to refine the search space for each parameter of the Persee model. The parameters are aggregated by their specificities as follow:

- Solar aperture coefficients (K^{air}, K^{env}, K^{mas}) are aggregated within K_{sol}
- U^{em}_{air} and U^{mas}_{air} are treated individually because of the specificity of their extrapolation.
- U^{ext}_{air}, U^{env}_{air}, U^{ext}_{env} are aggregated within UA
- C^{cir}, C^{em} are aggregated within C_{HDC}
- C^{air}, C^{env}, C^{mas} are aggregated within C_{bat}

Beforehand, the order of this heuristic algorithm has no importance, except for the solar aperture coefficient. Thus the error defers from the one from (6) by considering the RMS only during solar period. At each stage, the best-fit coefficient is selected from the assessment sample. This assessment sample is defined around the FPV. A discretization of the sample enables to assess 100 to 300 assessment in which we keep the value with the lowest RMSE. In the end, a new set of refined parameter is determined using their corresponding best-fit coefficient and their FPV.

4. Results

4.1. Simulation Hypothesis

- **Optimisation**: Considering the optimisation part, we consider a constraint in CO2 emission rate at district level of 20000kg and an economic objective function. The feed-in-tariffs of electricity consists in a conditioned one to day-and-night time slots.
- **MPC and cosimulation**: The horizon of the MPC, the time slots within the optimisation runs, is a 36 hours period. Both optimisation and simulation considers a 1 hour time step. Then, the co-simulation runs with a timeshift of 1 hours meaning that the control strategy is recalculated every timestep. The cosimulation runs during 60 days.
- **Thermal production**: On the thermal model part, the impact of the flexible building on its flowrate is neglected. We consider it as a constant value. The overall district heat production is adapted by considering the building flexible integrated in the district. The heat profile of each flexible building is subtracted from the district heat profile.
- **Building model**: At our current state of work, we consider a monozone building model and HDC model. Considering multi-zone building model in order to evaluate its effect on the calibration and flexibility is a perspective for further studies. 8 building on the 13 are modelled.
- **Calibration**: The full calibration process is set for five buildings; the first heuristic results are applied on others.

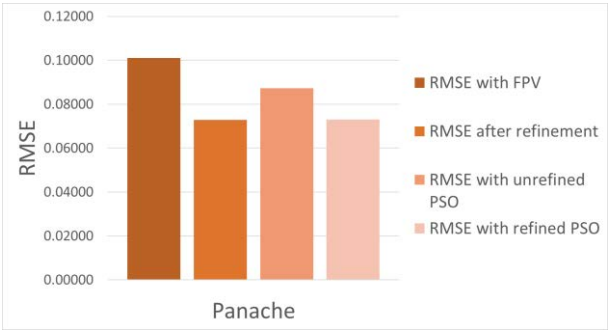
4.2. Calibration Results

For this case study, we applied the full calibration process presented in section 3.5. for the five main buildings. For the three last, the process end at the heuristic step of the second phase. In order to evaluate the calibration performances, the table 3 records the RMS for each building at each stage, in addition with a test of the performance of PSO algorithm using the unrefined search space. Considering the two PSO, we defined their search space giving the same minimal and maximal coefficient.

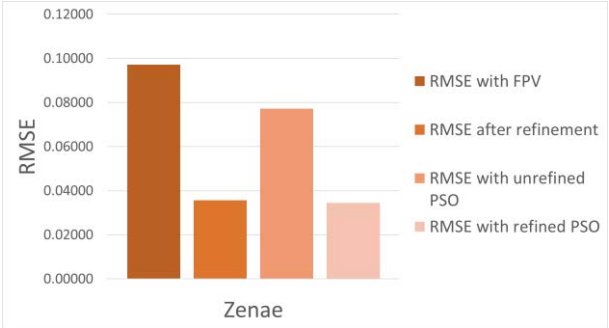
Table 3. Recording of RMS during the calibration process.

Buildings	RMSE with FPV	RMSE after refinement	RMSE with unrefined PSO	RMSE with refined PSO
CastelO	0.09359	0.06114	0.08039	0.06089
Panache	0.10103	0.07276	0.08729	0.07303
Python	0.07741	0.03935	0.06536	0.03924
Up	0.11137	0.09039	0.09707	0.0857
Zenae	0.09712	0.03566	0.07720	0.03453
Novae	0.05511	0.03210	-	-
Thales	0.07851	0.03514	-	-
Soleil	0.06842	0.06130	-	-

Figure 9 focuses on the two extreme buildings



(a)



(b)

Figure 9. Focus on two buildings a) building obtaining the worst amelioration with refining b) building obtaining the best amelioration with refining (Source: Authors)

At this stage, the refining seems to have a positive effect on the global error, considering the chosen indicator. At best case, the amelioration is around 60% from the first phase calibration with a mean value of 38% with the heuristic algorithm and 40% with refined PSO. The worst case is interesting because the PSO algorithm have found a slightly less performant set of parameter than the heuristic algorithm. Moreover, the gain from PSO is a mean of two point compared to the heuristic. Two possibilities can explain this fact. Firstly, the heuristic algorithm differs from the PSO on the solar aperture assessment. Indeed, for the heuristic algorithm, we have chosen to evaluate only the solar timeslots as those coefficients have no effect without solar irradiation on the model. Secondly, we have neglected a proper study on the configuration of the PSO, which could lead to underestimated performances. Section 4. Presents areas of improvement considering the calibration phase.

4.3. Co-simulation results

The main difficulty for the MILP model is to determine the flexibility coefficient for each flexible building model. This coefficient is set first using a standalone optimisation on the horizon time. Figure 10 shows the result for the chosen flexibility coefficient.

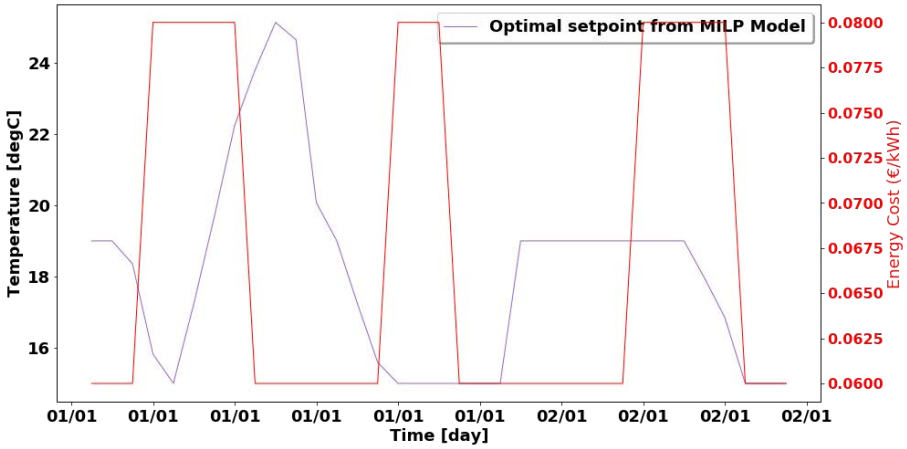


Figure 10. Optimal Air temperature from MILP Model on the horizon time (Source: Authors)

The multi-vector system is quite complex, leading to a difficulty to find a satisfying value for this coefficient. We applied this flexibility coefficient for the co-simulation. To give an idea of time solving for one building, a co-simulation with one building takes 8 minutes to run and 23 minutes with 8 buildings

Figure 11 shows the results concerning the co-simulation for one building.

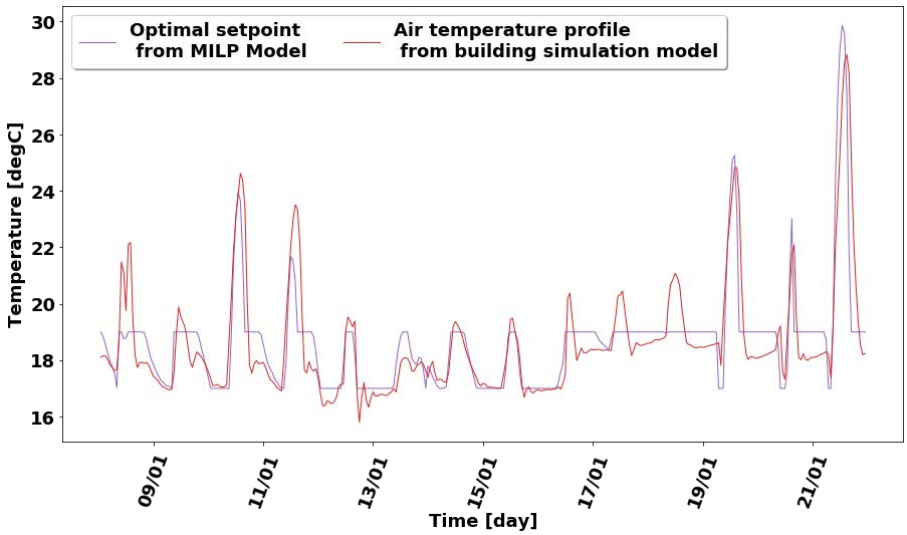

Figure 11. Set point temperature from MILP model profile and air temperature profile from building model (Source: Authors)

At this stage, we can obtain an effect on the temperature set point of EnergyPlus building model. However, those results aren't satisfying enough for one building and are the same kind for eight buildings. Further improvements would be necessary to obtain solid results at district scale.

5. Conclusion

This article presents a co-simulation procedure in order to process a flexibility assessment building by building. This co-simulation embeds an electric simulation model, a thermal model composed of a thermal production model, a heat distribution circuit model and a building model and a MILP model optimizer ensures MPC. The first aim is to calibrate the building models in order to implement them for co-simulation. A proper calibration procedure has been implemented with a satisfactory accuracy. Then we could test the co-simulation from one to eight buildings at district scale.

For future work, the calibration process could be improved by assess the configuration of the PSO algorithm on the one hand. On the other hand, the PSO process could be improved by splitting the search of solar aperture coefficients from the other parameters. In doing so, we could hope obtaining better results for calibration. Then, a better training phase could be implemented to refine the calibration process. On the co-simulation side, we would have to improve the flexibility coefficient study in order to find a procedure to set it. Another option that we would like to study is to reduce the time step from one hour to 10 minutes. Indeed, as we obtain decent computing time, this seems to be feasible. Reducing the time step of co-simulation could improve the sensitivity of the flexible building model and help to find a better flexibility coefficient.

Abstract:
Buildings contribute to approximately 30 % of global energy consumption, which renders their energy-efficient control an effective measure to reduce overall energy consumption. This paper presents a hierarchical distributed Model Predictive Control (MPC) for building energy systems based on nonlinear Modelica controller models. It combines hierarchical and distributed optimization approaches to split the optimization complexity within the temporal and spatial dimension. The hierarchical optimization approach considers different dynamics in complex building energy systems and ensures both anticipation for systems with high inertia and reactivity with regard to errors in the forecasting of the disturbance quantities. The distributed optimization approach divides the centralized optimization problem into subproblems to improve the scalability and adaptability of the control framework. The subproblems are solved in a parallel and iterative manner and account for both thermal (heat transfer over zone boundaries) and hydraulic inter-zone coupling (induced by a central, shared Heating, Ventilation and Air Conditioning (HVAC) system). A particular focus of the control approach is placed on robustness with respect to errors in the forecasting of the disturbances that impact the building dynamics. The control performance of the proposed MPC framework is evaluated in a simulative case study of heating and shading control of a nonlinear six-room-building Modelica model, which is exposed to different forecast accuracies for the disturbances of occupancy, solar radiation and air exchange. The case study exhibits the benefits of the control framework in terms of energy consumption, thermal discomfort and computation time in comparison to a reference control concept of a non-hierarchical distributed MPC configuration.

Keywords:
Distributed MPC; Hierarchical MPC; HVAC; Model Predictive Control (MPC); Modelica.

1. Introduction

Approximately 30 % of global energy consumption and 27 % of CO_2 emissions are attributed to the building sector [1]. Heating, Ventilation and Air Conditioning (HVAC) systems contribute to a major extent to building energy consumption [2] and therefore, offer a large potential for an increase in energy efficiency and reduction of energy consumption on a global scale. Currently, conventional control strategies as Rule-Based Control (RBC) or Proportional-Integrative-Differential (PID) controllers are implemented in buildings due to their simplicity and low computational requirements [3]. They represent inflexible and reactive (non-predictive) control approaches that are unable to control inert systems with large time delays, to minimize energy consumption while operating between comfort bounds as well as to consider system or comfort constraints and future disturbances.

Model Predictive Control (MPC) constitutes a promising control approach that addresses the aforementioned challenges and exhibits various benefits and energy savings from 15 to 50 % [4] compared to the conventional control strategies. The central part of an MPC is a model of the building energy system based on which future system behavior is predicted and the building is controlled in an anticipatory manner minimizing a (multi-objective) cost function over a prediction horizon. The predictive characteristic of the control suits inert systems with time delays and integrates future disturbances, e.g., in the form of weather and occupancy forecasts. Apart from this, conflicting optimization goals such as the simultaneous minimization of discomfort and energy consumption as well as system and comfort constraints can be taken into account.

The model generation part is crucial for the implementation of an MPC as it consumes most of the project time and costs [5]. Due to the unique characteristics of every single building, a modeling language has to

be modular and flexible and support the user-friendly generation of (large-scale) building models. The modeling language Modelica [6] complies with these requirements as it supports open-source, equation-based, acausal and object-oriented modeling and is equipped with a user-friendly graphical interface for connecting and parametrizing components. Modelica allows for the collection of building component models in shareable libraries such as the Modelica IBPSA library [7] or extensions building upon this library.

If MPC is applied to large-scale multi-zone buildings, large and computationally complex optimization problems are created, which results in increased computation times. This can also lead to scalability issues when the optimization problems cannot be solved in a suitable time restricting the real-time capability of the control. Distributed MPC approaches tackle these challenges by splitting the central optimization problem into subproblems, which are solved in a distributed manner while accounting for the interactions between the subproblems [8].

On the other hand, buildings generally incorporate components and disturbances of different dynamics and time scales. For example, low-temperature heating and cooling systems based on Thermal Activated Building Systems (TABS) are characterized by a high thermal mass and large time constants requiring a long prediction horizon. They are often complemented by secondary, more reactive actuators such as radiators or convectors, where smaller prediction horizons and control periods are suitable. The simultaneous control of actuators of different time scales and preservation of both anticipation and reactivity poses an additional challenge for the application of MPC in buildings. An approach to tackle this challenge is hierarchical MPC, which splits the optimization problem into layers of different dynamics [8].

Compared to the total number of studies on building MPC, the review of literature for MPC in large-scale buildings exhibits only a relatively small share of distributed optimization approaches. This may be attributed to the nonlinear and nonconvex characteristics of building energy systems that complicate convergence of the distributed optimization approaches [4]. The most widely applied mathematical methods for distributed building MPC are the primal-dual active-set method [9], Benders decomposition [10], dual decomposition [11], information exchange [12], non-iterative look-up tables [13], Nash equilibrium [14, 15] or Alternating Direction Method of Multipliers (ADMM) [16–19]. Among these, Nash equilibrium constitutes an uncooperative, parallel and iterative distributed optimization approach, which builds upon information exchange between subsystems. After every iteration, each subsystem sends and receives updated trajectories for the coupling variables to/from interconnected subsystems and solves its subproblem again. The subsystems converge to a ”Nash equilibrium” if for all subsystems, the local optimization results deviate less than a predefined threshold between two consecutive iterations. Nash equilibrium is applied for considering thermal coupling based on exchanged local temperature trajectories [14] or for taking into account hydraulic control input coupling [15]. ADMM represents a distributed optimization approach with an iterative and cooperative structure, which is carried out mostly in parallel. It is based on the augmented Lagrangian, i.e., the Lagrangian formulation plus an additional quadratic penalty term for improved convergence and robustness compared to dual decomposition. ADMM makes use of two sets of variables, which allows separating the central cost function and coupled dynamics as well as splitting the problem into subproblems. The fulfillment of the coupling constraints between the different variable sets is steered via dual variables penalizing the deviations within the cost functions. ADMM is applied for considering thermal and hydraulic coupling [16], indoor air quality in rooms coupled by a central Air Handling Unit (AHU) [17], maximum constraints on shared resources (e.g., maximum capacity of an AHU) [18] and sharing problems (sum of local control variables is input to the global cost function) [19].

Hierarchical building MPC approaches are applied to split optimization problems into different layers with varying dynamics and time scales, which are controlled based on different prediction horizons and sampling periods. Abreu et al. [20] implement a hierarchical building MPC, which consists of a scheduling layer sending output trajectories and power profiles to the lower layer with a shorter prediction horizon and sampling period. The latter tracks the forwarded output trajectories while taking into account the constraining trajectory of the power profile. Fiorentini et al. [21] implement a hierarchical MPC for the operation of an HVAC system including an AHU coupled to a thermal storage. The upper layer with a longer prediction horizon and sampling period calculates an optimal sequence of discrete operating modes, which are executed by the lower level while tracking a reference temperature sent by the upper level. Long et al. [22] develop a distributed hierarchical MPC controlling a ventilated multi-zone building. An upper centralized layer calculates reference temperature trajectories for a lower layer consisting of several local controllers, which solve their local problems in an isolated, decentralized way based on local information and the upper temperature trajectories to be tracked.

In previous works, the concepts of hierarchical [23] and distributed [24] building MPC based on nonlinear Modelica models have been individually developed. The hierarchical MPC splits the optimization problem into two layers of different dynamics, which are equipped with different prediction horizons and sampling periods to guarantee both anticipation and reactivity. The distributed MPC splits the centralized optimization problem into subproblems and takes into account thermal and hydraulic coupling between building zones using an optimization approach based on Nash equilibrium and ADMM. In this work, the hierarchical and distributed

MPC approach are combined into one MPC framework and applied to a multi-zone building that incorporates actuators of different dynamics. The control quality and the reactivity of the MPC are evaluated for different scenarios of forecasting accuracy for the disturbance quantities. The forecast errors can be regarded as any deviation between the predicted and actual real-world behavior of the building, which are expected to appear in practical MPC implementations. By using the hierarchical distributed MPC approach, the complexity of the original optimization problem is split in both the temporal and spatial dimension. This alleviates modular, local high-accuracy modeling and at the same time, improves the scalability, real-time capability and adaptability of the control approach.

2. Methodology

2.1. Distributed MPC

The methodology for the distributed MPC has been elaborated in [24]. The approach considers both thermal and hydraulic coupling among different building zones and is executed in an iterative and parallel way. It is based on an uncooperative optimization approach for thermal coupling using Nash equilibrium and a cooperative approach for hydraulic coupling using ADMM. A central coordinator updates information and monitors the convergence process of the overall optimization.

The uncooperative Nash optimization regards the room temperatures of neighboring zones as known disturbances and thereby, can calculate the heating flows exchanged over the local zone boundaries. After every optimization iteration, the locally calculated trajectories for the local room temperatures are sent to the coordinator. The coordinator forwards the temperature trajectories to all neighboring zones that are thermally coupled to the corresponding zone and the local optimizations are executed again with updated trajectories for the neighboring room temperatures. The local subproblems converge to the ”Nash equilibrium” if, for all local subsystems, averaged over the MPC horizon, the absolute deviation of the local room temperature trajectories between two consecutive distributed iterations does not deviate more than a prefixed Nash threshold.

The hydraulic coupling comprises interactions between the zones induced by a shared, central HVAC system. In the case study in Section 3., the central HVAC system is constituted by a shared TABS in the form of Concrete Core Activation (CCA) in the floor. TABS builds upon the activation of the thermal mass of a building in the form of the concrete and offers passive storage capacities to shift the time between energy supply and demand. Due to the high inertia of the thermal mass, one TABS/CCA section generally supplies multiple building zones with similar thermal properties, demand or orientation [25], which introduces strong coupling between the rooms. Within the case study, the central CCA consists of six identically dimensioned subsections (one per room) and is controlled via one shared control input that regulates the supply water mass flow supplied to each subsection. The hydraulic coupling is taken into account using a consensus ADMM approach. The optimization problem is decomposed by introducing local copies of the global CCA control input for every subsystem, which are optimized separately. Linear and quadratic ADMM terms are added to the cost functions of both the local subsystems (1) and the coordinator (2) to coordinate the consistency between the local copies and the global CCA control input. The coordinator monitors the convergence of the ADMM applying both a primal and dual residual criterion according to [24, 26].

The communication structure of the overall distributed optimization approach is shown in Fig. 1. In every distributed optimization iteration, the local subproblems (1) are optimized in parallel and the resulting local trajectories for the CCA control input and room temperature are sent to the global coordinator. The global coordinator uses the updated information to optimize the global cost function calculating new trajectories for the global CCA control input (2). In the second step, the dual ADMM variables (Lagrangian multipliers) are updated coordinating the consistency between the global and local copies of the CCA control input (3). The coordinator checks the convergence status for both ADMM and Nash optimization according to the user-specified thresholds. Then it forwards the trajectories for the global CCA control input, dual variables, local room temperatures and the convergence status to the subproblems, which continue the local optimization procedures according to the convergence status. If the subproblems have converged, they send the local control inputs for all actuators to the global coordinator, which converts the local CCA control inputs into an averaged value and runs a simulation over a sampling period (right branch). If the subproblems have not converged and the maximum number of distributed iterations per MPC iteration is not exceeded, the subproblems are solved again based on the new information sent by the global coordinator (left branch).

2.2. Hierarchical MPC

The hierarchical MPC divides the optimized problem within the temporal dimension into two layers of different dynamics and time scales as proposed in [23]. For the upper, slow MPC layer, a longer prediction horizon and sampling period are chosen, whereas for the lower, fast layer, the horizon and sampling period are smaller. Thereby, the slow layer focuses on anticipation of the control, which is specifically suitable for inert systems with time delay (e.g., TABS or thermal storage). Due to the small sampling periods of the fast MPC layer,

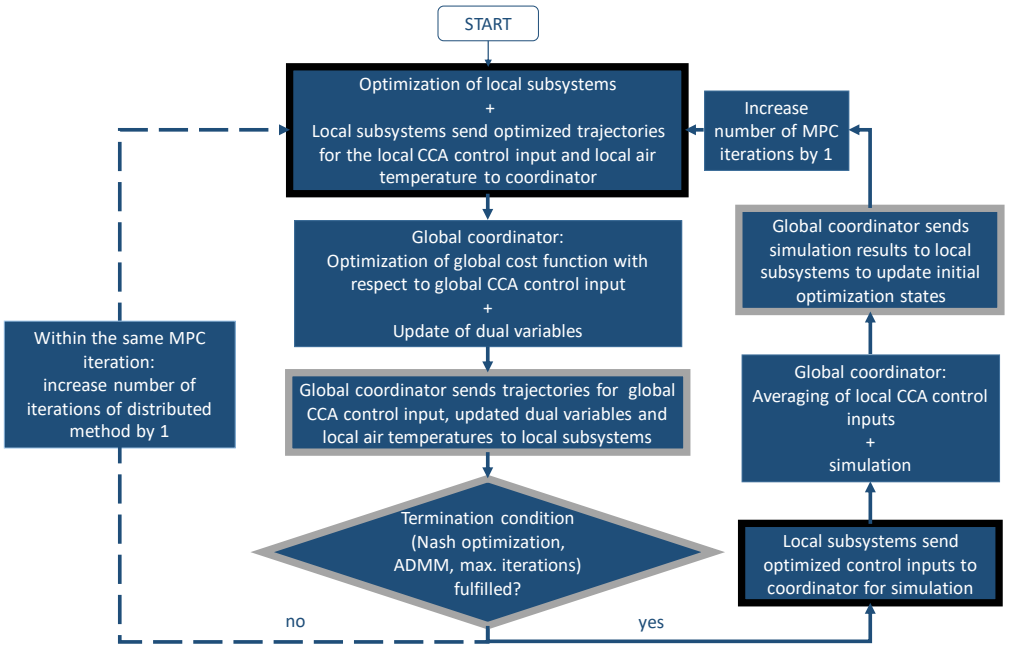

Figure 1: Overall communication structure of the distributed MPC (inputs to local MPC: gray frame, outputs of the local MPCs: black frame)

reactivity with regard to forecasting or unexpected influences can be ensured. The two layers communicate via state reference trajectories that are calculated by the slow layer and are sent to the fast layer to be tracked. Compared to a single MPC layer equipped with a long prediction horizon and small sampling period, the combination of the two layers increases the probability to preserve real-time capability.

2.3. Hierarchical Distributed MPC

The scheme of the aggregated hierarchical distributed MPC toolchain for the six-room-building use case is depicted in Fig. 2. Both the upper and lower hierarchical MPC layer are split into thermal zone subproblems in a distributed way (for each of the six rooms). Within each MPC layer, the subproblems are solved based on the distributed optimization approach based on Nash equilibrium and ADMM. An overall distributed MPC iteration is terminated if, in both the upper and lower MPC layer, the convergence criteria for the Nash equilibrium and ADMM are fulfilled or the maximum number of distributed iterations in one MPC iteration is exceeded. The cost functions of the subproblems in the lower layer contain quadratic tracking terms for the room temperature trajectories $T_{\mathrm{ref,i}}$ calculated by the room equivalent on the upper layer. The reference trajectories are recalculated in every distributed iteration of the upper MPC layer and the updated trajectories are forwarded to the lower layer. After convergence, the control inputs of the lower MPC layer are applied to the simulation model and based on the simulation results, the optimization states of the next optimization iteration are initialized both in the upper and lower MPC layer.

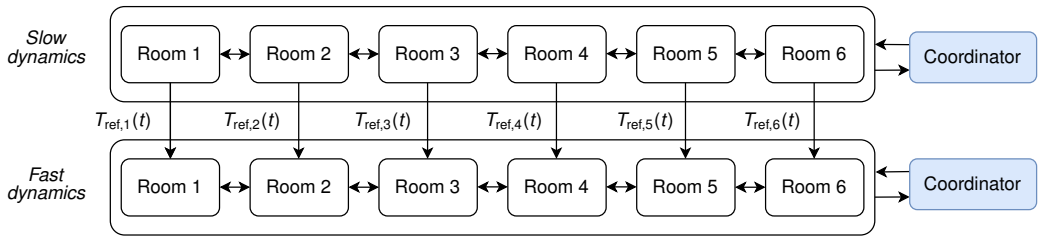

Figure 2: Communication structure of the hierarchical distributed MPC

3. Case study

In a simulative use case, the hierarchical distributed MPC is applied to the six-room-building shown in Fig. 3. The nonlinear model is generated based on the Modelica building simulation library AixLib [27] and comprises rooms that are thermally coupled via inner walls and data-driven models for air flow through doors [24]. All rooms are hydraulically coupled to a central, shared TABS implemented as CCA in the floor, which is operated via a central control input regulating the supply water mass flow. Each room is equipped with an identically

dimensioned CCA subsection, a convector, simplified pumps and an external window including external Venetian blinds for active solar shading [23]. Two pumps per room supply the CCA subsection and the hydraulically uncoupled convector with supply water mass flow rates calculated by the optimization (at fixed supply temperatures).

Control inputs of the subsystems are the local water mass flow rates to the convectors and the vertical position and inclination angle of the Venetian blinds. The shared control input of the central mass flow rate to the CCA applies to all subsystems. For occupant comfort, both thermal and visual comfort (minimum illuminance of 500 lux in occupied times) are considered. During the occupied periods (8 a.m.–12 p.m. and 1–6 p.m.), there is one person in rooms 3 and 5, two persons in rooms 1 and 6 and three persons in rooms 2 and 4. During unoccupied times the thermal comfort ranges are broadened according to a night set-back (occupied times: 293–295.5 K, unoccupied times: 292–296.5 K). Weather data is integrated based on an AixLib resource file of San Francisco, which represents a heating period. No model mismatch between the MPC controller and the simulation model is assumed to focus on the control performance of the hierarchical distributed MPC.

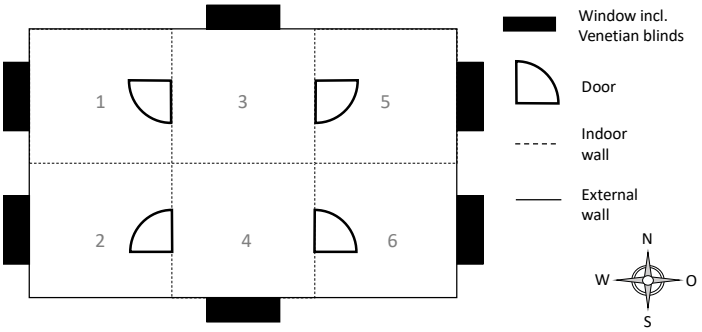

Figure 3: Building structure consisting of six thermal zones

For every subsystem $i \in \mathcal{N}$, the following local optimization problem is solved (for distributed iteration $k + 1$, the last term of the cost function including $T_{\text{ref,i}}$ is omitted for the upper hierarchical layer):

$$\begin{aligned}\{u_{\text{conv},i}, u_{\text{CCA,local},i}, u_{\text{al},i}, u_{\text{posShad},i}, u_{\text{inclAng},i}, \underline{\varepsilon}_i, \bar{\varepsilon}_i\}^{k+1} = \textit{argmin}_{u_{\text{conv},i}, u_{\text{CCA,local},i}, u_{\text{al},i}, u_{\text{posShad},i}, u_{\text{inclAng},i}, \underline{\varepsilon}_i, \bar{\varepsilon}_i} \\ \int_{t_0}^{t_f} [\alpha_{\text{conv}} \cdot u_{\text{conv},i} \cdot (T_{\text{supply,conv},i} - T_{\text{return,conv},i}) + \alpha_{\text{CCA}} \cdot u_{\text{CCA,local},i} \cdot (T_{\text{supply,CCA},i} - T_{\text{return,CCA},i}) + \\ \alpha_{\text{Light}} \cdot u_{\text{al},i} + \theta \cdot (\underline{\varepsilon}_i{}^2 + \bar{\varepsilon}_i^2) + \lambda^k_{\text{Dual,CCA},i} \cdot (u_{\text{CCA,local},i} - u^k_{\text{CCA,global}}) + \rho/2 \cdot (u_{\text{CCA,local},i} - u^k_{\text{CCA,global}})^2 + \\ \gamma \cdot (T_{\text{room,air,i}} - T_{\text{ref,i}})^2] \, dt \end{aligned} \quad (1)$$

The local cost functions (1) consist of the energy consumption of the convector, CCA and artificial lighting as well as discomfort (quadratic penalization of temperatures outside the comfort range through introduced slack variables $\underline{\varepsilon}_i$ and $\bar{\varepsilon}_i$). The terms are complemented by the linear and quadratic ADMM terms taking into account the consensus between the local and global CCA control variables (based on the Lagrangian multipliers $\lambda^k_{\text{Dual,CCA},i}$ and the ADMM penalty parameter ρ). The last term in the cost function applies only to subsystems in the lower hierarchical MPC layer and comprises the quadratic tracking of the reference temperature trajectories $T_{\text{ref,i}}$ sent by the room equivalent on the upper layer (weighted with γ).

$u_{\text{conv},i}$, $u_{\text{CCA,local},i}$, $u_{\text{al},i}$, $u_{\text{posShad},i}$ and $u_{\text{inclAng},i}$ correspond to the local control inputs of the convector and CCA supply water mass flows, artificial lighting, shading position and inclination angle of the Venetian blinds. $T_{\text{room,air},i}$ is the local room air temperature. $T_{\text{supply,conv},i}$, $T_{\text{return,conv},i}$, $T_{\text{supply,CCA},i}$ and $T_{\text{return,CCA},i}$ are the supply and return water temperatures of the convector and CCA. α_{conv} and α_{CCA} are energy weighting factors for the convector and CCA including the heat capacity of water, α_{Light} a weighting factor for the energy consumption of artificial lighting and θ a factor penalizing room temperatures outside the comfort range. The prediction horizon (t_0 - t_f) is 24 h for the upper MPC layer and 8 h for the lower layer, the sampling period is set to 15 min for the upper and to 5 min for the lower layer.

Based on the calculated trajectories for the local room-individual CCA control inputs $u^{k+1}_{\text{CCA,local},i}$ from (1), the global coordinator calculates the global CCA control input $u_{\text{CCA,global}}{}^{k+1}$ for iteration $k + 1$ (2). In the second step, the dual variables (Lagrangian multipliers) $\lambda^{k+1}_{\text{Dual,CCA},i}$ are updated for every zone (3).

$$u_{\text{CCA,global}}^{k+1} = argmin_{u_{\text{CCA,global}}} \int_{t_0}^{t_f} [\sum_{i \in \mathcal{N}} \lambda_{\text{Dual,CCA},i}^{k} \cdot (u_{\text{CCA,local},i}^{k+1} - u_{\text{CCA,global}}) + \rho/2 \cdot (u_{\text{CCA,local},i}^{k+1} - u_{\text{CCA,global}})^2] dt \quad (2)$$

$$\lambda_{\text{Dual,CCA},i}^{k+1} = \lambda_{\text{Dual,CCA},i}^{k} + \rho \cdot (u_{\text{CCA,local},i}^{k+1} - u_{\text{CCA,global}}^{k+1}) \quad (3)$$

The control quality of the implemented hierarchical distributed MPC is evaluated in terms of the following Key Performance Indicators (KPIs): energy consumption (for CCA, convector and artificial lighting; in MJ), thermal discomfort (quantification of room temperatures outside the comfort range; in Kh) as well as total computation time and computational time ratio. The computational time ratio represents the ratio of the total computation time to the simulated control time. A quotient smaller than 1 is equivalent to real-time capability of the control. The performance of the proposed hierarchical distributed MPC is compared to a non-hierarchical distributed equivalent consisting of only one MPC layer with a prediction horizon of 24 h and a sampling period of 15 min.

The control quality of the different control approaches is evaluated for different accuracy scenarios for the disturbance forecasts. In the first scenario, a perfect forecast for the disturbance quantities of occupancy, solar radiation (global horizontal, diffuse horizontal and direct normal) and air exchange rate is assumed. For the second and third scenario, forecast errors are artificially generated according to a normal (Gaussian) distribution, zero mean and varied standard deviations σ (based on the Python package *numpy*). A filter extracts negative values for radiation and occupancy. The occupancy value is rounded to an integer and during unoccupied times, no forecast errors are added to occupancy and solar radiation. The forecast error for occupancy represents a higher/lower number of occupants than forecasted, the error for solar radiation expresses the occurrence of unexpected clouds and the error for the air exchange constitutes higher or lower wind speeds than forecasted, which impact the air exchange of the building with ambient air. In the simulative case study, an old building structure with loose air tightness and high air infiltration with a base air exchange of 2.5 1/h is assumed to generate substantial heat demand and transfer the heat from solar and internal gains. The forecast errors can be considered representative of any deviation between the predicted and the real-world behavior of the buildings, such as errors in weather or occupancy forecasts, model errors or unexpected user influences (e.g., window/door opening or manual heating/shading). The standard deviations determining the dimension of the forecast errors are increased in intervals of 0.5 for occupancy, in intervals of 50 W/m^2 for solar radiation and in intervals of 0.1 1/h for the air exchange. The standard deviations are noted in the following manner: $\sigma = (\sigma_{\text{occupancy}}[-], \sigma_{\text{radiation}}[W/m^2], \sigma_{\text{air exchange}}[1/h])$. The optimizations are executed in JModelica.org 2.14 [28] (using linear HSL solver ma27 [29]) for gradient-based optimization of Modelica models with an interface to IPOPT 3.13.1 [30]. The simulation on the coupled building model has a horizon of 5 days. The optimizations are executed on an OpenStack instance with Ubuntu 18.04, 8 vCPUs and 32 GB RAM.

4. Results

Forecast scenario σ = (0,0,0)

For the perfect forecast scenario, the disturbances of outdoor temperature, solar radiation on each window facade and occupancy are depicted in Fig. 4. The results of the non-hierarchical and the hierarchical distributed MPC are shown in Fig. 5 and Fig. 6. The three last subplots "Actuator mass flow", "Shading position" and "Inclination angle" reveal a more dynamic operation of the control inputs for the hierarchical variant compared to its non-hierarchical equivalent, which is due to the higher temporal resolution and reactivity of the lower layer of the hierarchical MPC. At intervals of 5 min (compared to 15 min for the non-hierarchical variant), the hierarchical MPC receives updated measurements from the building and readjusts the control inputs. Since for the first scenario a perfect forecast is assumed, the local room temperatures in the "Local temperature" subplots resemble each other apart from individual violations at the beginning and end of the simulation horizon. The CCA covers the base load benefiting from a higher energy efficiency due to lower supply temperatures and is preheated to cover the heat demand at a later time, while the convectors are operated in a more reactive manner to cover peak loads. During the periods with heat gains from occupancy and solar radiation, the rooms are operated near the upper temperature bound to reduce heating and lighting energy by actively using the Venetian blinds to limit solar gains. During the non-occupancy periods, the temperatures are kept near the lower bound taking advantage of the night set-back to decrease heating energy consumption. The consumed energy is of a similar magnitude (681 MJ for the non-hierarchical and 683 MJ for the hierarchical variant). The hierarchical MPC can reduce thermal discomfort by 64 % (with 0.72 Kh compared to 1.99 Kh for the non-hierarchical MPC). As exhibited in the "CCA control input" subplot, the hierarchical variant regulates the CCA in a more dynamic manner, which results in the same Mean Average Error (MAE, 0.001 kg/s; averaged over all rooms) but a higher Root Mean Square Error (RMSE) for the ADMM consensus (0.003 kg/s compared to 0.002 kg/s). The computational time ratio of 0.191 for the hierarchical MPC (computation time of 82 359 s) is approximately 3 times higher than the one of 0.060 for the non-hierarchical MPC (computation time of 25 850 s), which is due to the execution of three lower MPC layer instances during one upper MPC layer MPC operation.

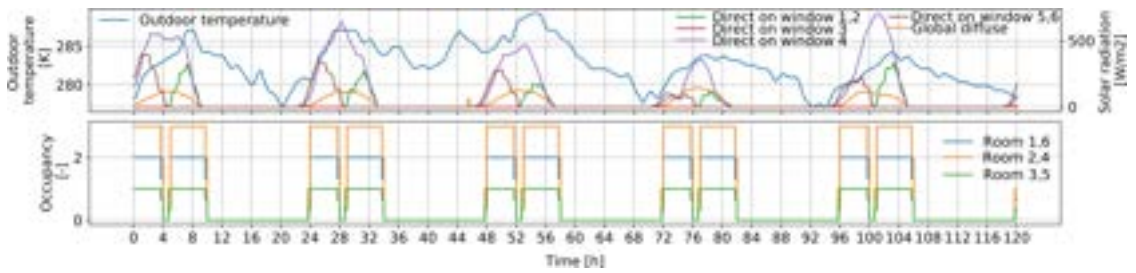

Figure 4: Disturbances for the standard deviations σ = (0,0,0) (perfect forecast)

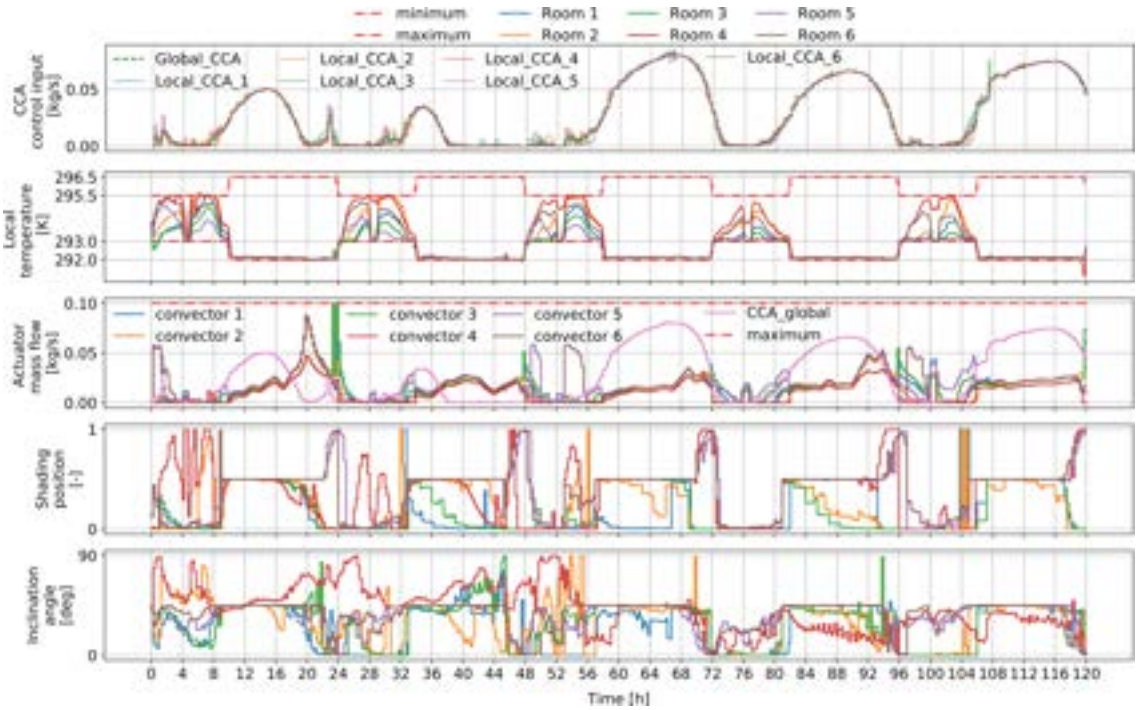

Figure 5: Non-hierarchical distributed MPC for the standard deviations σ = (0,0,0) (perfect forecast)

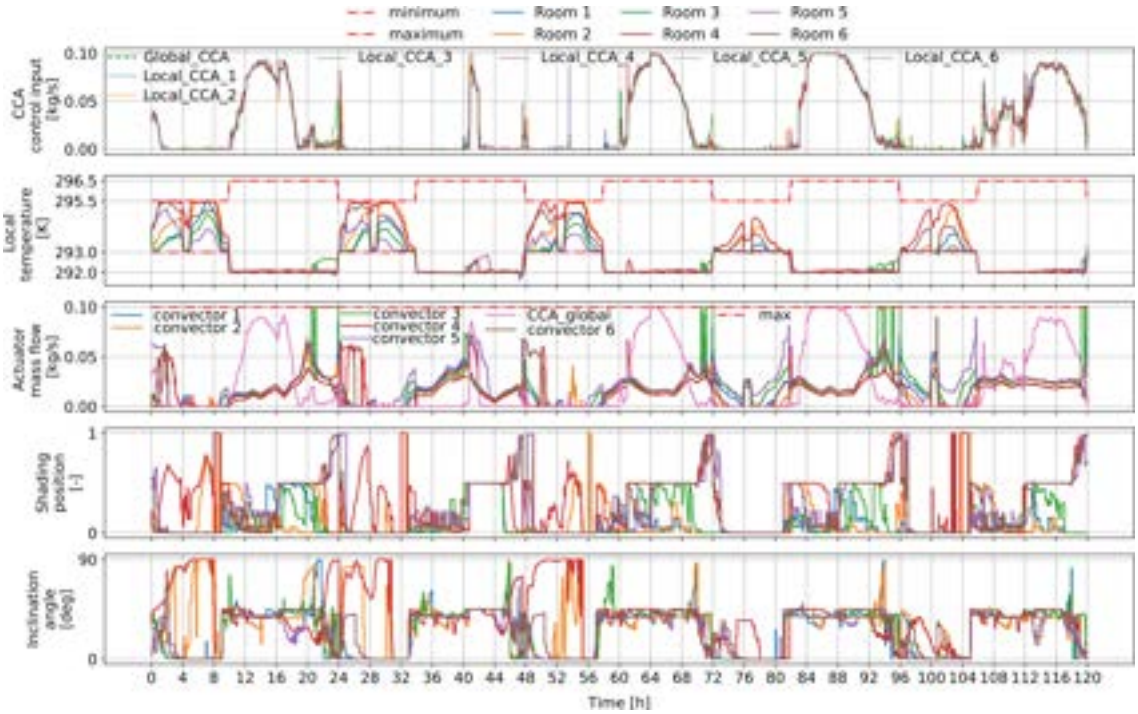

Figure 6: Hierarchical distributed MPC for the standard deviations σ = (0,0,0) (perfect forecast)

Forecast scenario σ = (0.5,50,0.1)

For the second scenario, the forecast errors are artificially generated based on normal distributions with fixed standard deviations for each disturbance quantity (0.5 for occupancy, 50 W/m^2 for the radiation quantities and 0.1 1/h for air exchange). The forecast errors are shown in Fig. 7 and range up to $\pm$1 for occupancy, $\pm$100 W/m^2 for the solar radiation quantities and $\pm$0.2 1/h for air exchange.

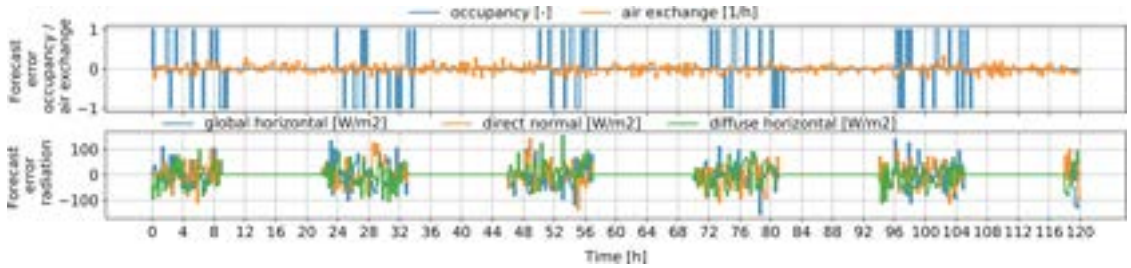

Figure 7: Forecast errors for the standard deviations σ = (0.5,50,0.1)

The simulation results for the non-hierarchical and the hierarchical distributed MPC are visualized in Fig. 8 and Fig. 9. As shown in the "Local temperature" subplots, the hierarchical MPC exhibits an increased reactivity to the occurring forecast errors and a higher capability of preserving thermal comfort and operating the room temperatures between the comfort bounds. For the non-hierarchical MPC, especially the lower comfort bounds are exceeded more frequently. This manifests itself during non-occupancy (e.g., during hours 38–46) and particularly during occupancy periods (e.g., during hours 48–58 and 72-84), when forecast errors are imposed on all disturbance quantities (see Fig. 7). The hierarchical MPC can reduce the thermal discomfort resulting from the operation of the non-hierarchical MPC (24.30 Kh) by 9.62 Kh (equivalent to a reduction of 39.6 %) resulting in a thermal discomfort of 14.68 Kh. The energy consumption for the hierarchical and non-hierarchical MPC are identical (679 MJ). The last three subplots of Fig. 8 and Fig. 9 reveal that the control inputs of the hierarchical MPC are operated in a more dynamic way to compensate for the forecast errors. The "CCA control input" subplots show a similar convergence for both MPC variants with few diverging outliers, which leads to an identical consensus MAE of 0.001 kg/s and an RMSE of 0.002 kg/s. The computation time for the hierarchical MPC (61 691 s) is approximately 3.4 times higher than the one for the non-hierarchical variant (18 173 s). The hierarchical MPC is seven times faster than real-time according to a computational time ratio of 0.14.

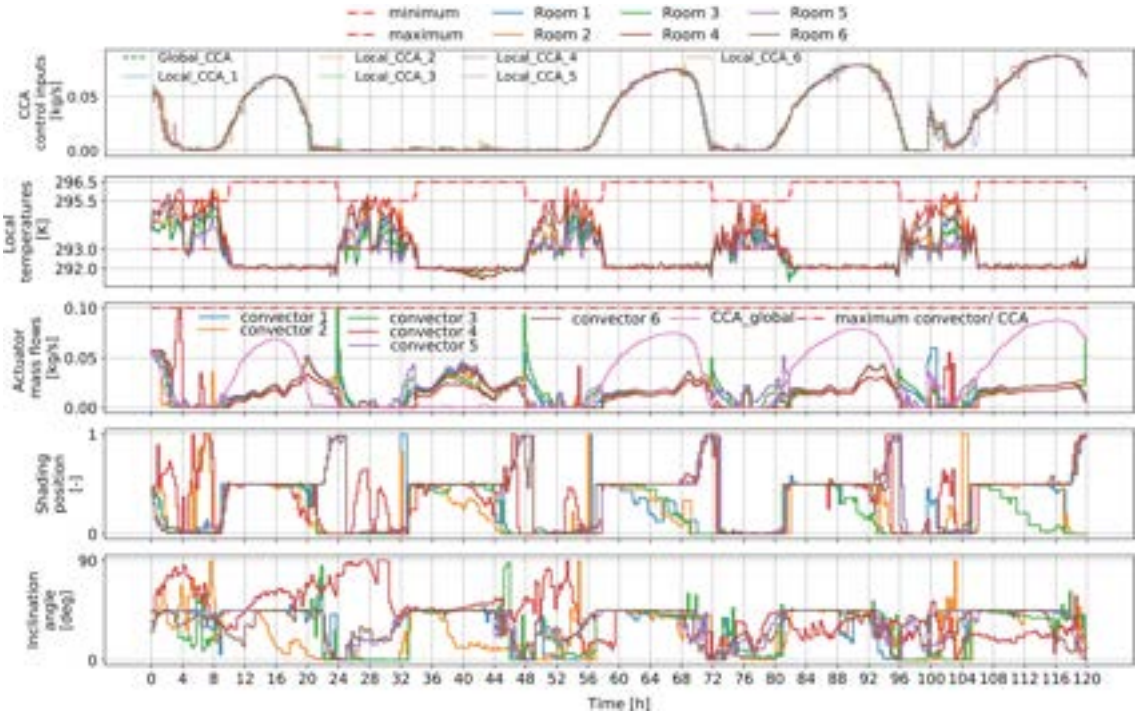

Figure 8: Non-hierarchical distributed MPC for the standard deviations σ = (0.5,50,0.1)

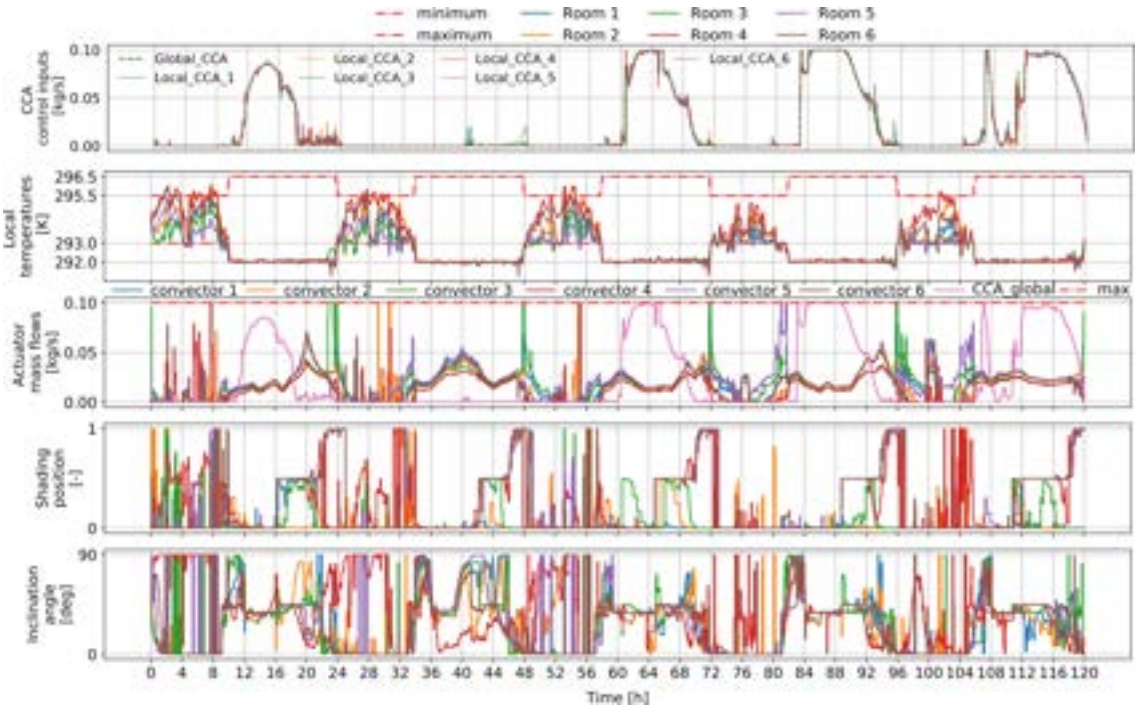

Figure 9: Hierarchical distributed MPC for the standard deviations σ = (0.5,50,0.1)

Forecast scenario σ = (1,100,0.2)

Figure 10 depicts the forecast errors for the σ = (1,100,0.2) scenario, which range up to $\pm$2 for occupancy, $\pm$200 W/m^2 for the solar radiation quantities and $\pm$0.4 1/h for air exchange. In Fig. 11 and Fig. 12, the performance of the non-hierarchical and hierarchical distributed MPC for this forecast scenario are shown. In analogy with the previous forecast scenario, the ”Local temperature” subplots manifest a substantially increased reactivity and ability of the hierarchical MPC to compensate for forecast errors. This shows itself by reducing the exceedance of both the lower (e.g., during hours 24–34, 34–48 and 72–82) and upper comfort bounds (e.g., during hours 100–106). The benefits of the hierarchical MPC are particularly revealed complying with the lower comfort bound, since in this case study, only heating actuators are included that are able to react to the forecast errors (apart from the predictive ”cooling” function of the solar shading). The exceedance of the comfort bounds, which is attributed to the deviation between predicted and real disturbance quantities, can be compensated in a shorter time by the hierarchical MPC benefiting from the small sampling period of the lower MPC layer. Thermal discomfort can be reduced from 43.25 Kh for the non-hierarchical to 30.91 Kh for the hierarchical MPC, which corresponds to a decrease of 28.5 % or an absolute reduction of 12.34 Kh. Again, the consumed energy is identical for both variants with 678 MJ.

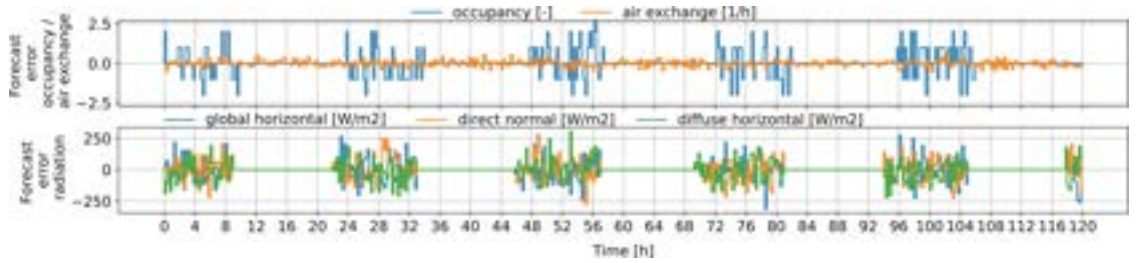

Figure 10: Forecast errors for the standard deviations σ = (1,100,0.2)

The subplots ”Actuator mass flow”, ”Shading position” and ”Inclination angle” exhibit the more dynamic operation of the control inputs. The potentially disturbing effect of frequent shading or wear and tear is not considered here. The focus is placed on the reactivity of the control and preservation of comfort. In future versions, constraining or penalizing the change in control inputs between two iterations could be added. The ”CCA control input” subplots show a comparable ADMM convergence for both MPC variants with an identical MAE of 0.001 kg/s and a consensus RMSE of 0.002 kg/s. The increased reactivity of the hierarchical MPC comes at the cost of three times larger computation times (computation time of 67 897 s for the hierarchical

and 20 245 s for the non-hierarchical MPC). With a computational time ratio of 0.16, the hierarchical MPC is six times faster than real-time.

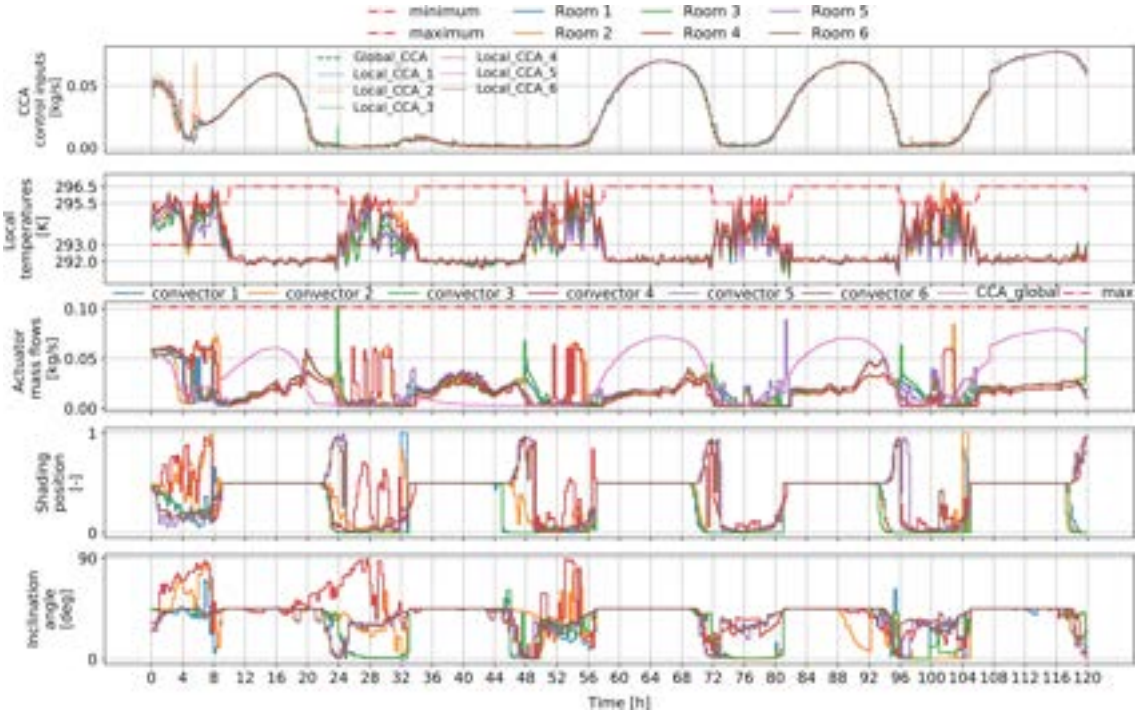

Figure 11: Non-hierarchical distributed MPC for the standard deviations σ = (1,100,0.2)

5. Conclusion

In this work, a hierarchical distributed MPC for building energy systems based on nonlinear Modelica controller models is presented. The MPC concept couples hierarchical and distributed optimization approaches to divide the optimization complexity within the temporal and spatial dimension and enable decoupled, modular modeling. The hierarchical optimization approach takes into account different dynamics in buildings and guarantees

both anticipation for components with high inertia and time delay as well as reactivity with respect to deviations between the predicted and the actual building behavior. The distributed optimization approach splits the optimization problem into subproblems to improve the scalability and real-time capability of the control while accounting for the coupling between the subproblems.

The flexibility and robustness of the proposed control approach are evaluated for different scenarios of the forecast accuracy for the disturbance quantities of occupancy, solar radiation and air exchange. The artificially generated forecast errors can be considered representative of any deviation between the predicted and real-world behavior of buildings. Applied to a six-room building Modelica model, the hierarchical distributed MPC demonstrates a considerably increased capability to keep the room temperatures within the comfort bounds and a relative discomfort reduction of 29 to 40 % for the scenarios with forecast errors in comparison to a non-hierarchical reference MPC. With an increase in forecast errors, the absolute thermal comfort that can be reduced by the hierarchical MPC increases. The increased reactivity comes at the cost of increased computation times. In the case study, the hierarchical distributed MPC manifests a good ADMM convergence and real-time capability by being six times faster than real-time.

In future work, the developed MPC framework will be practically applied to a multi-zone building including dynamic and inert (heating) actuators. Within the hierarchical MPC configuration, different model approximations/linearizations could be evaluated on the different layers focusing on specific components. Finally, integer optimization variables should be included for wider applicability in building control.

Abstract:

The growing penetration of renewable energies, which have a fluctuating nature, requires the enhancement of energy system flexibility. This can be achieved through sector integration, which encompasses the conversion of energy into the most convenient vectors. In this regard, a promising option is represented by Power-to-Gas (PtG) technologies. They allow the direct conversion of surplus renewable electricity into fuels (e.g. green hydrogen or methane) and its long-term storage, operating as seasonal storage. The potential of PtG systems can be unlocked if the waste heat produced by exothermic components (e.g. electrolyzer and methanation reactor) is recovered and fed, for instance, into a district heating network (DHN) to be supplied to an end-user. However, since the operation of PtG systems may be discontinuous, a full integration of the fuel, electrical and heating sectors is possible only with advanced management and control tools. This work presents a control strategy based on Model Predictive Control, with the aim of operating the production of methane from a PtG system and the supply of waste heat to a DHN with minimal cost. The case study comprises an electrolyzer, a methanation reactor, storage tanks for hydrogen and methane, a boiler and a heat pump for upgrading the temperature level of the recovered heat. The controller feasibility is demonstrated through a Model-in-the-Loop simulation platform and its performances are compared to that obtained with a conventional controller. The novel controller enables a 54 % increase in operating margin and more than halves carbon dioxide emissions. A better exploitation of renewable energy is also obtained (+ 4.6 %), as well as an increase in the share of heat recovered from the PtG plant.

1. Introduction

Due to the need to decarbonize the energy sector, a great effort is being made today to support the penetration of renewable energy sources (RES), and this is transforming the architecture of current energy systems. Indeed, the mismatch between energy production and demand creates challenges that add complexity and forces the integration of new technologies and solutions. This leads to a change in the conventional way of managing energy systems, and to the need to exploit the concept of Multi-Energy Systems (MES), which means to consider energy systems as a whole, and therefore to perform an overall optimization of energy exchanges, including sector integration.

Power-to-Gas (PtG) technologies are gaining importance in this context, enabling sector coupling through the production of synthetic fuels (i.e. electrofuels) from renewable electricity, as demonstrated by many ongoing research activities on this topic [1]. Electrofuels can be used as conventional fuels and even converted back into electricity when necessary: thus, they can serve as an energy storage solution avoiding renewable energy curtailments. As expected, the total efficiency of the process is low, but it can be increased by making profitable use of the waste heat. Indeed, being an exothermic process, when integrated into an energy system, a PtG plant can also provide additional heat to be used by the end-users. Böhm et al. [2] studied the potentials of coupling Power-to-Hydrogen with a District Heating Network (DHN), finding that there are several synergies and efficient interactions between them. While high-temperature electrolysis is comparable with industrial waste heat, low-temperature electrolysis is subject to infrastructure limitations: however, the modern low-temperature DHN represent an opportunity for its usage.

Due the complexity presented above, it is evident that when dealing with the problem of the future management of PtG systems integrated into MES, the control of such systems plays a key role. Indeed, how a PtG unit is integrated into the system and how it is operated, strongly influence its potential. Fischer et al. [3] found that Model Predictive Control (MPC) is a suitable control strategy for optimizing the operation of PtG technologies, mainly when such systems are integrated into complex MES. They successfully demonstrated the application

of an MPC for optimizing the operation of a PtG unit and on-site storage considering the limitations in energy networks and time variable electricity prices. Turk et al. [4] studied the application of an MPC for a system with PtG and gas storage for system flexibility, considering multiple uncertainties. The authors found that the MPC made it possible to reduce the wind curtailment and improve the economic performance of the system, compared with a traditional control strategy. They also investigated the impact of the MPC prediction horizon length on computational efficiency, finding that it should be selected based on the required computational efficiency and storage capacity of the system. Finally, Abdelghany et al. [5] investigated the implementation of a two-stage MPC for the integration of a PtG plant for hydrogen production from a wind farm, to be used for hydrogen-fueled road vehicles or for injection into the local grid. By using a two-stage predictive controller, they tackled different competing objectives and different time-scales, and optimally managed the interactions between the wind farm, end-user and power grid. As demonstrated by these studies, an intelligent control strategy is needed to successfully manage such systems. However, in the presented papers, the possibility of recovering the waste heat of the PtG plant was not considered.

Waste heat recovery was nonetheless studied by Huang et al. [6]. The authors analyzed the benefits of using a Mixed-Integer Linear Programming (MILP)-based economic MPC for the real time control of complex MES integrated with the production of hydrogen. They recovered the waste heat of a high temperature alkaline electrolyzer and used it directly in a DHN, achieving cost savings and a better exploitation of RES, compared to a conventional rule-based strategy.

Given the necessity to decarbonize current energy systems, a great effort is being made today in studying and applying novel control strategies and optimization tools in real systems for the integration of new technologies and for the exploitation of sector coupling. Nevertheless, being a complex problem, with many degrees of freedom, it is necessary to keep studying different applications and the benefits of the integration of PtG technologies in energy systems. In particular, considerable effort is still needed in the study of the smart management of PtG plants and of waste heat recovery from it, in order to exploit all the potentials of this technology.

The main contributions of this paper are the following:

- The development of a novel MPC controller with an integrated MILP algorithm for the optimal control of a PtG plant for the production of methane, coupled with a DHN for waste heat recovery.
- An innovative solution for recovering the waste heat from the PtG plant. A heat recovery circuit (HRC), which works at low temperatures, i.e. (40÷55) °C, is used to recover the waste heat of the PEM electrolyzer, the methanation reactor and the condenser, and then the low-temperature heat at 55 °C is upgraded by an industrial heat pump (HP) and is used in a DHN, as outlined in Figure 1.
- The quantification of the benefits of using the innovative control solution, compared to a conventional rule-based control strategy, by the implementation of both solutions in a Model-in-the-Loop (MiL) configuration.

2. Method

This section presents the methods exploited in this work: the concept of MPC, the optimization algorithm developed for its implementation and the detailed model used for the MiL application.

2.1. Model Predictive Control

The optimal control of a MES using smart control strategies is becoming more and more common and it is catching the attention of researchers and industries. Indeed, when using advanced control strategies, it is possible to perform the optimal management of complex systems, which follows the implemented objectives (such as cost or energy consumption minimization).

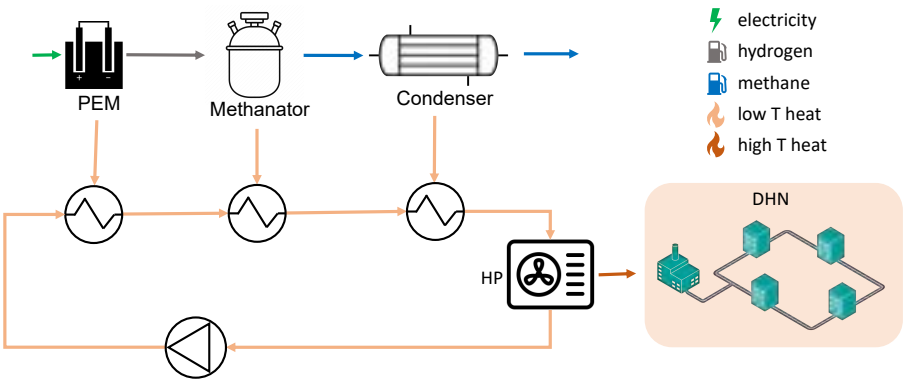

Figure 1: A schematic representation of the heat recovery from the Power-to-Gas plant.

MPC is a smart control strategy that has been demonstrated to be successful for many applications [7]. In this type of controllers, an optimization algorithm is embedded, which includes a simplified model of the system to control. At every time-step, the algorithm receives information on the actual behavior of the system, and calculates an optimal trajectory for the inputs over a future time-horizon, also known as prediction horizon, which is discretized into a certain number of time-steps. From this trajectory, only the first signal is implemented into the real system (e.g. as a set-point in low-level controllers), and after a time-step is passed, the system states are estimated and given again to the controller, together with the forecast of the disturbances, which repeats the calculation for a new prediction horizon.

With this control strategy, an optimal control of the system is allowed: the controller gives the optimal inputs to the system every time-step (e.g. 15 minutes), and there is an implicit feedback and feed-forward on the disturbances. Nevertheless, an adequate algorithm is needed to use this control strategy, which has to be fast and contain the model of the system to control. In this work, a MILP algorithm is used, which is described in detail in Paragraph 2.2.. The aforementioned advantages of using this technique, such as the consideration of the predicted disturbances, the possibility to handle constraints and the concomitant optimization, make MPC a suitable control technique for MES [6].

2.2. Optimization algorithm

As explained above, to develop an MPC controller, an optimization algorithm is required. It is embedded in the controller and calculates the optimal future trajectory for the control variables. Moreover, the algorithm needs to be fast, since it is run at every time-step, and needs to optimize the system over the entire prediction horizon. Among the existing optimization algorithms, the Mixed-Integer Linear Programming technique has revealed to be a successful optimization model for MES, if properly tailored to the case study. Indeed, this strategy makes it possible to optimize the systems with good accuracy and reasonable computational complexity. In addition, efficient commercial solvers are available for such problems, and the global optimality of the solution is guaranteed [8]. When using such approach, the equations that describe the physical behavior of the system must be linear, and therefore they need to be linearized. It is possible to model a general MES using the following components:

- **Conversion systems**: they represent all the plants involved, which transform the energy from one (or more) form to another one (or more), e.g. boilers, heat pumps, electrolyzers. To model them, the input-output relationship is linearized, and piecewise linearization can be used to consider variations in efficiency with the load [9, 10]. This formulation needs auxiliary variables and constraints, which are described in detail in [11]. Moreover, when necessary, the piecewise linearization has been performed on two variables (e.g. to model the compressor, the electrical energy used depends both on the gas mass flow rate and on the pressure ratio). While the piecewise linearization of one-degree of freedom performance curves is relatively straightforward, when the piecewise linearization is made on two variables, several piecewise linear approximation approaches exist. In this work, the triangle method was applied to those components that needed it [11]. In addition, for each plant, three operating modes can be modeled (ON, OFF and standby), and it is possible to set a start-up cost, as well as a minimum up-time (UT) and down-time (DT), and operating ramps, by adding additional equations and binary variables to the problem.
- **Energy storages**: they represent every component that can store energy, e.g. batteries, thermal energy storages, gas storage tanks. The equation that describes them relates the energy stored at the current time-step to the one stored at the previous time-step, by taking into account charge, discharge and self-discharge efficiencies.
- **Energy networks**: they are modeled as energy sinks/sources, to/from which the energy system can exchange energy by buying or selling it with certain costs, e.g. electricity grids, natural gas networks.
- **End-users and RES**: they are modeled as energy sinks/sources, with the needs to be fulfilled or the production rate given as disturbances to the algorithm.
- **Energy nodes**: they are not physical nodes, however, they are used to make sure the energy balance for each energy vector is fulfilled every time-step.

The optimization variables are all the power flows and the energy stored, and the algorithm calculates their optimal management for each time-step, in order to minimize the implemented objective function over the prediction horizon.

2.3. Simulation platform

As previously mentioned, the management presented was tested in a Model-in-the-Loop configuration. A detailed nonlinear model, which emulates the real system, was developed in the MATLAB®/Simulink® environment, and it was built by assembling the models of single energy system components. The application

consists of a wind farm, a PtG system for the production of synthetic methane and a DHN, which ensures heat supply to an end-user.

The Simulink® library used to model the DHN has already been presented in previous works [12], and it is composed of the pumping station blocks (expansion vessels and pumps), the heating network blocks (pipelines) and the thermal power unit blocks (boilers and heat exchangers). Nevertheless, for the present application, new components were developed, that constitute the PtG plant. The main components and how they were modeled is presented below.

Wind farm: this is an algebraic model which, starting from the undisturbed wind velocity module and direction $\mathbf{u}_{wind}$, and given the geometry of the wind turbines and their position in the wind farm, calculates the output electrical power production. It considers the wake effect by applying the Jensen wake model [13] and once the corrected wind velocity $\mathbf{u}_{wind_{corr}}$ for each turbine is determined, uses the power curve of the turbines to calculate the electricity generated: $P_{el} = f(\mathbf{u}_{wind_{corr}})$.

PEM electrolyzer: this is an algebraic model that, given the electrical power supplied and the operating mode returns the amount of hydrogen and the thermal power generated. It has three different operating modes: ON, OFF (i.e. no consumption, no production, cold start-up needed to switch on) and standby (i.e. no production, consumption of a certain amount of nominal electrical power, warm start-up needed to switch on). During the steady state operation, the relation for the efficiency of the electrolyzer is derived by interpolating operating data

$$\eta = \rho HHV \frac{aP_{el}^b + c}{P_{el}}, \tag{1}$$

and it is used to calculate the hydrogen flow rate produced as follows

$$\dot{V}_{H_2} = \frac{1}{\rho HHV} \eta P_{el}, \tag{2}$$

with ρ being the gas density, HHV its high heating value and P_{el} the input electrical power. The thermal power generated is calculated using the following equation

$$P_{th} = (1 - \eta) P_{el} - P_{loss}, \tag{3}$$

where P_{loss} represents the power loss and is calculated as $P_{loss} = \alpha P_{nom} + \beta P_{el} + \gamma P_{nom}$: the first term represents the losses due to the auxiliary systems, while the latter terms represent the linear model of the power losses in the conversion from AC to DC.

Methanation reactor: this is an algebraic model that correlates the input hydrogen flow to the output methane flow and thermal power generated. Similarly to the electrolyzer, it has three operating modes: ON, OFF and standby. In the steady state operation, the output flow is calculated using the yield of reaction y, which is estimated based on linear interpolation of experimental data as follows

$$y = a \frac{GHSV}{GHSV_{nom}} + b \tag{4}$$

where GHSV (gas hourly space velocity) is the rate between the total volumetric flow rate at inlet and the reactor's volume, and evaluates the load of the reactor.

Gas compressor: this is an algebraic model that, given the rotational speed, the input flow and the output desired pressure, calculates the output flow and the electrical power consumption. The block contains the performance maps of the turbocompressor for the calculation of the mass flow rate and of the polytropic efficiency, given the corrected rotational speed and the pressure ratio.

Gas storage: the proposed model represents a node in which the input flow is mixed with the gas inside the storage. It is a dynamic model that uses the energy balance and continuity equations for pressure and temperature calculation. In terms of causality, the incoming and outcoming flows are known, and the model calculates the pressure, temperature and composition of the gas contained in the storage. The energy stored is calculated using the gas HHV.

Gas pipeline: this is a dynamic model which, given the inlet pressure, temperature and composition, and the outlet pressure, calculates the output mass flow rate, temperature and composition of the gas. The mass flow rate is calculated as follows

$$\dot{m} = sign(\Delta p) \sqrt{\frac{|\Delta p| \rho A_{cs}}{\frac{\lambda L}{D_{in}} + Z}}, \tag{5}$$

where Δp is the pressure drop in the pipeline, A_{cs} the cross-section area of the pipeline, ρ the gas density, λ the friction factor, L the pipe length, D_{in} the inner diameter, and Z the total concentrated pressure drop. The governing equation for the temperature is the following

$$\frac{dT_{out}}{dt} = \frac{1}{\rho c_v V}\left(\dot{m}\left[(c_p T)_{in} - (c_p T)_{out}\right] - \dot{Q}_w\right), \tag{6}$$

where c_p is the gas specific heat at constant pressure, c_v the average gas specific heat at constant volume, V the volume of the pipeline and $\dot{Q}_w$ the heat exchanged through the wall.

Gas pressure reduction valve: this is an algebraic model that takes as inputs the income and outcome pressure, temperature and composition of the gas, and opening ratio of the valve φ , and returns the mass flow rate through the valve. The mass flow rate is calculated using the expansion factor Y, as

$$\dot{m} = N_x c_v Y \sqrt{\rho_{in} \Delta p}, \tag{7}$$

where N_x is a coefficient introduced to match the measurement units used.

Heat pump: this is an algebraic model in which the thermal power absorbed and that supplied by the heat pump are calculated based on the temperature of the cold and hot sources (T_c and T_h) and on the electrical power used P_{el}. The actual COP is calculated as follows

$$COP = \frac{COP_{nom}}{C_c(1-(1-C_c)}\frac{P_{el,nom}}{P_{el}}, \tag{8}$$

where C_c is a correction factor usually declared by the manufacturer, $COP_{nom} = \frac{COP_{max}}{\eta_{II}}$ and η_{II} is calculated with a lookup table with $\eta_{II} = f(T_c, T_h)$.

The inputs, outputs and states of the new components are reported in Table 1, while for the pumping station, heating network and thermal power unit blocks, the reader can refer to [12].

3. Application

This section describes the case study chosen and the main characteristics of the simulations. In addition, it presents how the control strategies have been implemented in the MiL application.

3.1. Case study description

The case study considered consists of a PtG plant for the production of synthetic methane, using the renewable electricity generated by a wind power plant. A simplified representation of the energy system is displayed in Figure 2.

The energy system is connected to the electrical grid and to the natural gas network, and it can exchange electricity and gas with them by buying and selling energy. The end-user has both electrical and thermal needs: the first are fulfilled by using the renewable electricity or by buying electricity from the power grid, while the latter are met with a gas-fueled boiler, and by recovering the waste heat from the PtG plant. Indeed, as mentioned above, two hot water circuits are employed: the HRC that works at low temperatures (40÷55) °C, in which three heat exchangers recover the waste heat from the PEM electrolyzer (available at a temperature of 55 °C), condenser (80 °C) and methanation reactor (290 °C), and the DHN which works at higher temperatures (60÷80) °C and is used for end-user heat supply (see Figure 1). An industrial heat pump (HP) connects the two circuits and upgrades the heat at 55 °C to the 80 °C needed for the DHN. The characteristics of the plants are shown in Table 2.

In Figure 2, all the energy flows involved are shown: the electricity produced by the wind farm can be used both for the fulfillment of the electrical needs, or by the PEM electrolyzer (PEM) that produces hydrogen,

Table 1: System components summary (Al = Algebraic, Dy = Dynamic).

Component	Model	Inputs	Outputs	States
Wind farm	Al	$\mathbf{u}_{wind}$	P_{el}	-

	Maximum pressure (bar)	35		Maximum pressure (bar)	7.5
	Minimum pressure (bar)	2.5		Minimum pressure (bar)	3.5
Heat pump	Nominal inlet power (kW)	380			

and it is also consumed by the methane compressor and by the HP. The produced hydrogen can be stored in the hydrogen storage (HS) or used by the methanation reactor, which produces methane at low pressure (2.5 bar), which needs to be compressed before being used or stored in the methane storage (MS). After the compression, the methane can both be stored, sold, or used to feed the boiler, which produces the heat for end-user supply. In this work, the MPC controller is applied to a so-called system digital twin, which is a dynamic model, built by means of properly connecting the models of the single components involved which are developed in Simulink® and presented in Paragraph 2.3.. This allows the new control strategy to be tested, without affecting the operation of a real system. The controller is implemented as a supervisory controller, and gives the values of the manipulated variables calculated by the optimization algorithm as input set-points to low-level controllers (e.g. PID controllers) already implemented in the system.

3.2. Simulation setup

The main objective of this study is to compare the actual savings potential and the different management of the proposed MILP-based MPC with the use of a conventional rule-based control strategy. The following paragraphs present the two control strategies and describe how they are implemented.

3.2.1. MPC control

The schematic diagram of the MiL application of the MPC is shown in Figure 3: the MPC was set with a prediction horizon of two days and a time-step of one hour. At each time-step, the controller (i) gets the actual value of the system initialization variables, (ii) updates the forecast of the disturbances and the initial conditions and (iii) calls the optimization algorithm, which is run and returns the values of the optimal control variables as a result. The initialization and control variables, as well as the disturbances are described in Figure 3.

The objective function implemented is the maximization of the total operating margin of the system, which includes the costs of the electricity and natural gas bought and sold from/to the networks. The MILP algorithm described in Paragraph 2.2. was developed and adapted to the case study presented. The features of the linearization conducted to formulate the MILP algorithm are shown in Table 3, where it is specified whether or not the piecewise linearization has been conducted, its dimension, as well as the number of intervals employed. In addition, it is indicated if the UT, DT and operating ramps are modeled, as well as which operating modes are used.

The disturbances given to the MPC are the forecasts of end-user needs and the electrical power generated by the wind farm, and they are displayed in Figure 4 for the second simulated day. It is worth pointing out

that these forecasts are different from the disturbances applied to the Simulink® model, which represent the actual disturbances and are obtained by applying random deviations to the ideal disturbances given to the controller. In this way it is possible to evaluate how the predictive controller reacts to disturbances other than those expected, which usually happens in real applications.

3.2.2. Rule-based control

Depending on the definition of the conventional control strategy, the improvement due to management with the MPC control can vary, therefore a suitable and efficient rule-based control was developed. With this control strategy, the same set-points given by the MPC are calculated based on the logic displayed in Table 4.

It needs to be mentioned that the boiler set-point is not calculated with this control logic, and its input power is regulated through a PI controller, which keeps the supply temperature of the DHN equal to 80 °C. In addition, the actual amount of methane exchanged with the network is the set-point given for the methane sold minus the methane needed for the boiler.

3.3. Key Performance Indicators

To evaluate the results obtained, some Key Performance Indicators (KPIs) regarding the cumulative results of the second simulated day were analyzed. The KPIs identified are:

- Operating margin (EUR): the net revenue of the electricity and methane exchanged with the networks. Thus, it is the difference between the cost of the energy sold and the cost of the energy bought during the simulated period.
- CO_2 emissions ($kg_{CO_2,eq}$): the amount of carbon dioxide which is emitted due to the operation of the energy system. In particular, it considers the emissions related to the methane and electricity bought from the networks. Indeed, it was assumed that the electricity produced by the wind farm is associated with zero emissions, as well as the synthetic methane produced with the PtG plant. For the electrical grid, a coefficient of 224 gCO_2/kWh was considered [14], while for the gas 200.8 gCO_2/kWh [15].
- RES usage (%): the percentage of renewable electricity which is used by the system, and therefore not sold to the electrical grid.
- Gas production (kWh): the amount of methane produced by the Power-to-Gas system.
- Heat recovered share (%): the percentage of user thermal needs covered with the heat recovered from the PtG plant.

Table 3: Features of the model linearization for MILP formulation.

Component	Method	Intervals	Parameters	UT/DT	Ramps	Op. modes
Electrolyzer	piecewise 1D	1×3	$P_{out_{H_2}}, P_{out_{th}} = f(P_{in_{el}})$	no	no	ON/OFF/standby
Methanator	piecewise 1D	1×2	$P_{out_M}, P_{out_{th}} = f(P_{in_{H_2}})$	yes	yes	ON/OFF/standby
Gas compressor	piecewise 2D	2×2	$P_{in_{el}} = f(P_{in_{ng}}, E_{stor_{ng}})$	no	no	ON/OFF
Boiler	linear	1×1	$\eta_B = 92.2\,\%$	no	no	ON/OFF
Heat pump	linear	1×1	$COP = 5.42$	no	no	ON/OFF
H_2 storage	linear	1×1	$\eta_{ch} = \eta_d = 95\,\%$	-	-	-
Methane storage	linear	1×1	$\eta_{ch} = 95\,\%$, $\eta_d = 0.85\,\%$	-	-	-

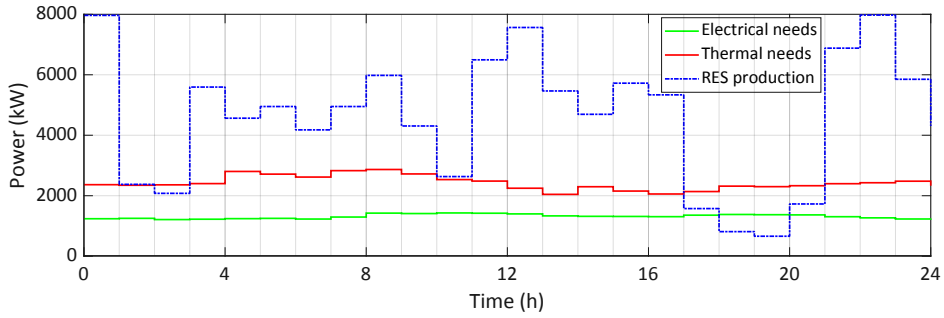

Figure 4: Forecasts of the disturbances given to the MPC controller for the second day.

Table 4: Rule-based control strategy definition.

Variable	Condition	Set-point value
Electrolyzer input power	$SoC_{HS} \leq 80\,\%$	$\min\{P_{nom}, (P_{wind} - P_{el_{user}})\}$
	otherwise	0
Methanator input power	$SoC_{HS} > 60\,\%$ & $SoC_{MS} \leq 95\,\%$	P_{nom}
	$SoC_{HS} > 60\,\%$ & $SoC_{MS} > 95\,\%$	$0.5\ P_{nom}$
	otherwise	0
Heat pump input power	methanator ON & $P_{th_{user}} > 0$	P_{nom}
	otherwise	0
Methane sold	$SoC_{MS} > 70\,\%$	1200 kW
	$30\,\% \leq SoC_{MS} \leq 70\,\%$	600 kW
	$SoC_{MS} < 30\,\%$	0 kW

4. Results and discussion

As previously explained, the aim of the simulations is to test the benefits of a novel controller based on MPC applied to a PtG plant coupled with a DHN. In order to do so, the novel control strategy was compared to a conventional rule-based one (see Paragraph 3.2.). The simulations were carried out over two days: nevertheless, the rule-based control strategy is used in both simulations on the first day, in order to have the same initial conditions for the second day, in which the two control strategies are compared. Therefore, the results are collected during the second day and only these results will be discussed.

Figure 5 shows how the electricity is managed with the two control strategies during the second day: it displays the energy balance among production, usage and exchange with the grid. It is possible to note that with the MPC strategy, less electricity is exchanged with the grid, and the renewable electricity is mainly used to work the electrolyzer and the HP for heat recovery. Indeed, this can be also seen in Figure 6: here, the total amount of energy exchanged with the networks during the entire day is displayed. With the rule-based control, a larger amount of electricity is sold to the grid, and at the same time a larger amount of methane needs to be bought from the gas network. Indeed, when the electrolyzer and methanation reactor are not operating, it is necessary to buy the gas needed to work the boiler, in order to fulfill the thermal needs of the user. This result shows that

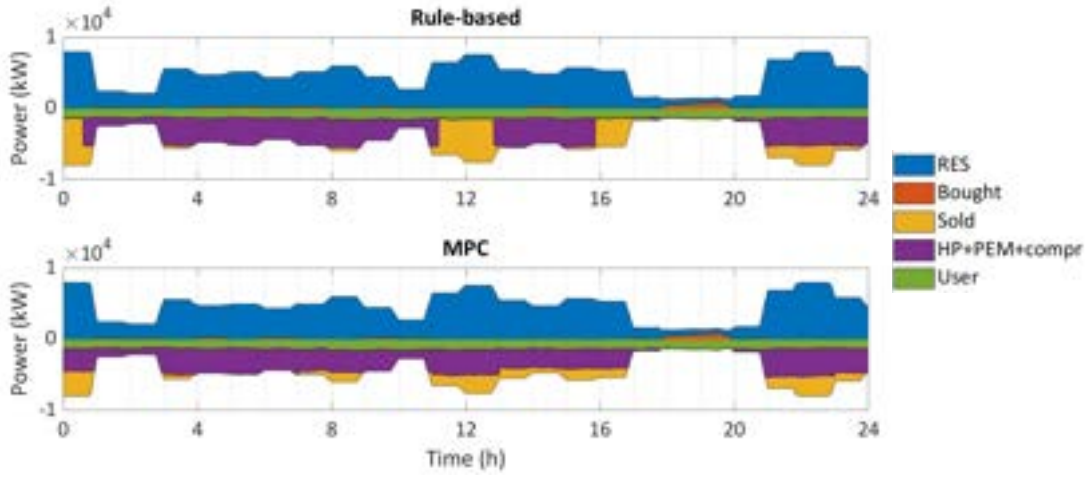

Figure 5: Energy balance at the electricity node (RES = wind power produced, Bought/Sold = exchanges with the power grid, HP = heat pump, PEM = PEM electrolyzer, compr = compressor, User = user needs).

it is better to exploit the self-produced energy as much as possible and to reduce the energy exchanges with the networks to a minimum to obtain a cheaper operation for the system. In addition, with such management, grid unbalances are prevented, as well as renewable energy curtailments.

In Figure 7, both the set-point and the actual input power to the methanation reactor are shown. The set-point is the actual set-point exiting the low-level proportional controller, and thus takes into consideration a correction based on the behavior of the hydrogen storage that corrects it in order not to exceed the storage limits. It can be seen that with the two control strategies the management is different. In fact, with the rule-based control, the set-point is kept constant most of the time at part load, while with the MPC a more precise set-point can be defined, which allows makes it possible to optimally manage the system and minimize the objective function.

Figure 8 shows the actual input power of the electrolyzer with the two approaches, and the State of Charge of the hydrogen storage. Indeed, these two dimensions are strongly related to each other. It can be noted that with the rule-based control strategy there are some periods in which the electrolyzer must be switched off since the hydrogen storage is too full. This does not happen with the MPC, which can optimally manage the electrolyzer and switch it off only when there is not enough RES production (see Figure 4).

In Table 5 the values obtained for the KPIs identified in Paragraph 3.3. are displayed. As expected, the operating margin of the system is higher when the MPC is used, since its maximization is the objective implemented in the optimization, and in one day it is possible to increase the operating margin by 54 % (around 475 EUR). In addition, with the MPC better results are obtained also for the CO_2 emissions, which are more than halved compared with the ones obtained using the rule-based control. Furthermore, when looking at the RES usage,

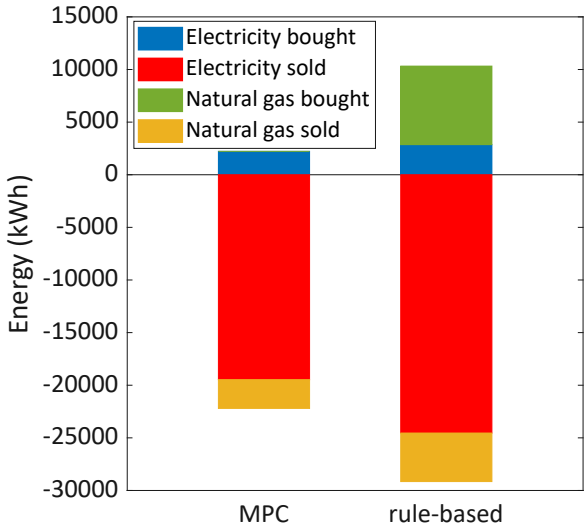

Figure 6: Bar plot with energy exchanged with the networks during the entire day.

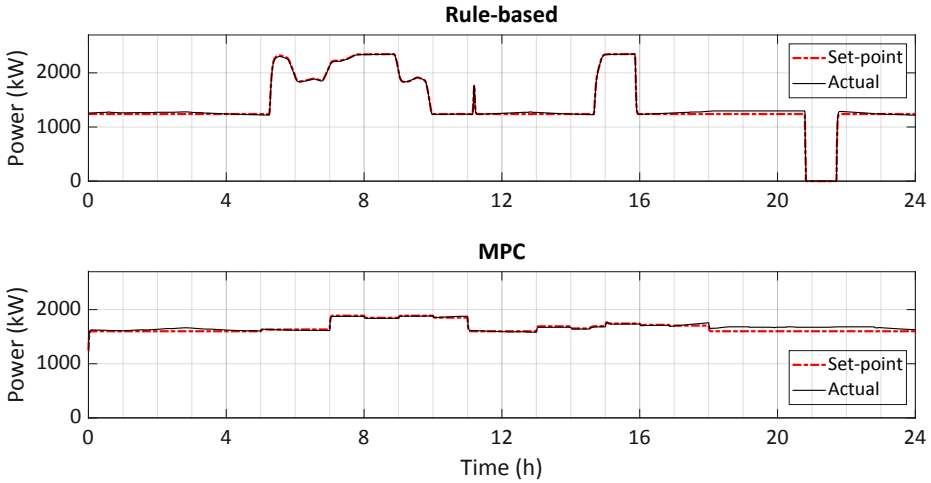

Figure 7: Input power set-point given to the methanation reactor with the two control strategies and actual input power.

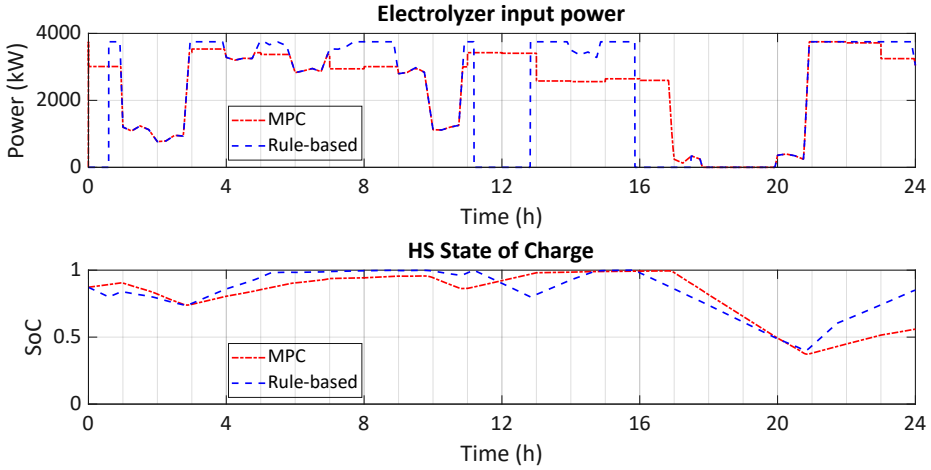

Figure 8: Actual input power of the electrolyzer and State of Charge of the hydrogen storage with the two control strategies.

Table 5: Values of the KPIs with the two control strategies.

Value	Rule-based control	MPC	Difference
Operating margin	874 EUR	1 349 EUR	**+ 475 EUR**
CO_2 emissions	2 139 $kg_{CO_2,eq}$	498 $kg_{CO_2,eq}$	**- 1 641** $kg_{CO_2,eq}$
RES usage	77.7 %	82.3 %	**+ 4.6 %**
Gas production	86 390 kWh	102 366 kWh	**+ 15 976 kWh**
Heat recovered share	42.0 %	44.8 %	**+ 2.8 %**

it is shown that with the MPC 4.6 % more renewable energy is exploited, and this leads also to a higher production of methane. Finally, the recovered heat is higher with the MPC: in particular with this strategy 44.8 % of the thermal demand is met by the recovered heat (2.8 % more than with the rule-based control).

It is worth noting that with the MPC better results are obtained for all the KPIs: this shows that maximizing the operating margin, the management of the system is more efficient under several aspects.

5. Conclusions

The energy transition is forcing the penetration of renewable energy sources and of new technologies into energy systems. Among them, Power-to-Gas solutions allow the production of synthetic fuels from renewable electricity, enable the storage of surplus electricity and permit sector integration. Due to these changes, energy systems are becoming increasingly complex and it is necessary to employ efficient and intelligent control strategies to manage them, in order to fully unlock the benefits of the novel solutions.

In this work, a controller based on Model Predictive Control was presented and it was applied to an integrated system with the production of methane from renewable electricity, with the objective of increasing the operating margin. Besides, a novel solution to recover the waste heat from Power-to-Gas exothermic components was proposed, which uses a heat pump to upgrade the heat available at low-temperature from the plant to the level of the supply temperature needed by a district heating network. The developed controller was tested in a Model-in-the-Loop configuration and compared to a traditional rule-based control strategy.

The results show that with the developed controller it is possible to have smarter energy management: indeed, the operation of the components and storage tanks is improved and the operating margin of the system is increased by 54 % in one day. In addition, with the novel controller 4.6 % more renewable electricity is exploited and the total emissions of carbon dioxide are strongly reduced, compared with the rule-based control.

Future studies will examine how the controller performs when adapted to different case studies and the use of different objective functions, which may include the minimization of energy consumption or carbon dioxide emissions. Furthermore, to fully understand the possible role of Power-to-Gas in the energy transition toward a sustainable energy framework, its potential as a long-term storage solution needs to be identified. To do that, the developed controller will be coupled with a supervisory controller, based on Model Predictive Control, which will provide it with further constraints regarding the correct long-term operation of the system. In this way, it would be possible to fully exploit the capabilities of Power-to-Gas as a seasonal storage solution.

Nomenclature

A_{cs}	Cross-section area of pipeline, m^2
C_c	Correction factor, $-$
c_p	Specific heat at constant pressure, $J/(kgK)$
c_v	Specific heat at constant volume, $J/(kgK)$
D_{in}	Inner diameter of pipeline, m
DT	Down-Time
DHN	District Heating Network
E	Energy, kWh
HHV	High Heating Value, kJ/kg
HRC	Heat Recovery Circuit
KPIs	Key Performance Indicators
L	Length of pipeline, m
λ	Friction factor, $-$
$\dot{m}$	Mass flow rate, kg/s
MES	Multi-Energy System
MiL	Model-in-the-Loop
MILP	Mixed-Integer Linear Programming
MPC	Model Predictive Control
N	Rotational speed, rpm
η	Efficiency, $-$
P	Power, kW
p	Pressure, Pa
PtG	Power-to-Gas
φ	Valve opening ratio,
$\dot{Q}_w$	Heat lost through wall, J/s
ρ	Density, kg/m^3
SoC	State of Charge
t	Time, h
T	Temperature, K
$\mathbf{u}$	Velocity, m/s
UT	Up-Time
V	Volume, m^3
$\dot{V}$	Volumetric flow rate, m^3/s
x	Mole fraction, $-$
y	Yield of reaction, $-$
Y	Valve expansion factor, $-$
Z	Total concentrated pressure drop through the pipeline, Pa

Large building stock energy simulation for the design of district heating networks : A case study on building retrofit policies

Mazarine Roquet[a] and Pierre Dewallef[b]

[a] University of Liège, Liège, Belgium, mazarine.roquet@uliege.be
[b] University of Liège, Liège, Belgium, p.dewallef@uliege.be

Abstract:

The Belgian building sector is responsible for a significant share of greenhouse gas emissions, partly because of the poor quality of its insulation and partly because fossil fuels are the main energy source for heating buildings. To decarbonize the heating of urban housing, district heating networks are good candidates. Indeed, district heating networks allow to improve load factor, to combine heat and power, to recover waste heat or to diversify the energy sources, including renewable sources (biomass, solar, geothermal, etc.). To design an efficient district heating network and take most of the improved load factor, a very precise knowledge of the heating needs of the buildings connected to the network is required. Thus, the first part of this work consists in creating robust, detailed, and automated physical models of the building stock, its equipment, and its use profiles to obtain detailed hourly load curve. The modelling tool used is the existing open-source Modelica library IDEAS, developed by the KU Leuven. The second part of the work includes the construction of a district heating network model and its regulation. This model is then coupled to the building simulation model. The combination of these two models allows to study the impact of a change in setpoint temperature in buildings or a massive insulation of the building stock on the buildings load curves and than on the regulation of the district heating network. The considered case study is a six buildings district of the University of Liège located on the Sart Tilman campus. The application of the building modelling methodology and energy saving policies to the test case shows that the approach considered is appropriate from a practical (easy scalable) and accuracy point of view and that energy saving measures cannot be taken without studying the consequences on the network operation.

Keywords:

District Heating Network, Building Simulation, Retrofit Policies, Large Building Stock

1. Introduction

The building sector is responsible of a significant part of the greenhouse gas emissions in Europe. According to [1], it is second largest contributor to greenhouse gas emissions in Belgium. This state of affair is mainly due to the use of fossil fuel combustion to heat the building and provide domestic hot water. The recourse to other primary energy sources is often expensive or not feasible when considering each building individually. District heating networks, on the other side, offer a different perspective by grouping the heat demands of different buildings on one single infrastructure thus providing economy of scales. District heating networks are also known to better exploit renewable energy resources such as biomass, solar or geothermal energy. Yet, developing and operating district heating networks is a challenging task as heat is difficult to transport efficiently and requires large investments.

Apart from the obvious economy of scales obtained from centralised rather than local heat production, an important advantage of district heating networks resides in the fact that all connected consumers will not need their peak consumption at the same time. Therefore, the rated power of the district heating network may be lower than the sum of the connected peak demand of the individual consumers. This improves the load factor and allows to leverage the high investment costs. Yet, taking advantage of the aggregation of loads requires a very accurate knowledge of the heating demands all throughout the year. To do so, monitoring data could be used to analyse the opportunity of district heating networks and optimise their structure and operation [2], however monitoring data for heating demands are very difficult to find and simulation is very often used instead to deduce heat demand curves.

A very large number of methodologies have been developed to obtain these demand curves from the building characteristics. They range from the very well known degree-days method [3] coupled to daily demand profiles [4] to the use of heating degree-hours and other methods such the one developed in the library *Demandlib* (see [5] for more details) that is based on air temperature and benchmark data. The very first scope of these

approaches is to simulate very large stock of buildings with synthetic information (the surface and the usage of the building) to determine an average heating demand curve directly from annual energy consumption data. These methods have the advantage of requiring very little data but do not take into account the individual properties of the buildings (e.g., orientation, occupant behaviour, ...) and also depend on a standard base temperature under which the building requires heating [6]. A slightly more advanced approach is considered by the library TEASER (see [7] for more details) where building archetypes, statistical data and national and international standards are used to simulate a large number of buildings from a minimum of information while maintaining the accuracy.

In this work, the aforementioned methods are not appropriate as the individual character of every buildings is overlooked, which prevents from properly predicting the peak loads and therefore to correctly evaluate the opportunity of lumping different loads altogether on one district heating system to improve the load factor. For example, while the tool TEASER enables the simulation of a large number of buildings in a dynamic and rapid manner, it is still built from archetypes. One of the goal of this contribution is to be able to model buildings taking into account their particular characteristics when they are available while considering standard configuration when they are not. It is especially the case for tertiary buildings whose structure changes widely from one building to the other and where different usages will generate totally different heat demand curve. The desired modelling must therefore be parametrised, based on observable characteristics, while remaining fast, robust and, hopefully, accurate. The first contribution of this work consists in defining a quick and accurate modelling methodology applicable to tertiary buildings. Moreover, the fact that the model is parametrised with observable characteristics (insulation thickness, orientation, window type, schedule of heating, regulation, ...) rather than on standards makes it possible to investigate specific energy saving measures in great details and to evaluate their influence on the operation of district heating networks.

The important outcome of the simulation are the peak demand (both in time and amplitude), the base demand and the total energy consumption per month and per year. As a result, it is possible to evaluate the impact of energy saving measures on the regulation and operation of the district heating network. On the one hand, a methodology to model the buildings is first established. Then, the district heating network is introduced and the basic assumptions are laid out. Two energy saving measures are considered herein namely, a change in user behaviour (i.e., a modification of the setpoint temperature in the buildings), and an additional thermal insulation.

In this contribution, the building stock model based on the library IDEAS [8] is used to build the simulation model which, in turn, is coupled to a district heating simulation model so as to underline the strong dependency between building renovation and/or regulation strategies and the operation/design of a district heating network. The outcome of a more accurate building simulation based on the actual and specific building architecture/use coupled to a model of the heat distribution is a more accurate evaluation of its thermal losses and pumping work therefore improving the evaluation of the heat transport efficiency. Both the building model and the district heating network model are thermal inertial models, taken into account the heat storage in the structure for the former and the dynamic behaviour of heat transport for the latter. More, these models are intended to compare the energy needs of the buildings and the district heating network for different energy policies and to study their impact on the network operation. Therefore, this article does not quantify the amount of primary energy required to operate the network or the associated emissions.

This contribution is primarily concerned on explaining the basic assumptions and philosophy of the building simulation model and then underlines its usage in the frame of district heating network operation. This is done by following an application framework from the campus of the University of Liège which is already equipped with a district heating network and where energy saving measures are currently discussed. For sake of simplicity, the test case is limited to a subset of 6 buildings among the 60 buildings located on the Campus. This application is insightful to understand the influence of building renovation and occupant behaviour on the future choice for the district heating network.

The methodology followed in this paper is described in Section 2.. Subsections 2.1. aims at describing the proposed building model, the one whose compatibility with the modelling of the tertiary sector must be studied. Subsection 2.2. describes the district heating network model and its assumptions. Then, Subsection 2.3. presents the reference test case studied as well as the variants considered as retrofit policies. The results of the simulations are then presented in Section 3.. This section is divided in different parts. First, the compatibility of the building model with the tertiary sector is assessed thanks to a validation through monitoring data. Then district heating simulation results for the variants are showed.

2. Methodology

The characteristics of a building simulation model is highly dependent upon its final use. Many building simulation models are intended to forecast the comfort conditions or for control of HVAC equipment and thus require a very detailed description of the building architectural structure. These models are usually accurate but require

an enormous amount of parameters not always available for existing buildings plus a significant amount of time to setup the model. These approaches are achievable when one is interested in one specific building but is not very accessible when hundreds of buildings or more have to be dealt with. Another important aspect resides in the connection of the building model to the district heating network that must be done in a standardised way whatever the complexity of the connected building, i.e., hourly heating and electrical demand.

2.1. Building simulation model

In order to benefit from previous research works in the modelling of district heating network (see [4]), the platform Dymola [9] has been first selected as a common platform. It has the advantage to support the open language Modelica and possesses numerous libraries for the building energy simulation. One specific library has been used as a building block for the building energy simulation, namely the library IDEAS (Integrated District Energy Assessment by Simulation) and developed by the KU Leuven (the interested reader is merely referred to [8] for a more complete information). It is a proven and robust library with a thorough manual available which provides rapid and safe implementation. It also provides, if necessary, a nice graphical user interface and does not require a very large number of parameters to be used. It is able to handle very simple buildings like houses and appartements but is also easily customisable to create complex building configurations like the ones considered hereafter.

For the buildings models, different assumptions are made. The building is divided into zones representing a set of rooms sharing the same temperature and ventilation requirements. This division into zones represents a simplification of the modelling as the thermal inertia of the internal walls is not taken into account when several rooms are lumped together. As an example, Fig. 1 exhibits the original available drawing of a building and the corresponding zones. A further simplification consists in reducing the shape of the buildings to rectangular zones so as to simplify the representation of complex buildings while keeping the exposed surfaces unchanged as well as their orientation. Each zone consists of a uniform air volume, a heating model, a ventilation model and the exterior surfaces (interior walls, exterior walls, windows, floors and ceilings). The model of a zone can be seen in Fig. 2.

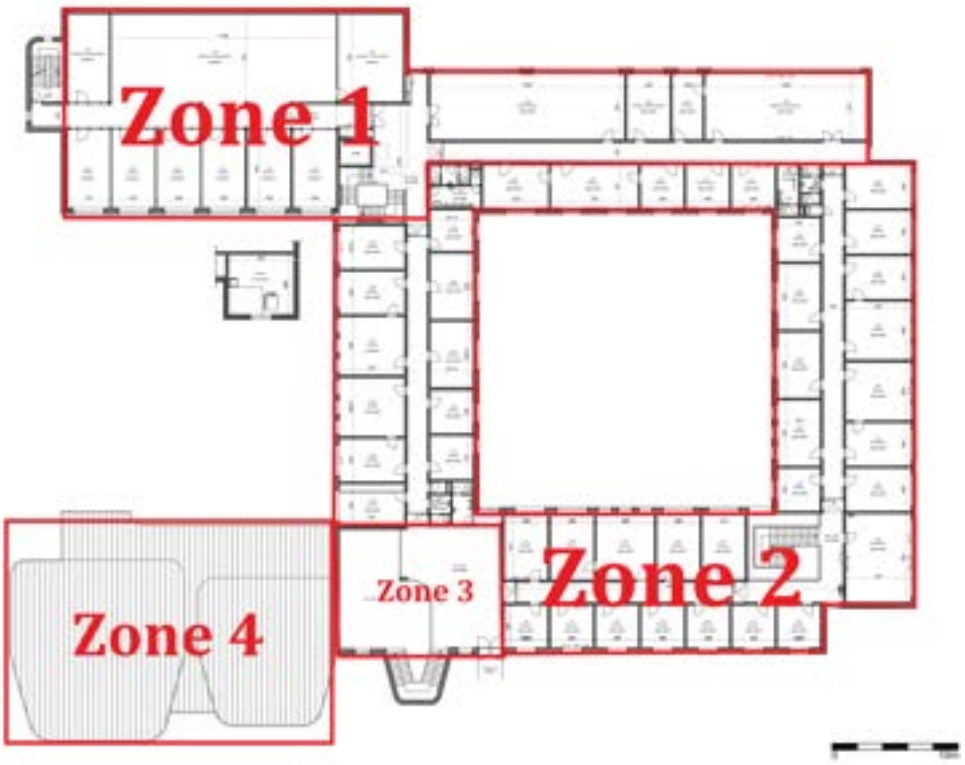

Figure 1: Building B37 first floor and its zones simplification.

The main air volume considers the large wavelength radiative heat exchanges and the radiative heat gain distribution, as well as the air infiltrations. It is very important to highlight the fact that the model computes the heat demand necessary to maintain the comfort conditions but does not assume any type of heating device used in the building and therefore imposes no restriction on level of temperature at which the heat should be delivered. This is done on purpose to focus on the energy demand as the building model is intended to be integrated to a district heating network for which different levels of temperatures can be considered. The

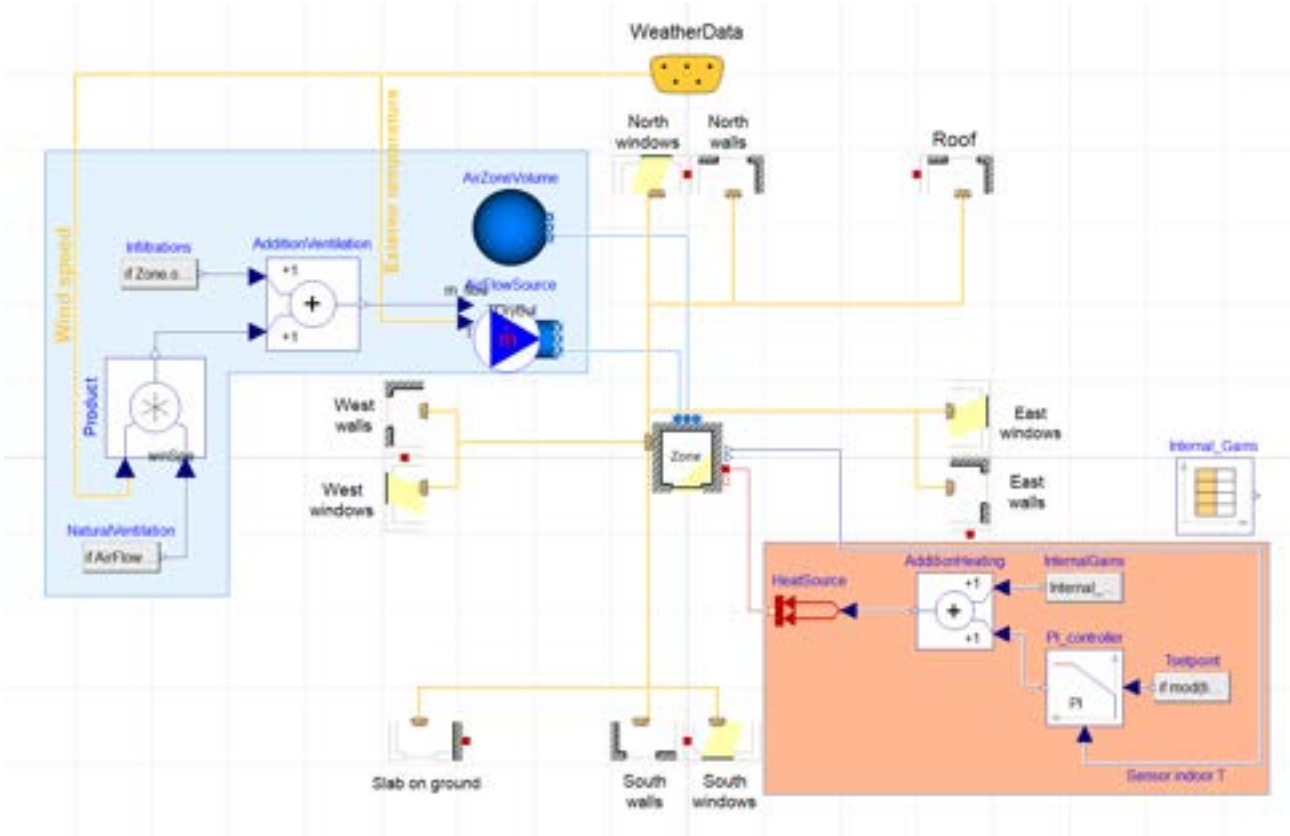

Figure 2: Dymola model for buildings zone model. The blue zone is the ventilation model, with infiltrations and natural ventilation based on wind speed. The red zone is the heating model which depends on the setpoint temperature, indoor temperature and internal gains. The weather data block contains the weather file. The walls, windows, roof and slab on ground models main parameters are the surface, the construction materials and the orientation.

necessary heating power to be extracted from the district heating network to maintain the indoor temperature is controlled by a PI controller comparing the measured temperature in the zone to the setpoint temperature.

The model for the ventilation is, for the time being kept at its simplest expression and considers only natural ventilation through window opening. When the indoor temperature rises above 23℃, the windows are open and the exchanged air flow rate is calculated based on the wind speed and the indoor and outdoor pressures. The heat transfers (by conduction, convection and radiation) between one zone and the adjacent ones or the exterior environment are considered in the exterior surfaces models. This model also takes into account internal free gains related to occupancy, lighting and appliances. A typical meteorological year weather file is linked to each building model in order to use external conditions such as temperature, solar radiation, humidity and wind speed.

The different data needed to make the building model described above are the main dimensions of the building required to estimate the heated volume and the exterior surface areas (solid and windowed), their orientation, the infiltration rate, the building materials, a local weather file and the usage of the building. By the *usage*, it is meant the control strategy, the occupancy level, the lighting and the appliances. This model is of course simplified but has the advantage of rapid development mainly because of the zone blocks that can be easily parameterised from accessible data. The most influencing parameters in terms of accuracy are the control strategy (schedule and setpoint), the occupancy, the building envelope and the air flow interactions (infiltrations and ventilation) (a more detailed explanation of these aspects can be found in [11]).

The construction of building models from the IDEAS library according to the proposed method has been developed on the basis of the test case of the International Energy Agency EBC Annex 60 [12]. To prove the easy scalability of the approach, an automated procedure to build the models for this test case has been realized. It allows an automatic model generation based on standard configurations customised according to the specific building location, orientation and size. This test case includes a set of 23 residential buildings, detached, semi-detached and terraced houses, and an office building. That approach proved to be satisfactory in terms of accuracy both individually and globally. In this contribution, an important question addresses the accuracy and feasibility of the approach on tertiary buildings where it is much more difficult to replicate

standard configurations.

2.2. District Heating Network Simulation

In this contribution a particular focus is put on the heat transport efficiency to satisfy the needs of the connected buildings. The basic brick of this network is the district heating piping made of one supply and one return pipe thermally insulated and buried into the ground. The model used for the pipes is the one collaboratively developed in the context of the Annex 60 Modelica Library and the IBPSA Project 1 Modelica Library [14]. This model is very simple to setup as it is based on a plug flow model (i.e., non-compressible fluid) to forecast the dynamic behaviour of the heat transport (i.e., the transport delays) and requires only the pipe length and diameter to be specified. The friction (i.e., pressure) and thermal losses are calculated to provide an accurate and complete picture of the transport losses. The general layout of the model is exhibited in Fig. 3 showing that all the buildings are connected by deriving a portion of the flow to supply heat to the substation. The only dynamic effect in the one-dimensional flow model is the thermal inertia. Both the mass and the momentum inertia are considered negligible on the time scale of one-hour which is the basic time step considered in this study.

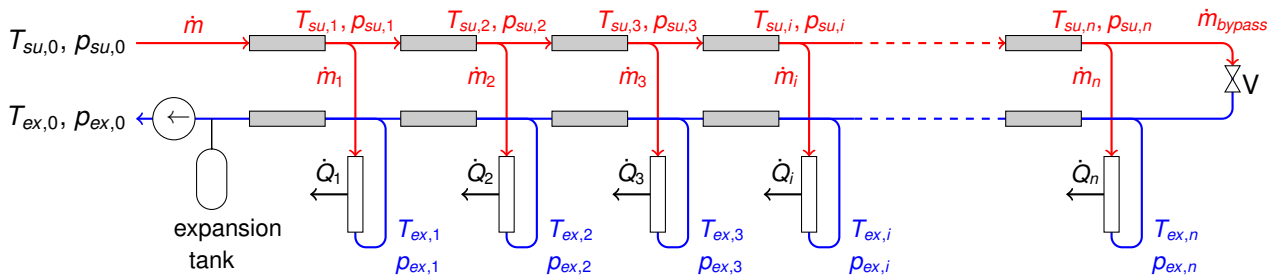

Figure 3: The model of district heating network where the pipes are in grey and the substation heat exchangers are in white. The supply flow is in red and the return flow is in blue.

The mass and momentum conservation involve:

$$\dot{m} = \sum_{i=1}^{i=n} \dot{m}_i + \dot{m}_{bypass} \text{ and } p_{su,i} - p_{ex,i} = K_{hex,i}\dot{m}_i^2, \tag{1}$$

together with pipe friction losses:

$$p_{su,i} - p_{su,i-1} = K_{su,i}\left(\dot{m} - \sum_{k=1}^{k=i-1} \dot{m}_i\right)^2 \text{ and } p_{ex,i-1} - p_{ex,i} = K_{ex,i}\left(\dot{m} - \sum_{k=1}^{k=i-1} \dot{m}_i\right)^2 \tag{2}$$

where $K_{hex,i}$, $K_{su,i}$ and $K_{ex,i}$ are constant characteristics of the heat exchanger and pipe configuration. The mass flow rate in the piping system is forced by a circulation pump with a characteristic:

$$p_{su,0} - p_{ex,0} = \frac{\Delta p_0}{N_{nom}^2} \cdot N^2 + c_2 \cdot \dot{m}^2, \text{ such that, } W_{pump} = \frac{\dot{m}}{\rho} \cdot (p_{su,0} - p_{ex,0}) \cdot \Delta t, \tag{3}$$

where Δp_0 is the no flow head at nominal rotational speed that is a function of the squared rotational speed, c_2 a constant specifying the nominal operating conditions and Δt is the considered time period. The rotational speed N is controlled by a PI controller between 20% and 100% of its nominal value so as to maintain the return temperature $T_{ex,0}$ at the setpoint value. For low flow conditions (i.e., that would correspond to $N < 20\%N_0$) the return temperature is allowed to fluctuate. An efficiency of 60% is considered to compute the electricity consumption of the pumps.

The only time dependency is due to the dynamic of the heat transport into the pipe introducing a delay between the entry temperature and the exhaust. Therefore, the pipe exhaust temperature $T_{su,i}(t)$ and the thermal losses $\dot{Q}_{loss,i}(t)$ depend on the past history of temperatures $\{T_{su,i-1}(0) \dots T_{su,i-1}(t)\}$ and mass flow rates $\{\dot{m}(0) \dots \dot{m}(t)\}$ and $\{\dot{m}_i(0) \dots \dot{m}_i(t)\}$. A similar reasoning holds for the return pipes. The detailed resolution algorithm used to determine the pipe exhaust temperature and thermal losses is beyond the scope of this contribution and the interested reader is merely referred to [14] for a more thorough information.

The supply temperature $T_{su,0}$ is ensured by a heat source (from the Modelica library *Buildings* [13]) representing the centralised heat generation. The return pipe temperature results from the heat extraction at each of the substation according to the building heat demand. Again for sake of simplicity, the heat transfer across

the substation is not fully modelled and the heat demand is directly extracted from the primary flow with a minimum bound on the exhaust temperature $T_{ex,i}$ in order to ensure it is always above the inner temperature of the building (plus the pinch point of the different heat exchangers) according to:

$$\dot{Q}_i = \min \left[\dot{m}_i \cdot c_p \cdot (T_{su,i} - T_{ex,i}) \; ; \; \dot{m}_i \cdot c_p \cdot (T_{su,i} - T_{ex,min}) \right] \tag{4}$$

where $T_{ex,min}$ is fixed according to the heat exchanger and substation configuration (here $T_{ex,min} = 35\,^{\circ}\text{C}$).

The different aforementioned equations are implemented in Modelica on the Dymola program with the hourly heat demand curves of the buildings as an input for the substation models. This implies that the indoor comfort conditions of the buildings are not evaluated inside the district heating network model. The goal of the network through the substation model is to satisfy the load as much as possible.

Finally, the network is equipped with a bypass circuit whose mass flow rate is controlled by a valve according to:

$$p_{su,n} - p_{ex,n} = K_{valve} \dot{m}_{bypass} \tag{5}$$

where again K_{valve} is constant characteristic. An expansion tank upstream of the pump is also installed to ensure a constant pressure $p_{ex,0}$ at the pump supply.

The independent variables are the supply temperature $T_{su,0}$, the return pressure $p_{ex,0}$, the setpoint for the return temperature $T_{ex,0}$ and the set of heat rates $\dot{Q}_i \; \forall i \in [1,6]$. With these boundary conditions and a suitable initial state of the system, the set of differential algebraic equations is solved by Dymola.

It is important to note that, according to equation 4, the required heat might not be available at the substation if the mass flow rate is not sufficient. If such conditions happen, there is no feedback on the building model to adapt the inner conditions accordingly to ensure the robustness of the resolution algorithm. Instead, an alarm is triggered that comfort conditions might not be met.

2.3. Case studies

2.3.1. Description

The objective of this test case is twofold. At first, it is intended to verify the accuracy of the model for tertiary buildings. The case of the university campus is particularly suited as lots of monitoring data are easily accessible for validation in terms in supply and exhaust temperature and mass flow rate. Secondly, the set of buildings is a good test to verify the integration of the building models into the district heating network in terms of robustness and accuracy. It is also a nice way to verify the scalability of the approach by replicating the procedure for the implementation of the model on existing buildings with very different characteristics.

The studied test case is the district heating network of the Polytech district on the Sart-Tilman campus of the University of Liège. This considered district is composed of 6 buildings: B28, B37, B47, B49, B52 and B65. They have various functions, such as classrooms, offices, laboratories, cafeteria, and a library. They, consequently, have different heating schedules or temperature settings. These buildings were also built in different time periods, between the 1970s and 2010s, and therefore have varying levels of insulation. The case studies only take into account the heating of the buildings and not the domestic hot water. The network is operated between 80 °C and 60 °C. The weather file used is a TMY file of the weather station of Uccle, the reference weather station in Belgium, with some modifications for the exterior temperature, to account for specific extreme conditions.

The reference case is based on the current use of the buildings and 6 buildings have been modelled and divided into zones based on the available existing drawings. The parameters specific to each building are collected namely, the heated volumes, the window areas, the wall orientations, the insulation materials, the heating schedules, the occupancy rates, the internal free gains and the setpoint temperature. For example, for the building B37, which is mainly an office and classroom building, the heating schedule is from 8 am to 5 pm, internal gains of a computer are considered by occupant, the temperature setpoint is 21 °C, etc.

The proposed model is particularly well suited for testing the influence of user behaviour as the inner setpoint temperature are easily accessible. Moreover, as the building model is essentially dynamic, transient effects due to thermal inertia are taken into account so that the effect of user behaviour on the heat demand can be expected to be accurately assessed.

Also changing thermal insulation and/or adding some insulation is straightforward and can be done by changing the value of different parameters, without having to rebuild the model from scratch. Quantifying load curve changes following a building modification is therefore quick and easy and can be done in less than 2 hours, computation time included. The time required depend on the number of zones and surfaces. The fewer zones and areas there are, the faster the modification, hence the interest in optimizing the zones and areas.

2.3.2. Change in user behaviour

The first modification to be considered is a change in user behaviour realised by modifying the inner setpoint temperature and to check the influence on the operation of the district heating network. For each building,

the setpoint temperature in each zone is lowered from 21 °C to 19 °C, while keeping all other parameters unchanged. This modification follows closely what happened during the energy crisis during the year 2022 and the results are great interest for the authorities of the university.

2.3.3. Insulation of the building stock

The second modification consists in increasing the thermal insulation of the building stock. Not all the buildings are equal with such a modification as some pretty old buildings will see their heat demand greatly influenced while more recent ones will not. Again, this case study reflects some of the actions taken by the authorities of the university to decrease on the long term the building energy consumption. The following rules are followed:

- For buildings with single glazing, replace the existing frames with new PVC and double glazing frames.
- For buildings already having double glazing, do not replace frames and glazing.
- For all buildings, add a 14 cm thick layer of glass wool insulation, in addition to any existing insulation.

Glass wool is an affordable and commonly used material. Its price ranges between 20 and 25 $€/m^2$ [1] and its thermal conductivity between 0.03 and 0.05 $W\,m^{-1}\,K^{-1}$ [15] which is superior to the insulation already installed on the buildings.

3. Results

3.1. Validation of the buildings models

Before proceeding to the different test cases, a validation phase is carried out to check whether or not the accuracy of the model is compatible with our application framework, namely the simulation of tertiary buildings. The simulation results of the 6 buildings of the Sart Tilman campus are compared to the available monitoring data in Table 1. Fig. 4 exhibits the heating demand curve of the B52 building offices during one winter day. It shows that the simulation results compare well to the monitoring results. The curves show the same pattern, with similar peak demands occurring at the same time of day. The root mean squared (RMS) error between the simulation results and the monitoring data is 85 kW. Accordingly, it can be concluded that the proposed methodology is applicable to tertiary building. In addition to the result accuracy, the modelling method allows the building models to be quickly setup (between half a day and two days depending on the number of zones in the building) and exhibits great robustness in terms of computation. Moreover, the standardisation of the approach enables different people to collaborate and associate their model as an input to the district heating network model.

Table 1: Buildings heating consumptions from monitoring data and simulation heating needs for the 3 scenarios [MWh]

	Monitoring data [MWh]	Reference scenario [MWh]	Scenario A [MWh]	Scenario B [MWh]
B28	642	544	482	299
B37	242	186	162	160
B47	Not available	66	59	44
B49	Not available	112	89	89
B52	1396	1219	1062	1129
B65	17	13	10	11
Total	/	2140	1864	1732

3.2. Impact on peak load and buildings annual energy consumption

As detailed in the previous section, two improvement scenarios are considered: the so-called *scenario A* where the setpoint is decreased to 19 °C and the *scenario B* consisting of an increased thermal insulation.

An interesting point of view is to compare the load curves of the different scenarios as exhibited in Fig. 5 and representing the cumulative number of hours during which a certain level of power is at least required. The intercept of the load curve with the y-axis (the heating power) is the peak load which is unchanged for scenario A with respect to the reference case while scenario B exhibits a decreased peak load from 3.9 MW to 3.5 MW (minus 10 %). The area under the load curve being the total energy consumed within a year, Fig. 5 shows that the reference case forecasts an annual energy demand of 2140 MWh which decreases to 1864 MWh and 1732 MWh respectively for the scenarios A and B respectively. The energy savings are therefore respectively 13% and 19% for each of the two variants.

[1] https://conseils-thermiques.org/contenu/laine-de-verre.php

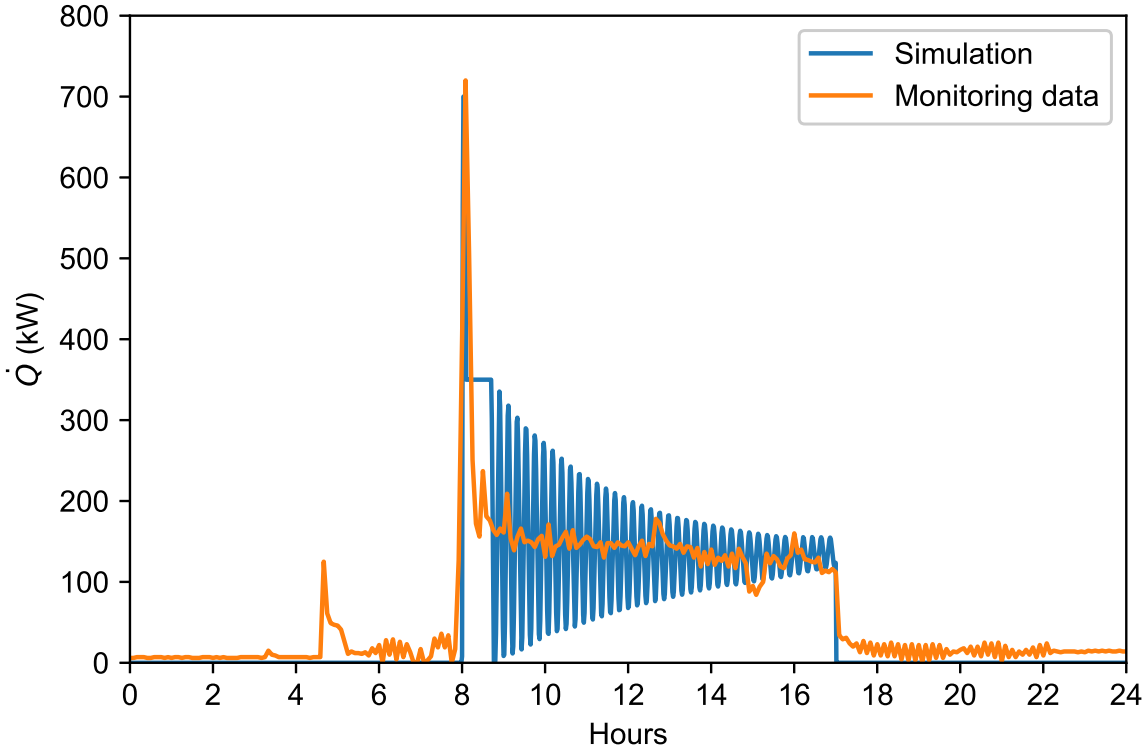

Figure 4: Heating demand profile of B52 offices over a winter day in 2022, simulation and monitoring results. RMS error over the year is 85 kW.

If one take a closer look at a smaller scale for the different buildings, it is is also insightful to see the discrepancies between the efficiency of one single measure on different buildings. Table 1 contains the simulated annual heating consumption for the three cases and the six buildings. It is interesting to see that already insulated buildings are less sensitive to energy saving measures. Indeed, for scenario B, with the added insulation layer, the average energy saving is around 23%. But by focusing on already insulated buildings, this economy is only of 12%, while it is of 33% for older buildings. For scenario A, the average energy savings are around 15%, and the results are quite similar for insulated and not insulated buildings. The conclusion is that a decrease of the setpoint temperature allows a uniform savings on the whole buildings, while the massive insulation of the building stock gives better energy savings on the least well insulated buildings.

3.3. Impact on electrical consumption of pumps and thermal losses

Heat transport efficiency is defined here as the ratio between the heat delivered to the building to the heat supplied to the district network and is a very important performance indicator, yet not the only one, as it characterises the rational energy use.

Table 2 summarizes the annual energy supplied to the district heating network, the annual heat losses and the annual pumping electricity consumption for the three considered cases. Reducing the setpoint temperature to 19 °C decreases energy consumption (minus 8.3%) while insulating the buildings results in an energy saving of 12.3%. In terms of electricity consumption from the pumps, the savings are 10.9% and 19.6% respectively for scenarios A and B.

This can readily be understood by a decrease of the mass flow rate for scenarios A and B which has a major effect on pumping consumption that is directly proportional to the mass flow rate while thermal losses are not significantly impacted as they are mainly driven by the pipe diameter and the supply and return temperatures that remained constant across the different test cases.

The heat losses represent 38.2% of the total injected energy into the district heating network for the 19 °C case. This figure goes to 40.0% for the scenario B, against 34.5% for the reference case. This shows that in the reference case, 65.5% of the energy consumed by the entire network is used for buildings heating while for the two scenarios this figure decreases to 61.8% and 60.0% of the total energy supply.

Heat transport efficiency might be a misleading figure as improving the energy efficiency of the buildings de-

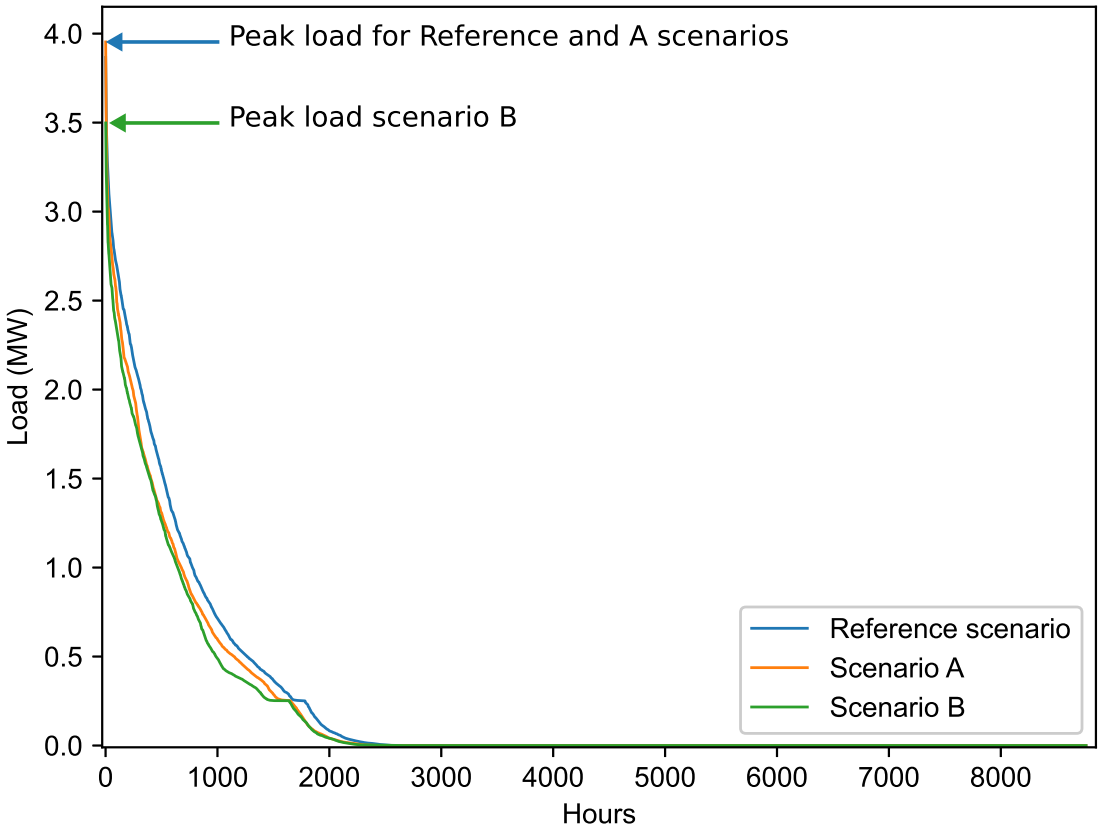

Figure 5: Overall load duration curves for the reference scenario and the two variants.

creases the energy efficiency of the network. Yet, one must bear in mind that the total energy input decreased but the transport losses are more difficult to decrease.

Moreover, the present analysis is purely made on an energy basis but the economic and/or environmental cost of heat and electricity should be taken into account. Nonetheless, these discussions also show that energy saving policies on building connected to district heating network cannot be done without studying the consequences on the operation of the network.

Table 2: DHN energy supply, heat losses and electrical pump consumption for the 3 cases (expressed in MWh)

	Reference scenario [MWh]	Scenario A [MWh]	Scenario B [MWh]
DHN energy supply	3292	3018	2886
DHN heat losses	1152	1154	1154
Electrical pump consumption	46	41	37

4. Conclusion

This work is primarily dedicated to the development of an integrated approach of building energy simulation for large building stock. This modelling approach allows a quick yet accurate simulation so as to obtain hourly buildings heat demand. The final objective is to connect these building models to a district heating network model. The knowledge of the load curves and peak demand (both in time and amplitude) has been shown to be essential. The main assumptions have been explained to introduce the building simulation model, based on the IDEAS Modelica library providing ease of use and robustness.

One important question also concerned the validity of the approach, already validated for residential building, for the tertiary buildings that are more heterogeneous in nature and use. The test case presented herein tends to demonstrate that the approach is purposeful both from a practical (it is easily scalable) and from an accuracy

point of view. The different models have been validated based on monitoring data showing that both the peak demand and the annual energy consumption represent faithfully the actual situation.

One important aspect characterising the present approach is that most of the methodologies for large scale building simulation are based on a top-down approaches starting from the annual energy consumption (based on benchmark) spread across the year on an hourly basis using pre-defined daily profiles and average daily or hourly temperature profiles. Contrarily, the presented method is a bottom-up approach based on the structure and use of the building able to predict both the peak demand and annual energy accurately thus providing a straightforward way to forecast the efficiency of energy saving measures.

In a second step, two energy saving scenarios are applied to evaluate their impact on the load curve and, in turn, on the operation of the district heating network. The considered energy saving measures are a modification of the setpoint temperature in the buildings and an increased insulation of the building envelope. The main conclusions drawn from the simulations is that when a district heating network is used it is very difficult to separate building energy saving measures from the network operation/design.

The presented model still requires some improvements mainly on the side of a better regulation by adapting more actively the supply temperature to the heat demand to decrease the thermal losses. The model of the substation also needs to be improved to avoid the recourse to a minimum exhaust temperature and model the heat exchanger efficiency to forecast the maximum heat demand supplied by the substation. However, the basic philosophy of the different developed models seems to be purposeful to consider very large district with thousands of buildings.

Nomenclature

$\dot{m}$	mass flow rate, kg/s
p	pressure, Pa
K	pressure drop coefficient, $kg^{-1}m^{-2}$
N	pump rotation speed, rpm
W	pump work, J
ρ	density, kg/m^3
$\dot{Q}$	power, W
$\dot{T}$	temperature, K
c_p	specific heat, J/(kgK)

Subscripts and superscripts

i	substation index
su	supply to the substation
ex	exhaust of the substation

Abstract:

In the research field of district heating networks (DHNs), there is a need for more analysis on the economic optimization of the design and dynamic operation considering precise representations of the temperature and pressure drops in the pipes of the system. In this study, we develop a model tested in an academic case study of a DHN composed of a production unit, a distribution network, and twenty consumers. The dynamic behavior of the DHN is due to the variability of the heat demand and ambient temperature over a daily period. Inside the pipes, the temperature variation is described by a dynamic one-dimensional heat transfer equation while the pressure drops are computed using the Darcy-Weisbach equation. Energy and mass balances are applied in the interconnecting nodes of the system. In addition, the model includes design and operational constraints of the DHN. All these equations lead to a partial differential algebraic equation (PDAE) problem. Using the method of orthogonal collocation on finite elements (OCFE), the differential terms are discretized to obtain a set of algebraic equations. The resulting non-linear programming (NLP) problem is solved with an equation-oriented (simultaneous) approach using the solver CONOPT. The aim of the optimization is to find the best trade-off between the capital expenditures (CAPEX) of the pipes and the operational expenditures (OPEX) by considering the pipe diameters, temporal values of mass flows and spatio-temporal values of temperatures of each pipe as continuous optimization variables. The CAPEX include the cost of the pipes and the cost of deploying them in trenches. The OPEX include both production and pumping costs which are related to thermal losses and pressure drops, respectively. As the pumping cost is significantly lower than the heat production cost, the results showed that it is more economical to reduce the thermal losses than the pressure drops.

1. Introduction

Heating and cooling demand accounts for around half of global final energy consumption. Nearly half of this energy is used in industrial processes, 46% is used in residential and commercial buildings mainly for space and water heating. Most of the energy used for heating and cooling continues to be produced from non-renewable sources. Consequently, heating and cooling is responsible for 40% of energy-related greenhouse gas emissions [1]. The development of district heating and cooling (DHC) systems is a good answer to face these energy and environmental issues. This technology has the advantage of accelerating energy transition by integrating an important part of renewable sources and waste heat. Due to their considerable investment and operational costs, currently in the energy field, one of the important challenges is the development of tools and methods for the optimization of DHC networks.

According to how the time dependency is taken into account in the model, it is possible to classify the works on the optimization of DHC into four main categories: steady-state, quasi-steady-state, dynamic multi-period, and dynamic. In the steady state models, the optimization is performed with no time dependency considering averaged values for the operating parameters like mass flows and temperatures in the system. In most of the cases, the optimization problem is of the mixed integer programming type [2–4]. In [2] and [3] mixed integer linear programming (MILP) approaches are used for the optimizations of the operational cost and the total annual cost, respectively. Linear equations for the computation of thermal losses and pressure drops in the pipes are defined. In [4], the authors chose a mixed integer non-linear programming (MINLP) approach where the global cost of a district heating network (DHN) is optimized over 30 years. The thermal losses and pressure drops were computed with more precise equations. For the 3 previous studies, the discrete variables represent the design choices (connection in the topology nodes and/or the choices of production technologies). On the

other hand, the continuous variables represent the operating parameters (production power, flows, temperatures, …). The authors of [5] opted for a non-linear programming (NLP) resolution where they used a numerical continuation strategy that gradually forces the design variables towards discrete choices. Steady-state models are interesting for long-term studies, but one of their main drawbacks is not considering a variable heat demand.

In what we classified as quasi-steady-state studies, it is possible to consider different values of the heat demand. The optimization is performed within a time interval which is subdivided into periods. For each period, the heat demand is averaged. The problem is a succession of steady-state problems. In this type of studies, Liu et al. [6] modeled an optimization of design parameters of a solar heating network. They took into account only discrete decision variables which were the network layout variables and pipe diameters. Sameti and Haghighat [7] studied the optimal design and operation of a DHN with a cogeneration unit. A MILP model was employed, and different buildings with different heat demands were considered. This kind of model is suitable for medium-term studies; however, it presents limits with dynamic aspects. As it does not include differential equations, for example, it is impossible to have the evolution of a thermal energy storage (TES) tank from one period to another.

In terms of time discretization, the studies we classify in the dynamic multi-period approach are quite similar to the previous category. The main difference is that they include at least one differential equation. In this category, Deng et al. [8] developed a MINLP model to perform what they called an optimal scheduling of a DHC. For each period, they define whether the technology is working or not, and the amount of power it produces (or charges/discharges in case of storage). Wirtz et al. [9] were also interested in the choice of technologies and the amount of produced and stored power of a DHC with multiple production technologies and TES. In addition, they optimized the temperature in the distribution network and the thermal losses. We have also Söderman [10] who optimized the topology and the operation to minimize the total annual cost of a district cooling network (DCN). He considered different consumers with different heat demands in each period. Another interesting study is the optimization of Khir and Haouari [11] of a DCN. They optimized chiller plant capacity, storage tank capacity, piping network size and layout, and produced and stored power during every period. In their operation, they ensure that supplied temperature corresponds to the desired one and that pressure drops are within the allowable limits. This type of works is suitable for medium-term studies with inclusion of dynamic aspects. In contrast, as they consider an important time step (≥ 1 hour), it is difficult to perform real-time control and/or to have precise evolutions of physical phenomena in the pipes.

What we chose to classify as dynamic approaches are the works that considered a small time step (<1 hour) and a short period of study (1-3 days generally). Two sub-categories can be distinguished, the studies that are for real-time optimization and the ones for dynamic offline optimization. In real-time models, Cox et al. [12] used a genetic algorithm to have the optimum control strategy of the operation of chillers and ice storage of a DCN. Lu et al. [13] developed a NLP optimization for the regulation of the operating parameters of a DHN. The limit with real-time models is that they require the calculation of the command in a short time. Therefore, they do not have precise thermo-hydraulic modeling of the pipes. This is where the interest of dynamic offline optimization (DOO) comes in with the possibility of having longer computation time; therefore, more accurate modeling of the pipes. In the DOO, Schweiger et al. [14] proposed a methodology to decompose a MINLP optimal control problem of a DHN into two sub-problems. A mixed problem to minimize the operational cost and a continuous one to minimize the production temperature. Nova Rincon et al. [15] studied another aspect of the optimal operation of a DCN. To avoid the technical issue of “Low ΔT syndrome” which reduces the efficiency of the system, they optimized the mass flows and temperatures in the distribution network to minimize the difference between the outlet temperature of consumers and a design outlet temperature. As they solve differential equations with a small time step, the DOO approaches have significant resolution times. To our knowledge, this is why we do not find studies that optimize at the same time the design and the dynamic operation of a DHC with accurate thermo-hydraulic modeling of the pipes. The originality of this work is that we conduct an optimization of the pipe diameters and the dynamic operation of a DHN with an economic objective function while having a precise modeling of the pipes.

In this study, we present a methodology for the optimal operation of an academic case study of a DHN comprised of twenty consumers over a daily study period. In addition to the optimization of mass flows and temperatures in the distribution network, the pipe diameters are also optimized. Considering a variable ambient temperature, a dynamic one-dimensional heat transfer equation is used to define the temperature evolution in the pipes. The Darcy-Weisbach equation is employed to compute the pressure drops in the distribution network. In the following parts, firstly we expose the case study. Secondly, we introduce the physical, the design and the operational constraints in addition to the objective function of the problem. Finally, we present the results and conclusions.

2. Case study

For this study, we used the same topology of the network presented in Figure 2 of [15] that serves 20 different consumers. In the outward path, there are 41 pipes, 21 main pipes ($0 - 20$) and 20 lateral pipes ($in_1 - in_{20}$). The lateral pipes are directly connected to the consumers through a sub-station unit where the thermal power

is transferred from the distribution network to the consumer's heating system. The return path is also comprised of 41 pipes that are parallel to the outward path ($0_r - 20_r$ and $out_1 - out_{20}$). The network is then constituted by 1 production unit, 20 substations and 82 pipes with a total length close to 19 km. In what follows, we use k as the index for all the pipes, p, p_r, in_p and out_p as the sub-indexes for main outward pipes, main return pipes, lateral pipes entering consumers and lateral pipes leaving consumers, respectively.

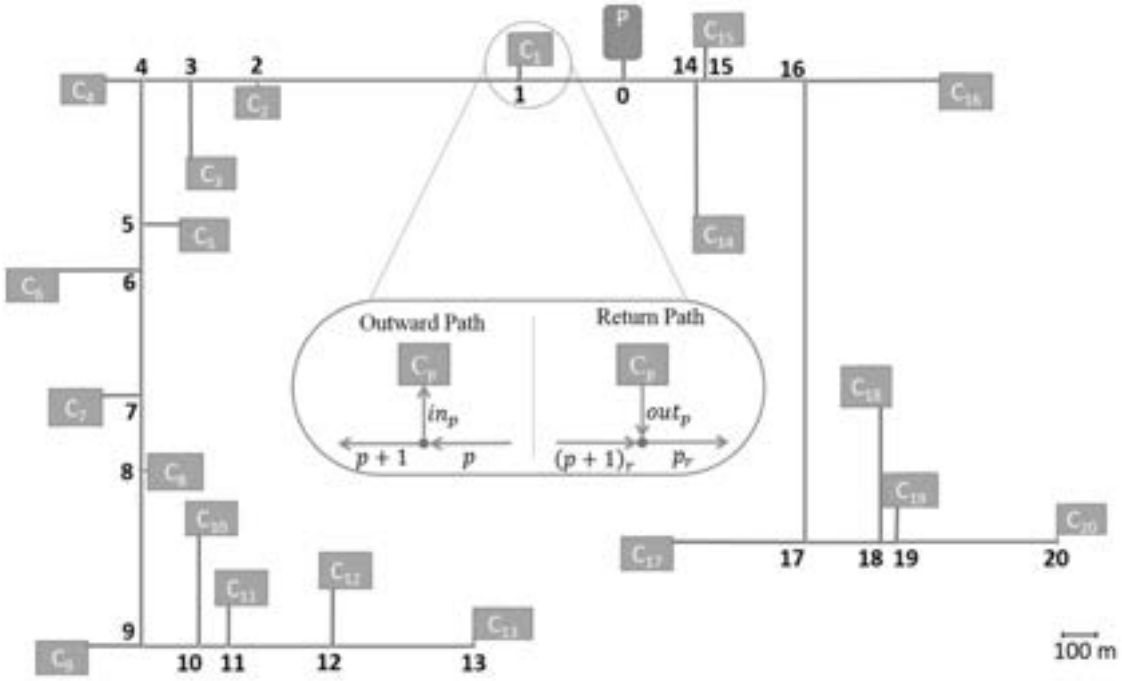

Figure 1. Representation of the network's configuration [15].

Concerning the heat demand, the same daily profiles used in district B of [16] are taking into account. Two types of profiles are considered, one for residential buildings, and one for commercial buildings. Table 1 shows the distribution of the type of buildings and their peak demand. The two profiles are represented as a function of the peak demand of each consumer as shown in Figure 2. To have a continuous representation of the two types of profile over time, a fit function was introduced for each profile. The two heat demand profiles of Figure 2 are defined by a sum of sinusoidal functions of the form:

$$Demand(t) = \sum_{i=1}^{8} \alpha_i \cdot \sin(\beta_i \cdot t + \gamma_i) \quad (1)$$

where α_i, β_i and γ_i are coefficients of the demand function.

Table 1. Type of consumers and their peak demands.

Consumer	Type	Peak demand	Consumer	Type	Peak demand
C_1	Commercial	1500	C_{11}	Commercial	720
C_2	Commercial	1260	C_{12}	Residential	180
C_3	Residential	360	C_{13}	Residential	450
C_4	Commercial	1440	C_{14}	Commercial	1500
C_5	Residential	210	C_{15}	Commercial	1050
C_6	Commercial	1020	C_{16}	Commercial	540
C_7	Residential	240	C_{17}	Commercial	990
C_8	Commercial	600	C_{18}	Commercial	1200
C_9	Commercial	990	C_{19}	Commercial	1170
C_{10}	Commercial	420	C_{20}	Commercial	1110

In Figure 3, the total heat demand of the network is represented. Its evolution is quite the same as the one of the commercial demand, because there are 15 commercial buildings in this case study and they have a higher peak demand than residential buildings. In the same figure, we also have the ambient temperature evolution which is one of a not very cold winter day.

3. System modeling

The model of the DHN is comprised of energy and mass conservation equations at each node and sub-station of the system. Inside every pipe, a heat transfer equation describes the temperature evolution. In this latter,

the mass flow is time dependent, while the temperature is time and space dependent. In addition, the Darcy-Weisbach equation describes the dynamic evolution of pressure drops in the pipes. In the following parts, we will detail the different equations of the system. These equations represent the physical, design and operational constraints of the optimization problem.

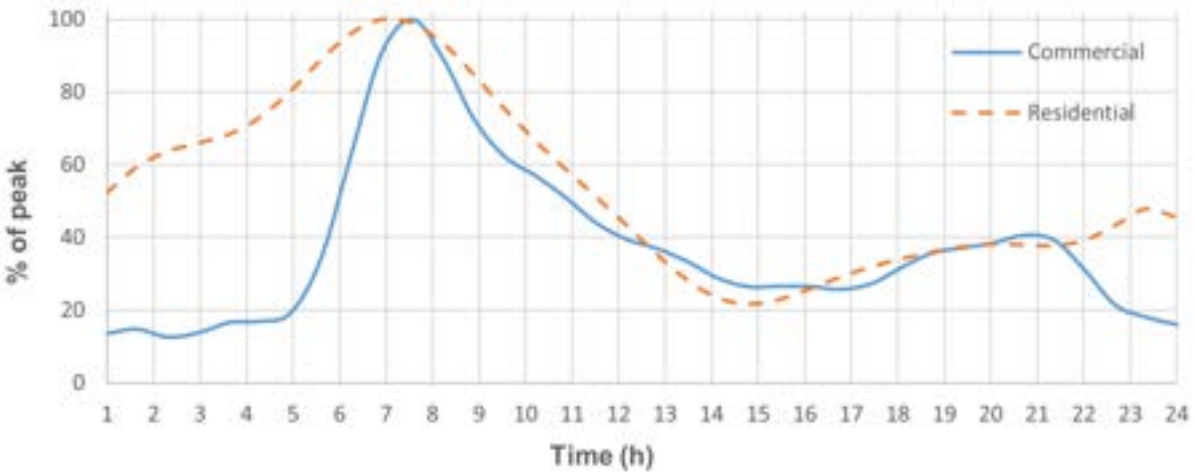

Figure 2. Heat demand profiles.

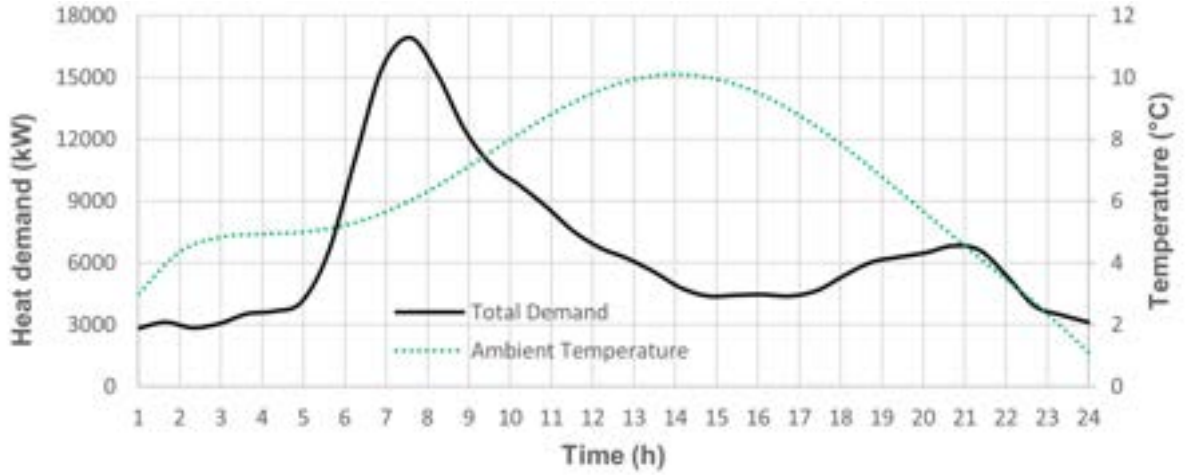

Figure 3. Total heat demand and ambient temperature profiles.

3.1. Production unit, nodes and sub-station

At the production level, we consider one fixed technology that delivers the hot water at a constant temperature:

$$T_{p=0}(t, x = 0) = constant \quad (2)$$

At every interconnecting node of the network, the mass balance is applied. For the outward path, we have:

$$\dot{m}_p(t) = \dot{m}_{p+1}(t) + \dot{m}_{in_p}(t) \quad p = 1 \dots 12, 14 \dots 19$$

$$\dot{m}_p(t) = \dot{m}_{in_p}(t) \quad p = 13, 20 \quad (3)$$

$$\dot{m}_0(t) = \dot{m}_1(t) + \dot{m}_{14}(t)$$

For the return path, we have:

$$\dot{m}_{p_r}(t) = \dot{m}_{(p+1)_r}(t) + \dot{m}_{out_p}(t) \quad p = 1 \dots 12, 14 \dots 19$$

$$\dot{m}_{p_r}(t) = \dot{m}_{out_p}(t) \quad p = 13, 20 \quad (3)$$

$$\dot{m}_{0_r}(t) = \dot{m}_{1_r}(t) + \dot{m}_{14_r}(t)$$

In the outward path, the nodes are splitters so the temperature entering the node is equal to the temperature leaving it:

$$T_p(t, x = L_p) = T_{p+1}(t, x = 0) = T_{in_p}(t, x = 0) \quad p = 1 \dots 12, 14 \dots 19$$

$$T_p(t, x = L_p) = T_{in_p}(t, x = 0) \quad p = 13, 20 \tag{4}$$

$$T_0(t, x = L_p) = T_1(t, x = 0,) = T_{14}(t, x = 0)$$

In the return path, the nodes are mixers. We apply an energy balance considering the equality between the inlet and outlet enthalpy flows. Assuming a constant specific heat capacity between the inlet and the outlet, the equation is:

$$\dot{m}_{p_r}(t) \cdot T_{p_r}(t, x = 0) = \dot{m}_{(p+1)_r}(t) \cdot T_{(p+1)_r}(t, x = L_{(p+1)_r}) + \dot{m}_{out_p}(t) T_{out_p}(t, x = L_{out_p}) \quad p = 1 \dots 12, 14 \dots 19$$

$$T_{p_r}(t, x = 0) = T_{out_p}\left(t, x = L_{out_p}\right) \quad p = 13, 20 \tag{5}$$

$$\dot{m}_{0_r}(t) \cdot T_{0_r}(t, x = 0) = \dot{m}_{1_r}(t) \cdot T_{1_r}(t, x = L_{1_r}) + \dot{m}_{14_r}(t) T_{14_r}(t, x = L_{14_r})$$

L, $\dot{m}(t)$ and $T(x, t)$ are the pipe length, mass flow and temperature of water in the pipes. x and t represent the time and distance dependencies.

The sub-station unit is also defined by mass and energy balance equations. The flow going from the outward path to the substation is equal to the flow going from the substation to the return path. Assuming a constant specific heat capacity, the energy balance is defined to have a difference in enthalpy flows between the inlet and the outlet equal to the demand. The conservation equations of the sub-station are:

$$\dot{m}_{in_p}(t) = \dot{m}_{out_p}(t) \quad p = 1 \dots 20 \tag{6}$$

$$Demand(t) = \dot{m}_{in_p}(t) \cdot \mathrm{c}_w \cdot \left[T_{in_p}(t, x = L_{in_p}) - T_{out_p}(t, x = 0)\right] \quad p = 1 \dots 20 \tag{7}$$

c_w is the specific heat capacity of water.

3.2. Thermal model of the pipe

As stated in [17], the choice of an adequate pipeline model that gives a good trade-off between accurate physics and computing costs is a key challenge for DHN optimization. As proposed in previous studies [14,18,19] we use a one-dimensional energy balance in the pipe which is described by the partial differential equation (PDE) written in Eq. (8). This heat transfer equation is submitted to the following assumptions:

- Plug flow
- Neglected axial conductive heat transfer in the fluid
- Material properties are constant and independent of temperature
- Thermal interaction between the supply and return pipes is not included
- Thermal inertia of the pipes, casing and insulation is neglected

$$\rho \cdot c_w \cdot A_k \cdot \frac{\partial T_k(t,x)}{\partial t} + \dot{m}_k(t) \cdot c_w \cdot \frac{\partial T_k(t,x)}{\partial t} = \frac{T_s(t) - T_k(t,x)}{R_k(t)} \tag{8}$$

$$k = \{0, \dots, 20, 0_r, \dots, 20_r, in_1, \dots, in_{20}, out_1, \dots, out_{20}\}$$

ρ and A are the water density and cross section area, respectively. $R(t)$ represents the total dynamic thermal resistance per unit length of pipe and $T_s(t)$ is the temperature of the soil surface.

The total thermal resistance over time $R(t)$ depends on the thermal conductivities of the pipe, insulation, casing and soil. $R(t)$ depends also on the internal convective heat transfer between the water and the inner wall of the pipe and is given by [18]:

$$R_k(t) = \frac{1}{2\pi r_{a_k} \bar{h}_k(t)} + \frac{\ln\left(\frac{r_b}{r_{ak}}\right)}{2\pi\lambda_{ab}} + \frac{\ln\left(\frac{r_c}{r_b}\right)}{2\pi\lambda_{bc}} + \frac{\ln\left(\frac{r_d}{r_c}\right)}{2\pi\lambda_{cd}} + \frac{1}{S_k \lambda_s} \tag{9}$$

where λ_{ab}, λ_{bc}, λ_{cd} and λ_s represent the thermal conductivities of the pipe, insulation, casing and soil, respectively, and r_a, r_b, r_c and r_d are the different radiuses from the inner wall of the pipe to the casing, as it is shown in Figure 4.

S is the conduction shape factor, for $d > 3r_d$, it can be approximated by [20]:

$$S_k = \frac{2 \cdot \pi \cdot L_k}{\ln\left(\frac{4 \cdot d}{2 \cdot r_d}\right)} \tag{10}$$

where d is the distance between the pipe axis and the soil surface.

$\bar{h}(t)$ is the convective heat transfer coefficient over time averaged for the entire length of the pipe, it is computed by:

$$\overline{h_k}(t) = \frac{\overline{Nu_k}(t) \cdot \lambda_w}{D_{a_k}} \tag{11}$$

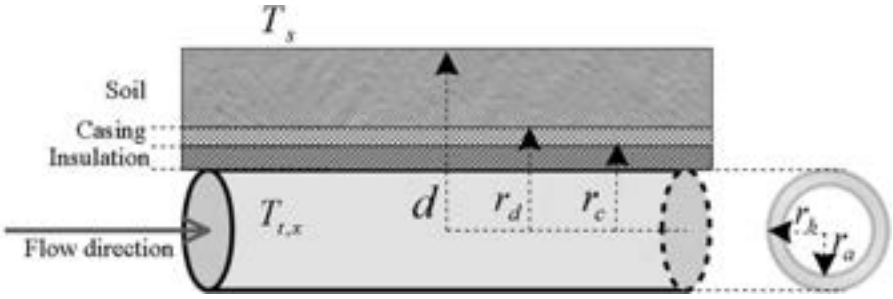

Figure 4. Representation of the buried pipe [15].

where D_a is the pipe internal diameter ($D_a = 2r_a$), $\overline{Nu}(t)$ is the Nusselt number over time averaged for the entire length of the pipe and λ_w is the thermal conductivity of water. Assuming that the system operates under a turbulent regime (Reynolds ≥ 9000), we use the correlation of Dittus-Boelter [21] to compute the Nusselt number in a circular tube:

$$\overline{Nu}_k(t) = 0.023 \cdot (Re_k(t))^{0.8} \cdot Pr^{0.4} \tag{12}$$

$Re(t)$ and Pr are the Reynolds number over time and the Prandtl number, respectively:

$$Re_k(t) = \frac{2 \cdot \rho \cdot v_k(t) \cdot D_{a_k}}{\mu} \tag{13}$$

$$Pr = \frac{\mu \cdot c_w}{\lambda_w} \tag{14}$$

$v(t)$ and μ are the flow velocity over time and dynamic viscosity of water, respectively.

3.3. Hydraulic model of the pipe

The work of the pumps in the distribution network is directly related to the pressure drops. For each pipe, to compute the linear pressure drops, the Darcy-Weisbach equation is used:

$$\Delta P_{linear_k}(t) = f_k(t) \cdot \frac{L_k}{D_{a_k}} \cdot \rho \cdot \frac{[v_k(t)]^2}{2} \quad k = \{0, \dots, 20, 0_r, \dots, 20_r, in_1, \dots, in_{20}, out_1, \dots, out_{20}\} \tag{15}$$

$f(t)$ represents the friction factor over time which depends on the flow regime and the rugosity of the pipe. For $4 \cdot 10^3 \leq Re \leq 10^8$ and a relative roughness ε/D smaller than 10^{-2}, it can be computed by the form of Colebrook-White equation proposed by Moody [22]:

$$f_k(t) = 0.0055 \left\{ 1 + \left[2 \cdot 10^4 \left(\frac{\varepsilon}{D_{a_k}} \right) + \frac{10^6}{Re_k(t)} \right]^{1/3} \right\} \tag{16}$$

We assume that we have smooth pipes, which means $\varepsilon/D_{a_k} = 0$. The singular pressure drops are assumed to be equal to 30% of the total pressure drops [4]. In each branch, the total pressure drop is equal to the sum of the linear and singular pressure drops. As we have parallel connections, we choose the longest path to compute the linear pressure drops. For the left branch (LB), the pressure drop is:

$$\Delta P_{Total_{LB}}(t) = \frac{1}{0.7} \sum_{k_{LB}} \Delta P_{linear_k}(t) \tag{17}$$

with: $k_{LB} = \{1, \dots, 13, 1_r, \dots, 13_r, in_{13}, out_{13}\}$

For the right branch (RB), the pressure drop is:

$$\Delta P_{Total_{RB}}(t) = \frac{1}{0.7} \sum_{k_{RB}} \Delta P_{linear_k}(t) \tag{18}$$

with: $k_{RB} = \{14, \dots, 20, 14_r, \dots, 20_r, in_{20}, out_{20}\}$

The fact that the LB is longer and serves more consumers than the RB, suggests that the $\Delta P_{Total_{LB}}(t)$ should be higher than the $\Delta P_{Total_{RB}}(t)$. We assume that at every time step, the pressure drop of the LB is higher than the one of the RB. We also neglect the singular pressure drops in the pipes 0 and 0_r. The electrical power required for the pump is:

$$Pw_{pump}(t) = \frac{\dot{m}_0(t)}{\eta\rho}\left[\Delta P_{linear_0}(t) + \Delta P_{linear_{0_r}}(t) + \Delta P_{Total_{LB}}(t)\right] \quad (19)$$

η is the pump efficiency, it represents the total efficiency of the pump which includes mechanical, transmission and motor efficiencies. η is assumed to be equal to 70%.

Depending on the inner diameter of the pipe, a maximum flow velocity is recommended, which limits the specific pressure drop over the pipe length. A threshold of maximum specific pressure drop of 100-150 Pa/m is common to avoid corrosion and increased pumping energy [23]. Using the recommended flow velocities for sizing pipes reported in [24], we imposed an inequality constraint on each pipe to don't exceed a maximum flow velocity per diameter:

$$v_k(t) \leq v_{max_k} \quad (20)$$

We consider that every consumer have to respect a contractual outlet temperature, for this purpose we defined this equality constraint:

$$T_{out_p}(t, x = 0) = constant \quad p = 1 \dots 20 \quad (21)$$

In order to have values that are available in reality, the diameters of the pipes are bounded to a maximum value of 0.57m that is based on the commercial availability of PVC pipes:

$$D_{a_k} \leq 0.57 \quad (22)$$

The set of Eq. (2) to (22) represent the equality and inequality constraints of the optimization problem, resulting in a partial differential algebraic equation (PDAE) system. The orthogonal collocation on finite elements (OCFE) method was used to discretize the PDE (8) in order to transform the PDAE system into a set of algebraic equations. The details of the implementation of the OCFE and the discretized mathematical model of the system are presented in the appendices A and B of [15], respectively.

4. Objective function

The objective function includes the operational expenditures (OPEX) of the system and the capital expenditures (CAPEX) of the pipes. The OPEX comprise both heat production and pumping costs. The heat production cost "$Cost_{prod}$" is obtained by multiplying the total thermal energy produced over the day by the unit cost of heat production:

$$Cost_{prod} = c_{hot} \cdot \int_1^{24} Pw_{hot}(t)\, dt \quad (23)$$

$$\text{with: } Pw_{hot}(t) = \dot{m}_0(t) \cdot c_w \cdot \left[T_0(t, 0) - T_{0_r}(t, L_{0_r})\right] \quad (24)$$

c_{hot} is the unit cost of heat production, its unity is (€/MWh), $\dot{m}_0(t)$ is the production mass flow (kg/s) and $T_0(t, 0)$ and $T_{0_r}(t, L_{0_r})$ are the production and return temperatures, respectively. The total thermal energy produced is computed by integrating with respect to time the thermal power $Pw_{hot}(t)$ which is equal to the difference between the enthalpy fluxes of production and return.

The pumping cost "$Cost_{pump}$" is the product of the total pumping energy over the day and the unit cost of electricity:

$$Cost_{pump} = c_{elec} \cdot \int_1^{24} Pw_{pump}(t)\, dt \quad (25)$$

c_{elec} represents the unit cost of electricity, its unity is (€/MWh). The pumping power of the network $Pw_{pump}(t)$ is integrated over the day to obtain the total pumping energy. As Gaussian quadrature methods are suited for the computation of integrals when the OCFE is used, for the resolution of the integrals presented in Eq. (23) and Eq. (25) the Gauss-Lobatto quadrature was employed.

The investment cost of the pipes "$Cost_{inves}$" which includes the cost of the pipes and the cost of deploying them in trenches is represented by a linear function as follows:

$$Cost_{inves} = \sum_k L_k \cdot (\alpha D_{a_k} + \beta) \quad (26)$$

Values of investment cost of different nominal diameter by unit length were given by a French company which operates DHN. Using these values, we create a linear regression to have a continuous representation of the cost depending on the diameter. Considering that the DHN of this case study has a lifetime of 30 years, we transform the coefficients of the linear regression (α and β) to have an investment cost for one day.

Using a Lagrange problem type formulation, the objective function is the sum of the three costs defined above:

$$\min_{\substack{D_{a_k} \\ \dot{m}_k(t) \\ T_k(x,t)}} \left(Cost_{prod} + Cost_{pump} + Cost_{inves}\right) \quad (27)$$

The optimization variables are the inner diameters of the pipes, the temporal values of mass flows, and spatio-temporal values of temperature in each pipe. This optimization aims to find the diameters that give the best trade-off between CAPEX and OPEX while finding the optimal operational values of mass flows and temperatures.

Since all the variables are continuous, Eq. from (2) to (26) and the objective function (27) constitute a dynamic NLP problem. The OCFE was employed on the PDE (8) to transform the problem into a set of algebraic equations. For the resolution, we used an equation-oriented (simultaneous) methodology, with the software GAMS for the modeling of the system, and the solver CONOPT for the solving.

As it is the case in most complex optimization problems, a resolution methodology was developed. The purpose of the methodology is to help the solver by creating a resolution process where we solve successive problems. We start from a simple problem and we get more complex until we finally solve the problem of this study. In the resolution process, we always use the last solution for the initial values of variables of the next problem.

5. Results and discussion

This optimization was done considering a production temperature of 92 °C and an outlet temperature of consumers equal to 72 °C. The unit cost of electricity was taken equal to 174 €/MWh. Concerning the unit cost of heat production, we considered the prices in France in 2022 for 3 different technologies: biomass boiler (50 €/MWh), gas boiler (150 €/MWh) and heat recovery (20 €/MWh). The thermo-physical properties of water are taken for the temperatures of 92 °C and 72 °C as it is shown in Table 2. In what follows, we will present some results obtained in the optimization of this case study.

Table 2. Thermophysical properties of water [20].

	ρ (kg/m^3)	c_w (kJ/(kg K))	$\mu \cdot 10^3$ (N s/m^2)	k (W/(m K))
Outward pipes (92 °C)	963.4	4.209	0.306	0.677
Return pipes (72 °C)	976.6	4.191	0.389	0.664

Figure 5 represents the daily evolutions of heat production and mass flow at the production level for the case of biomass boiler. We observe that the heat production has the same profile as the total demand with slightly higher values due to the thermal losses in the network. The thermal losses can also be observed in Figure 6 where the return temperature to the production is represented. The production mass flow of Figure 5 also has the same profile as the total demand. Since production temperature is constant and return temperature does not vary significantly, the mass flow follows the demand as it can be seen in Eq. (7). We obtain the same evolutions for the two other production technologies (gas boiler, heat recovery).

The pressure drops have daily profiles quite similar to the total demand due to the fact that they are proportional to the square of velocity (Figure 7). Inside the pipes, as there is a plug flow regime, the velocity and mass flow have the same profile. As expected, the pressure drop of the left branch is always higher than the one of the right branch which is explained by a more important demand on the left. In a real case, the DHN cannot operate under these pressure conditions. To guarantee a correct operation, it is necessary to have pressure control valves before mixing nodes that will maintain the same pressure drop in every parallel connection of pipes. Consequently, the pressure drop of the right branch will be equal to the one of the left.

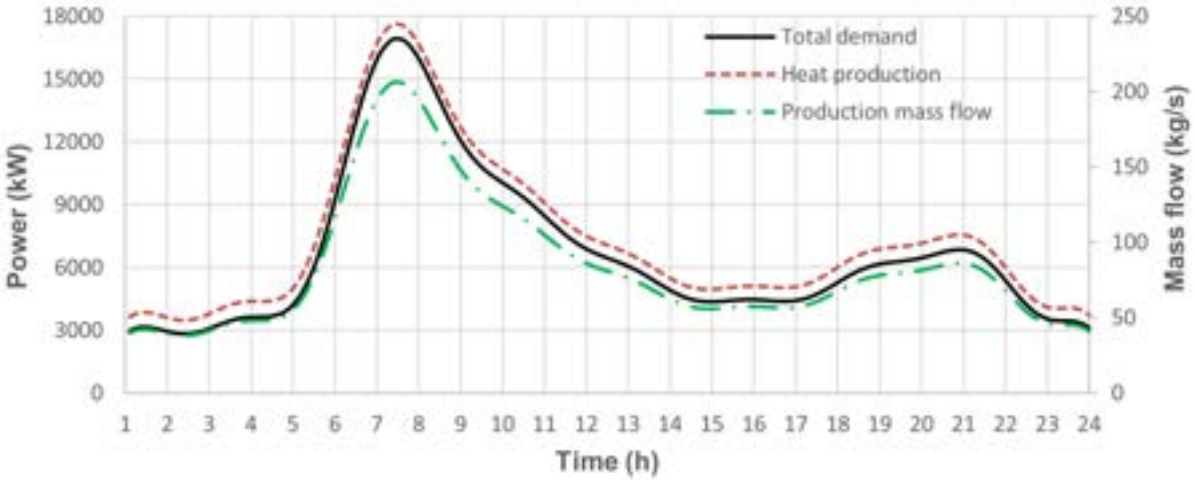

Figure 5. Heat production and production mass flow over time.

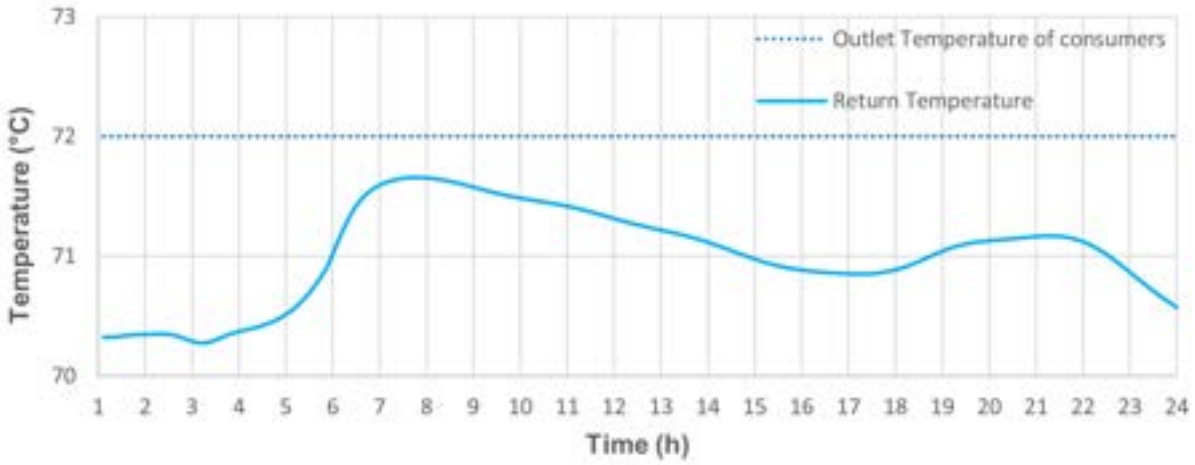

Figure 6. Outlet temperature of consumers and return temperature of the network over time.

In Table 3, we present the results of 3 optimizations where all the parameters are the same (c_{elec}, $Cost_{inves}$, $Demand(t)$, …) except for the unit cost of heat production (c_{hot}). Each unit cost represents a different production technology (gas, biomass and heat recovery). We observe that when c_{hot} increases, the heat produced energy decreases and the pumping energy increases. When the price of heat is more important, the solution tends to reduce the size of the diameters resulting in less investment for pipes, less thermal losses and more pressure drops as it can be observed in Figure 8.

Table 3. Optimization results for 3 different production technologies.

Type of production	Unit cost (€/MWh)	Total heat produced (MWh)	Total pumping energy (kWh)	Average diameter (mm)
Gas boiler	150	169.11	652.82	154.55
Biomass boiler	50	169.17	591.43	155.34
Heat recovery	20	169.20	567.35	155.86

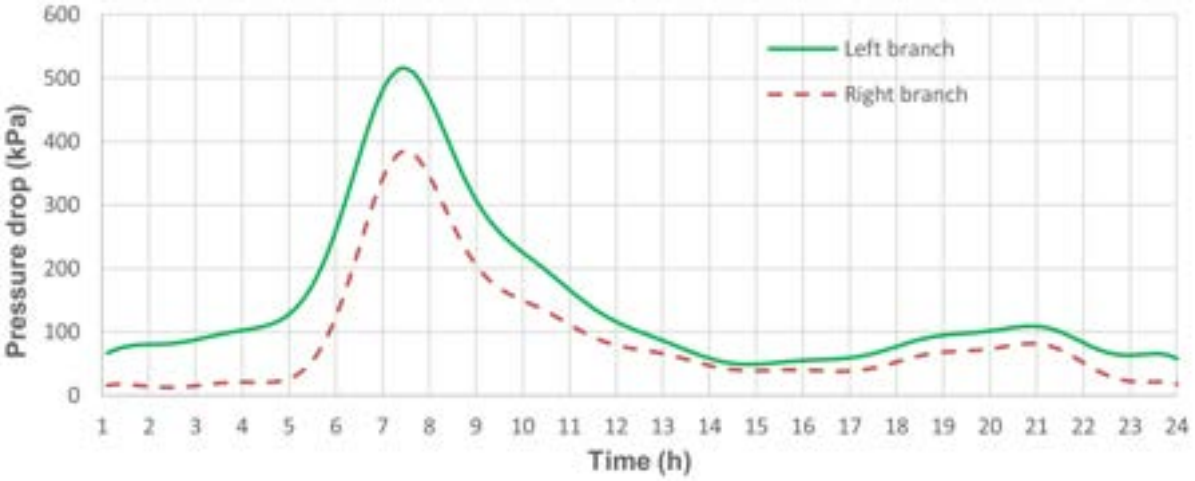

Figure 7. Pressure drops of the two branches of the network over time.

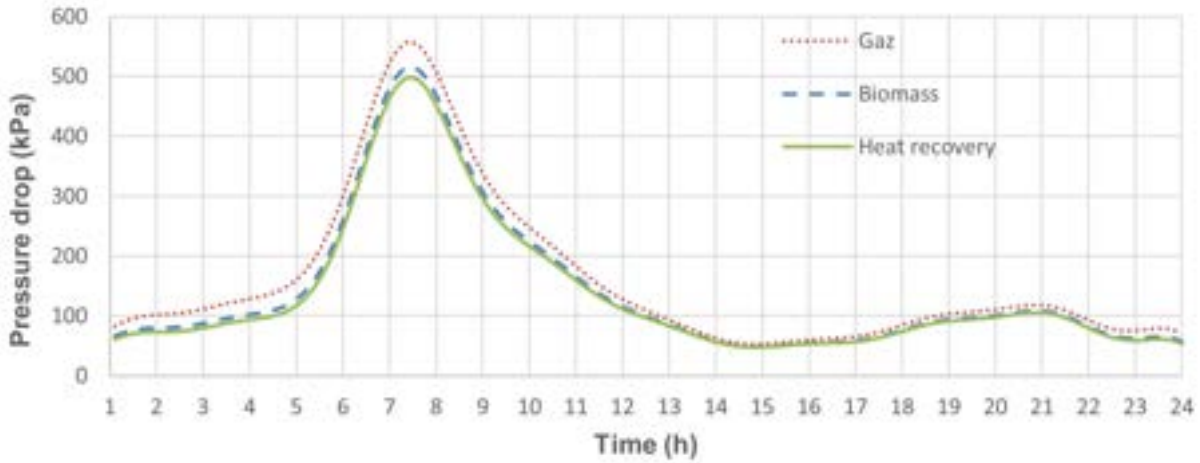

Figure 8. Pressure drop of the left branch of the network for 3 different production technologies.

6. Conclusions and perspectives

In this study, we developed a model for the optimization of the daily operation of a DHN. We optimized the pipe diameters in addition to the mass flows and temperatures in the distribution network. In the modeling of the pipes, the OCFE was used to discretize the heat transfer equation, and the Darcy-Weisbach equation described the pressure drops. The parametric study on the unit cost of heat production confirmed that it is better to have smaller diameters when the cost increases to reduce the thermal losses.

The results of this NLP optimization are a good starting point for a Mixed Integer Dynamic Optimization (MIDO). As we find only discrete values of diameters in the market, it is more interesting to solve a MIDO problem where the diameters will be discrete variables and mass flows and temperatures continuous ones. Moreover, to correctly design the pipes, it is necessary to take into account the operation of the DHN in the different seasons. An interesting study may be the consideration of different characteristic days (one for each season). Another interesting study is the consideration of more than one production unit and of a TES tank. The aim would be to optimize the management of all units while considering the same physical complexity in the pipes and the temperature distribution inside the TES. Currently, we are working on the development and the optimization of a model of this type.

Abstract:

A significant portion of energy expense of a residential household goes toward the provision of domestic hot water (DHW) ~19%. The use of solar thermal water heating provides a local way to offset this energy requirement with a renewable resource. Solar thermal water heating systems are commonly used in hot climates from Southern Europe to the Equator however in the past they were seen as not so economically viable in colder climates. The solar collector that is readily available on the market for DHW generation is the standard flat plate collector (SFPC), but they are not attractive for use in higher latitudes due to low operating temperature and high heat loss. Although convection suppression has been identified as a method to improve the performance of flat plate collector it has not yet achieved mainstream commercialisation. In this work we attempt to show that the conventional flat plate collector still has potential in higher latitude when modified to suppress convection heat loss. The modified FPC that is particularly of focus in this work is the one with honeycomb transparent insulation (MFPC). We compare the performance of SFPC and MFPC in colder climate considering different auxiliary heating options such as electricity, gas, and oil, at their recent energy prices. Using TRNSYS software, we modelled the annual energy generated by these collectors using a typical domestic load case and found that SFPC produced 1446.60 kWh/year while MFPC produced 1993.50 kWh/year. For a typical household with a daily hot water consumption of 200 L, SFPC requires 3858.69 kWh/year of auxiliary energy while MFPC requires 3458.24 kWh/year. The economic analysis shows that the MFPC with electrical heating is the highly viable option with a Net Present Value (NPV) of € 5078.95. The CO_2 emission reduction from the SFPC and MFPC with electrical auxiliary heating are 39.54 kgCO_2/year and 79.58 kgCO_2/year, respectively, compared to conventional electrical immersion heaters.

1. Introduction

The global carbon dioxide emissions from space heating and water heating have hit a record high of 2500 Mt in 2021 [1]. Utilizing solar thermal technology for water heating offers a local solution to mitigate the CO_2 emissions linked to this process. Solar thermal water heating systems are commonly used to offset the energy requirement for domestic hot water (DHW) in hot climates from Southern Europe to the Equator, however in the past they were seen as not so economically viable in colder climates. The trend in northern Europe and UK is to promote heat pump technology for space heating and domestic hot water however this will add significant additional load to the electrical grid. Heat pumps are more suited to space heating than domestic hot water due to the higher tank temperature required and often an auxiliary heater such as an electrical immersion is required to meeting the DHW load requirements. As such and a local source of heat for Domestic Hot Water (DHW) would still be beneficial in colder climates to reduce electricity demand. Flat plate collectors (FPC) are well established and readily available Solar Water Heaters (SWH), but it suffers from poor performance in colder climates due to heat loss [2]. Numerous concepts have been employed in the past to mitigate heat loss from solar collectors, and one such concept is Evacuated Tube Collector (ETC), in which the gap between the absorber and the glass cover is evacuated to eliminate convection and conduction heat loss [3]. Although ETCs are more effective than traditional FPCs and attain significantly

higher collector temperatures, they tend to be costly to manufacture and install [4]. Solar thermal collectors incorporating transparent insulation offer a promising design to minimize heat loss while simultaneously reducing costs and weight. However, despite their potential benefits, these collectors have not yet achieved widespread commercialization due to challenges in manufacturing and the need to address issues related to stagnation temperature [5]. The inclusion of transparent insulation within the air gap between the absorber and the glass cover effectively reduces convection heat loss. This enhances the employability of FPCs, particularly in colder weather conditions.

Numerous works on the experimental and numerical analysis of SHW system can be found in literature and here we provide a review of selected works from the literature, highlighting their key findings and contributions. Ayompe and Duffy [6] conducted a year-round experimental analysis of a forced circulation SHW system installed in Dublin, Ireland which demonstrated that an FPC SHW system with a 4m^2 collector area can yield a solar fraction of up to 32.2% for an annual global insolation of 15,680.4 MJ. Hazami et al. [7] investigated the year-round performance of FPC and ETC SHW systems that were commercialized in Tunisia. Their findings showed that the ETC system generated 9% more energy than the FPC system. Specifically, the ETC system, with a collector area of 3.4 m^2, achieved a solar fraction of 84.4%. Tiwari et al. [8] utilized numerical simulations to assess the efficacy of FPC systems in Indian climatic conditions. Their study revealed that an FPC system with a collector area of 5 m^2 can meet 70% of the residential hot water demand. Kalogirou et al. [9] proposed a novel TRNSYS model component to evaluate the effectiveness of thermosiphon solar hot water (SHW) systems, which they simulated in three different European climates: Freiburg (47.9990° N), Naples (40.8518° N), and Larnaca (34.9182° N). The model was validated by comparing its results with experimental data. The research findings demonstrate that as the latitude decreases from Freiburg to Larnaca, the simple payback period (SPB) of the SHW systems also decreases. Zainine et al. [10] employed TRNSYS simulation to optimize the flow rate for a solar domestic hot water (SDHW) system installed in Tunisia. They estimated that the optimal flow rate for the primary and secondary circuits, for maximum annual yield, were 10 kg/h m^2 and 15 kg/h m^2, respectively. Additionally, their economic analysis demonstrated that SHW systems with gas auxiliary heating are more economically feasible than replacing conventional electric heaters. Bernardo et al. [11] conducted a study on the benefits of retrofitting existing domestic hot water systems with SWH. Their findings indicated that incorporating a smaller tank with an immersion heater in series with the solar storage tank could lead to optimal performance, with a solar fraction of up to 50%. The study also demonstrated that the TRNSYS simulation software is a reliable tool for determining the thermal performance of SHW systems.

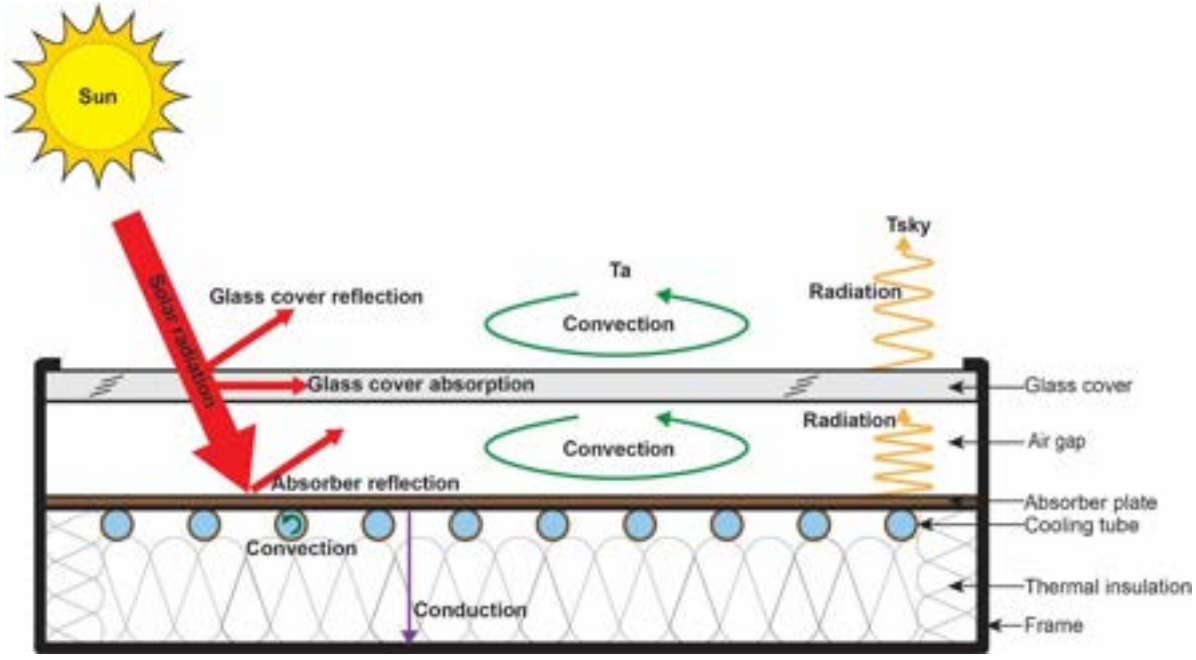
Vig et al. [12] studied a variable flow vacuum tube solar thermal collector system. Their research demonstrated that the variable flow SHW system collected more energy compared to the constant flow one. Their effect was particularly significant when the radiation was low or when the temperature of water in the storage tank was high. Hayek et al. [13] conducted experimental investigations on two types of ETC collectors in the Eastern Mediterranean climate. Their findings demonstrated that the heat pipe-based ETC collector was 15-20% more efficient than the water-in-glass ETC collector. However, due to their high initial cost, these ETC collectors are not an economically feasible option. Maraj et al. [14] reported the yearly energy performance of a heat pipe ETC collector under Mediterranean climatic conditions. Their findings indicated that the annual collector efficiency of the ETC system was 62%, while for an FPC system, it was 49.4%. This result demonstrates that the thermal performance of the ETC system was superior to the FPC system. Al-Madhhachi et al. [15] conducted a study on the potential of SHW systems in two cities in Iraq. Their findings indicated that the SHW system has the potential to supply almost 60% of the hot water demand in winter. Kalogirou and Papamarcou [16] conducted experiments and numerical simulations on a thermosyphon SHW system based on FPC. The results showed that a FPC system with a total collector area of 2.7 m^2 can meet all the hot water demand of a household during summer. The Economic analysis showed that the system has a simple payback period of 8 years and a net present value (NPV) of 161 $C£_{2000}$. Hobbi and Siddiqui [17] performed a simulation-based optimization study for a forced circulation solar water heating system in Canada. Their results showed that the proposed design could meet 83-97% and 30-62% of hot water demand in summer and winter, respectively. Gao et al. [18] compared the performance of water-in-glass and U-pipe evacuated-tube solar collectors and optimised their flow rate for maximum energy production. The literature review shows that the TRNSYS simulation is a reliable tool for the determination of the yearly performance of the SHW systems [19]. Zhou et al. [5] conducted a numerical study to investigate the impact of operating conditions on the performance of FPC integrated with Transparent Insulation Material (TIM). The results highlighted that FPC with TIM proves to be highly efficient, particularly in colder ambient temperatures. Specifically, the efficiency of FPC with TIM was found to be 6.2% higher compared to traditional FPC collectors. Kizildag et al. [20] conducted a comparative analysis between FPC and modified FPC incorporated with TIM. The results indicated a remarkable difference in energy production, with the modified FPC outperforming the standard collectors by 2.5 times during winter and 1.4 times during spring. Kessentini et al. [21] conducted a comprehensive study on FPC integrated with TIM and an overheating protection system. Their research demonstrated that the FPC with TIM can achieve performance levels comparable to commercially available solar collectors, all while maintaining a low-cost advantage. Despite

the proven effectiveness of convection-suppressed flat plate technology utilizing transparent insulation in cold weather conditions, its widespread commercialization has not yet been realized. In this study, we aim to compare the performance of conventional flat plate technology with convection-suppressed flat plate technology in a European climate, considering current energy prices.

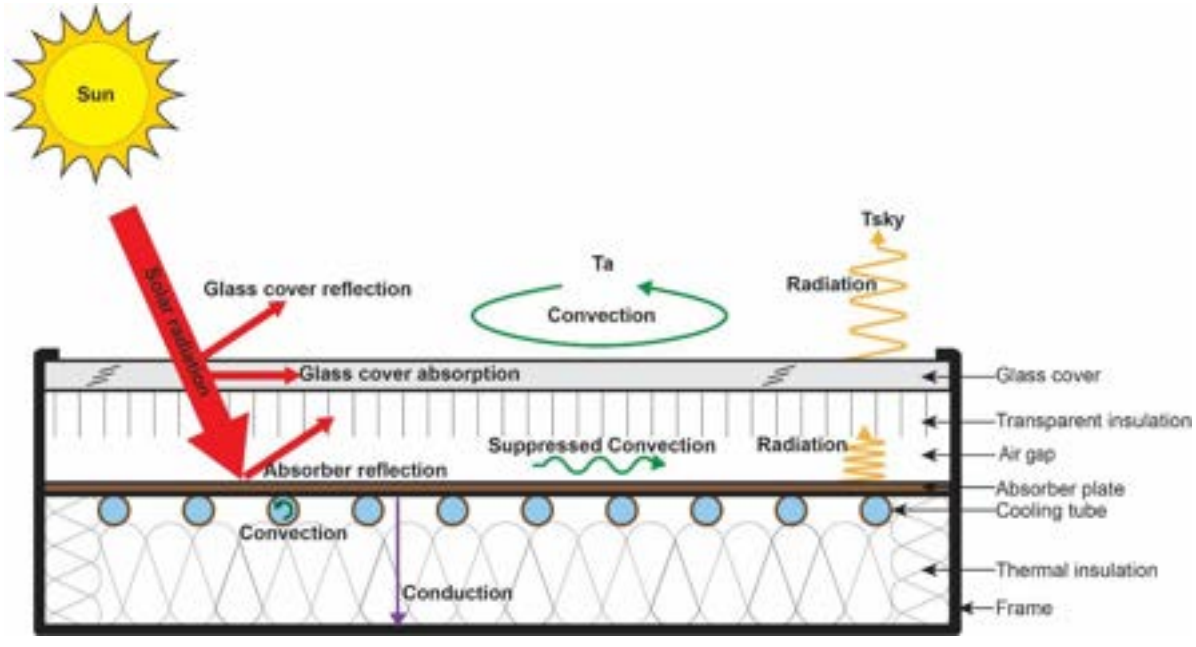
2. Modeling solar hot water heater system

2.1. System description

Flat plate collector refers to a particular geometry of solar collector employed for hot water generation. The FPC consists of an absorber plate that intercepts the incident light and generates thermal energy, which is transferred to water in the storage tank by the heat transfer fluid flowing through the cooling tubes attached to the absorber plate. To reduce the heat loss from the absorber, it is covered with a glass cover on top and thermal insulation at the sides and bottom. The glass cover on top reduces the convection heat loss and traps the long wave radiation emitted from the absorber plate thereby increasing the thermal energy available at the absorber. A solar selective coating is usually applied to the absorber plate which has strong absorption in the visible and near infra-red range and low emissivity in the infra-red range. The schematic of standard FPC and the modified FPC analysed in this work are given in Figure 1.



(a)



(b)

Figure. 1. Schematic of solar flat plate collector: a) SFPC, b) MFPC.

In the modified FPC design, a transparent insulation made of polycarbonate honeycomb is inserted in the airgap between the glass cover and the absorber plate with the aim to suppress the air circulation that is responsible for convection heat loss from the absorber plate. The performance of the solar thermal collector is described using a second order equation as a function of environmental and functional parameters and we use numerical simulation to determine the constants of the efficiency equation Eq. (1) [22].

$$\eta = a_0 - a_1 \frac{(T_m - T_a)}{G} - a_2 \frac{(T_m - T_a)^2}{G} \quad (1)$$

2.2. Numerical modeling for estimation of performance parameters

The steady state, two-dimensional thermal modeling of solar flat plate collector was done using the Multiphysics simulation software, COMSOL 6.1. For the numerical analysis, a portion of the FPC with one cooling tube was taken, this is supported by the assumption that the flow rate in each riser tube was the same. The specific collector being examined was the K420-EM2L, which was manufactured by KBB Kollektorbau GmbH and it has an aperture area of 1.97 m^2 [23]. Details of the computational domain and boundary conditions can be found in Figure 2. The thermophysical properties of the solid components that make up the FPC are constant and are listed in Table 1. It is assumed that the air flow between the absorber and the glass cover is laminar and incompressible. Therefore, the density of air is modeled as an incompressible ideal gas, using the Boussinesq approximation method [24]. The heat transfer and fluid flow problem were solved by solving the coupled continuity, momentum, and energy equations, with an additional transport equation for S2S radiation Eq. (2-4) [25].

Continuity equation, $\frac{\partial}{\partial x_j}(\rho u_j) = 0$ (2)

Momentum equation, $\frac{\partial}{\partial x_j}(\rho u_i u_j) = \frac{\partial}{\partial x_j}\left[\mu\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)\right] + \rho g_i \beta\,(T - T_\infty)$ (3)

Energy equation, $\frac{\partial}{\partial x_j}(\rho u_j C_p T) = \frac{\partial}{\partial x_j}\left[\lambda \frac{\partial T}{\partial x_j}\right] + \dot{Q}$ (4)

2.3. Boundary conditions and methodology

The solar radiation input to the collector is modelled by considering a volumetric heat source at the absorber and the glass cover Eq. (5,6) [27]. The laminar forced convection from the inside of the cooling tube is modeled with a convective heat transfer coefficient h_f calculated from the Nusselt number for the case with constant heat flux boundary condition (Nu_f=4.36), at mean water temperature $\left(T_m = \frac{T_{out} + T_{in}}{2}\right)$ [28]. The top and bottom surfaces of the collector are subjected to external natural convection due to ambient air in contact with the collector surface. There are two instances of radiation heat loss in the collector: one occurs externally from the glass cover to the sky, while the other occurs internally between the absorber and the glass cover [29]. Once the computational domain is assigned with material properties and boundary conditions, the necessary physics to solve laminar natural convection, heat transfer, and S2S radiation are added and coupled. The governing equations are solved using the stationary solver-multifrontal massively parallel sparse direct solver (MUMPS) with a relative tolerance of 0.001. The purpose of this simulation is to obtain the efficiency curve of the solar collector (η vs $\frac{T_m - T_a}{G}$), and therefore, a parametric study was done by varying the mean water temperature (285 K≤T_m≤350 K) keeping the insolation constant (G=800 W/m^2).

Heat generation in absorber, $\dot{Q}_{abs} = \frac{G\,\tau_g \alpha_p}{t_{abs}}$ (5)

Heat generation in glass cover, $\dot{Q}_g = \frac{G\,\alpha_g}{t_g}$ (6)

Table 1. Thermophysical properties of FPC collector [26].

Component	λ, (W/m-K)	ρ, (kg/m^3)	C_p, (J/kg-K)
Glass cover	1.38	2200	770
Absorber and cooling tube (Aluminium-D_o:12 mm, D_{in}:11 mm)	238	2700	900
Insulation	0.022	30	1000
Transparent insulation (Polycarbonate)	0.2	1200	1200

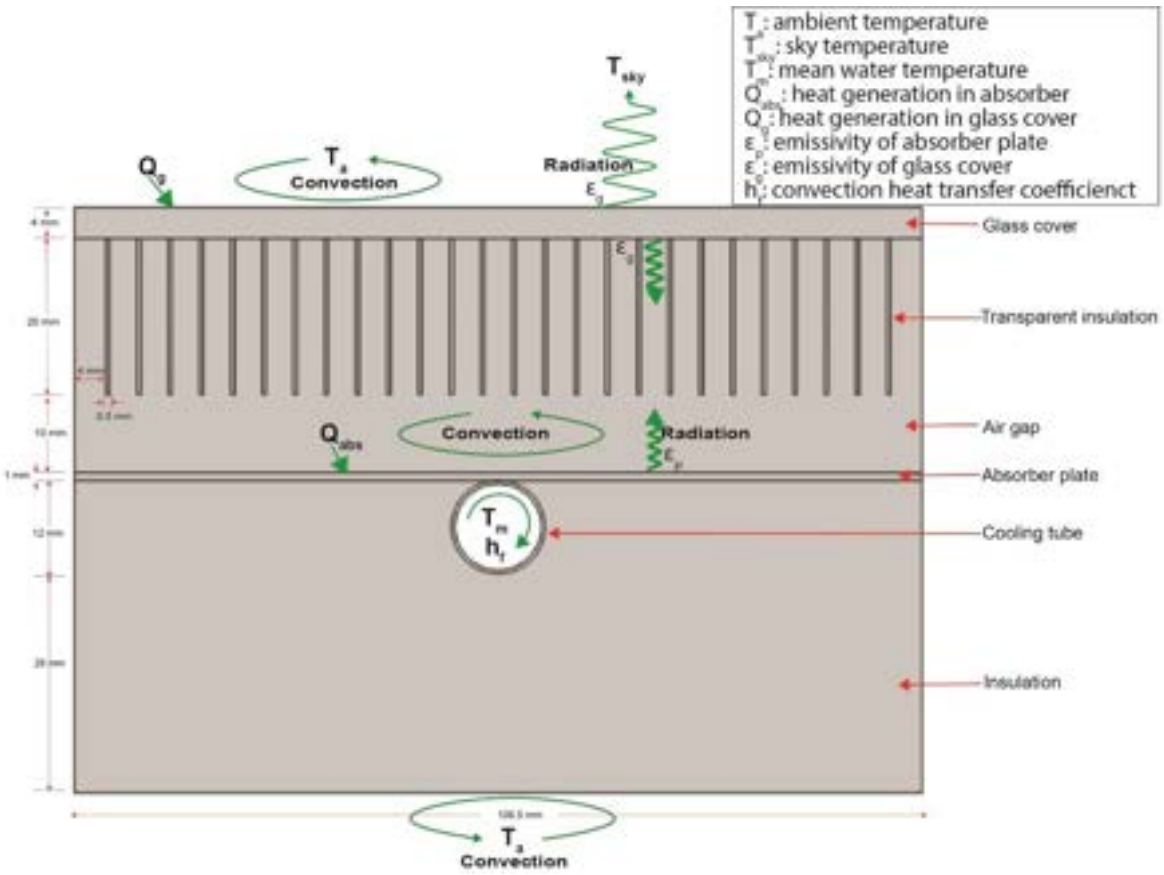


Figure. 2. Computational domain with boundary conditions.

2.4. Validation

The numerical model developed by Kim and Viskanta [30] for solving coupled laminar natural convection, surface radiation, and wall conduction in a differentially heated cavity is taken for validation. Figure 3 shows the plot of non-dimensional temperature $\left(\frac{T-T_c}{T_h-T_c}\right)$, obtained at the vertical wall; it can be seen that the proposed model agrees well with the existing model, with dimensionless temperature having a deviation between 0.25% and 7.61%.

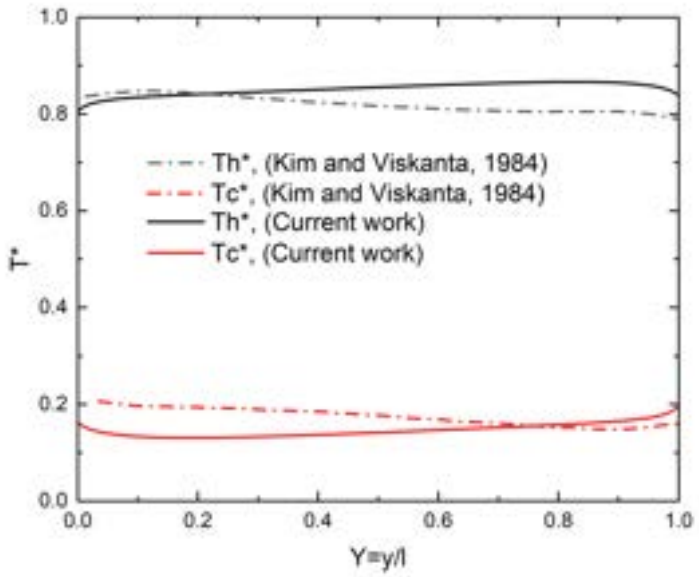

Figure. 3. Non-dimensional temperature obtained from the proposed model and the existing model.

2.5. TRNSYS simulation for the yearly energy produced

The useful thermal energy collected by the SFPC and MFPC over a year was obtained using the transient simulation software TRNSYS 18. In TRNSYS, models that represent the components of solar hot water system (Collector: Type 1b, Tank: Type 60d, Pump: Type 110) are connected similar to how they would be connected in real life. The forced circulation SHW system is implemented using a single tank model that has an internal heat exchanger coil connected to the solar collector. The hot water demand profile used is the EU reference tapping cycle 3 representing 200 L of hot water required in a day at 60 °C ($Q_{thermal}$ = 11.65 kWh/day) [31]. The storage tank has a built-in immersion heater (3kW) located at the middle of the tank and is turned ON in two batches, from 5 am to 7 am and 6 pm to 8 pm, whenever the tank top temperature falls below 55 °C. The overall heat loss coefficient of the tank is taken to be 1.6 W/m^{2}K [7]. The pump used is a constant flow rate pump and is controlled using an ON/OFF controller (Type: 2b). The controller sets the pump ON only when the difference in collector outlet water temperature and the tank bottom temperature exceeds 5°C, this is to ensure system operation at sufficient irradiance level. The FPC system modeling simulation diagram with interconnection of various components is given in Figure 4.

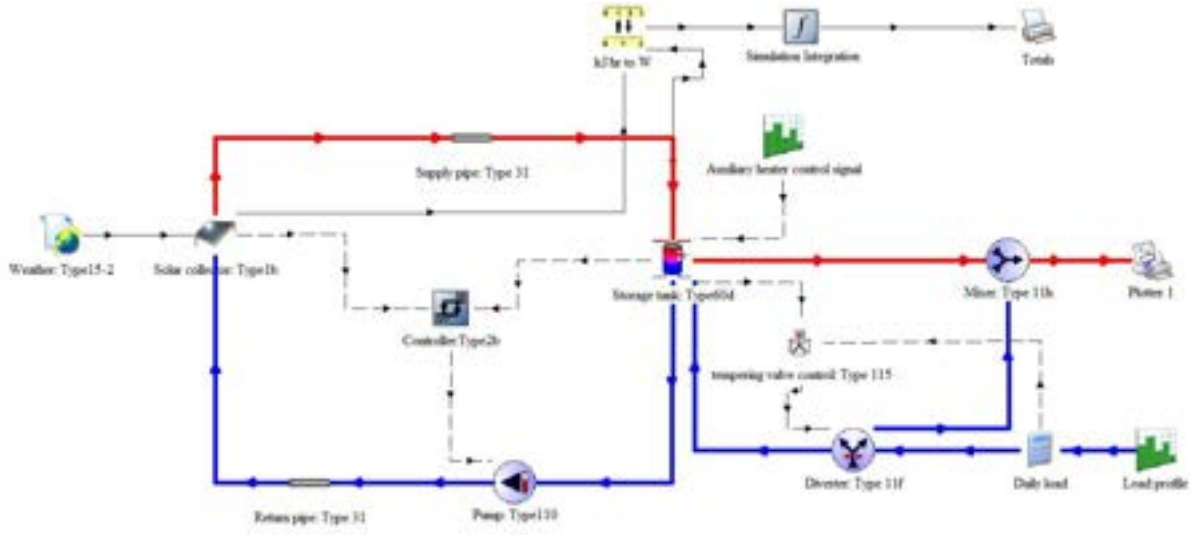

Figure. 4. TRNSYS simulation of SHW system modeling.

2.6. Economic and environment analysis

The economic evaluation parameters used in this study to show the benefit of installing a solar thermal hot water system are the net present value (NPV) and the simple payback period (SPB) Eq. (7,8) [29]. The NPV and SPB period are calculated for the two systems with different auxiliary fuels: electricity, oil, and gas at current energy price [32]. The economic analysis was done by assuming 8% annual discount rate and 20 years of useful life. The operation and maintenance cost were assumed to be 1% of the capital cost. The assumptions taken in the economic analysis of the solar hot water systems are listed in Table 2. The yearly CO_2 emission by the two solar hot water systems with different auxiliary fuel was calculated using Eq. (9). and are based on the country emission factor for CO_2 per unit of energy for particular fuel [33].

$$NPV = \sum_{j=1}^{N} Q_u \, C_{aux} \, \eta_{aux} \, \frac{(1+i)^{j-1}}{(1+d)^j} - \sum_{j=1}^{N} C_{o\&m} \frac{(1+i)^{j-1}}{(1+d)^j} - C_{capital} \quad (7)$$

$$SPB = \frac{C_{capital}}{Q_u \, C_{aux} \, \eta_{aux}} \quad (8)$$

$$Q_{CO2\ emission} = Q_{aux} \, S_{CO2} \quad (9)$$

Table 2. Economic analysis parameters [34,35].

Parameter	Value
Capital cost of FPC system	3500 €
Solar Water Heating Grant	1200 €
Inflation rate	3%
Cost of electricity	0.31 €/kWh
Cost of oil	0.14 €/kWh
Cost of gas	0.08 €/kWh
Efficiency of Electrical immersion heater	100%
Efficiency of oil boiler	65%
Efficiency of gas boiler	90%

3. Results and Discussion

3.1. FPC characteristics curve

The heat transfer and the fluid flow model are solved to determine the constants of the characteristic equation that describe the performance of solar thermal collector. Numerical simulations are done for the input conditions, such as incident radiation of 800 W/m^2, ambient temperature of 283 K, and collector tilt of 45°.The obtained efficiency curves along with their characteristic equation are given in Figure 5. The area under the efficiency curve reflects the useful energy gained, and it is evident that the MFPC collects more energy compared to the SFPC. The MFPC exhibits a 20% optical loss, whereas the SFPC has a 22% optical loss. The MFPC system's first and second order heat loss coefficients have been determined to be 1.7618 W/m^{2}K and 3.058$\times 10^{-3}$ W/m^{2}K^2, respectively. Meanwhile, the SFPC system has first and second order heat loss coefficients of 3.0632 W/m^{2}K and 7.7136$\times 10^{-3}$ W/m^{2}K^2, respectively.

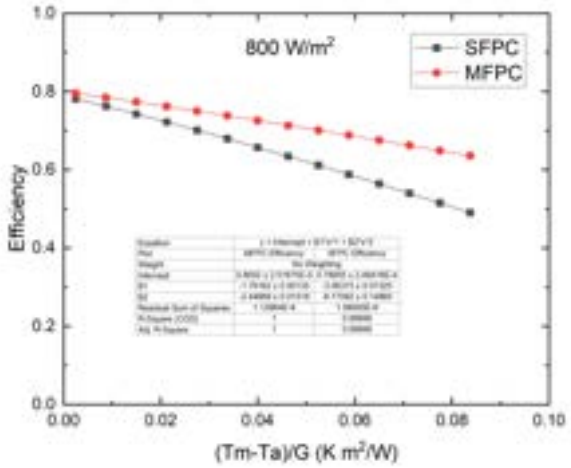

Figure. 5. TRNSYS simulation of SHW system modeling.

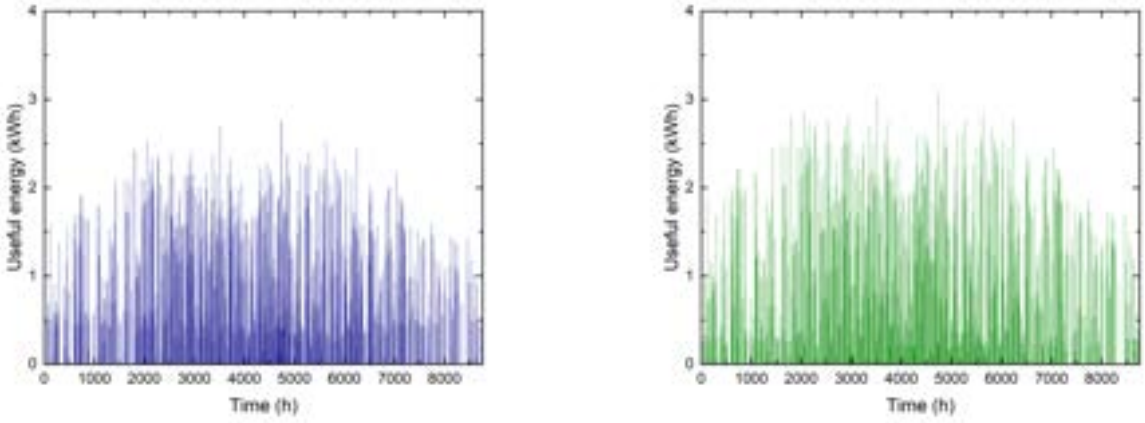
3.2. Yearly performance analysis

The yearly energy performance of the SFPC and MFPC SHW system was simulated in TRNSYS by using the performance parameters obtained from COMSOL simulations. The SHW system consisted of two FPC collectors connected in series each with absorber area 1.972 m^2. The collector tilt was taken to be 44°. The flow rate in the solar collector loop was maintained constant at 95 kg/h. The simulations were done for a year at 1 minute time step with meteorological data input relative to Dublin (53.3498° N, 6.2603° W). The SFPC and MFPC systems' yearly useful energy collected were 1446.60 kWh and 1993.50 kWh, respectively, as shown in Figure 6. The corresponding annual solar fractions of the SFPC and MFPC systems were 27.27% and 36.57%, respectively.



(a) SFPC (b) MFPC

Figure. 6. Useful energy generated by SFPC and MFPC for 4m^2 collector area installed in Dublin.

3.3. Economic feasibility and CO_2 emissions

The results of the NPV and SPB period calculations for both the SFPC and MFPC systems, using different types of fuel for auxiliary heating, are presented in Figures 7, respectively. The economic analysis reveals that FPC systems are financially viable only when electricity is used as the auxiliary fuel. After factoring in the solar grant, the NPV of the MFPC is notably high, amounting to € 5078.94. Additionally, the SFPC has a simple payback period of 5 years, whereas the MFPC has a comparatively shorter payback period of only 3.7 years when electricity is used as the auxiliary heating source. Table 3 shows the CO_2 emissions generated by the SFPC and MFPC systems when using different types of auxiliary fuel. It is evident that the CO_2 emissions are minimized when electricity is employed as the auxiliary heating source. The yearly CO_2 emissions from SFPC and MFPC SHW system with electricity as auxiliary heating is found to be 385.87 kg and 345.82 kg respectively. Using a conventional electrical immersion heater to generate hot water for a typical house result in an annual CO_2 emission of 425.22 $kgCO_2$. However, by implementing the proposed MFPC SHW system, this CO_2 emission could be significantly reduced to 345.82 $kgCO_2$/year.

Table 3. CO2 emission from SHW system [36].

Auxiliary fuel	$kgCO_2$/kWh	$kgCO_2$ emissions/year	
		SFPC	MFPC
Electricity	0.10	374.29	335.62
Gas	0.20	782.93	702.03
Oil	0.26	991.68	889.22

4. Conclusions

A study was conducted to investigate the feasibility of implementing a SHW system in a northern European climate, taking into account the current energy costs for auxiliary heating. The study focused on two different FPC systems, each with a total aperture area of 4m^2. Numerical simulations were utilized to obtain the efficiency parameters of the systems based on a simplistic heat transfer and fluid flow model. These parameters were then utilized in TRNSYS simulations to determine the yearly thermal performance of each system. The energy collected by the two systems are found to be be 1446.60 kWh/year and 1993.50 kWh/year respectively. Results indicated that FPC systems are still a financially viable option for hot water generation, particularly when using electricity as the auxiliary heating source. The modified FPC system exhibited the best performance, with a high NPV of € 5078.94 and a short SPB period of 3.7 years. Moreover, by employing the MFPC system with electrical auxiliary heating, 79.58 kgCO_2 reduction in annual emissions is achievable when compared to conventional electrical immersion heaters. Future work is to optimize the collector size for different hot water consumption profile and also to explore the feasibility of using ETC collectors.

Abstract:

Buildings account for 40% of the EU's final energy consumption and 36% of its energy-related GHG emissions. Therefore, to reduce the EU's GHG emissions it is needed to reduce the energy consumption and increase energy efficiency. For that, not only the design but also the maintenance of systems is essential to ensure the proper functioning and the energy efficiency. On the other hand, the environmental temperature is rising at a high rate because of the global warming. Therefore, this will undoubtedly influence on the energy efficiency of the buildings thermal systems. However, we can only estimate the effects from predictions based on previous data models.

In this work we develop a methodology in order to learn a predictive model of a simple thermal system of a building, consisting of a boiler and the distribution equipment that provides the dynamic DHW demand. The model is learn from databases obtained from a thermal system software to calculate the influence of climate change on the cost formation process. That is, we quantify the effects on costs due to outdoor temperature variation when the demand does not vary, based on thermoeconomic indices. The next step will be to incorporate heating demand that will also vary due to climate change.

The reference model of the thermal facility would serve to predict the behaviour when the climate changes, in order to implement it in maintenance tasks and thermoeconomic diagnosis for fault detection.

Keywords:

Predictive model; Thermal installation; Buildings; Climate-change.

1. Introduction

Buildings account for 40% of the EU's final energy consumption and 36% of its energy-related greenhouse gas (GHG) emissions. Therefore, reducing energy consumption and increasing energy efficiency are required to reduce the EU's GHG emissions [1].

On the other hand, due to climate change, environmental temperature is rising at a rapid pace. The global average temperature has risen by 0.76°C over the last 100 years [2] and, in addition, global average warming is estimated to be 2.2°C by 2100, 3.6°C by 2200 and 4.6°C by 2500, with all the consequences that this entails [3]. After all, buildings must generate thermal comfort and meet energy needs according to the variable external conditions and the profile of the users.

The research of predictive behavioural models to improve continuously the building installations and their maintenance is a key point to ensure the intelligent operation of equipment and to detect premature wear of engines. With predictive models learned from simulated thermal data, it is possible to set a competitive regime and timing of processes, to detect excess energy consumption, or to detect malfunctions.

For all these reasons, the key for a proper management and energy savings lies, among others, in predicting the operation of systems and the cost of the products required in the future, to (1) be able to take the necessary actions to adapt to new climatic conditions, and, to (2) slow down the increase in the Earth's surface temperatures, reducing GHG emissions. Thus, one of the keys to guarantee the proper functioning of thermal systems in buildings and to promote the energy efficiency are maintenance actions.

A survey of the state of the art of work applying thermoeconomics in combination with AI shows that there are some recent studies. The work in [4] creates a model that applies the principles of thermoeconomics to analyse

and optimize the performance of the Afyon geothermal power plant. This modelling approach is enhanced by using artificial neural networks to improve the plant's efficiency and cost-effectiveness. In Ref. [5] the thermoeconomics aspects of a system that combines geothermal and solar energy to produce both hydrogen and power are studied. This analysis involves using advanced techniques such as artificial neural networks and genetic algorithms to optimize the system's performance. In the work in [6] artificial intelligence and response surface methods are used in order to optimize the thermoeconomic performance of waste heat recovery system in a large internal combustion engine.

As shown in the literature, the studies are focused on the application of Thermoeconomics and Machine learning methods for optimising industrial systems. In this way, this study provides a methodology that combines both disciplines for maintenance work in building thermal systems.

Therefore, this paper presents a case study of a dynamic thermoeconomic analysis applied to a domestic hot water (DHW) installation and develops a methodology to create a model, which aims to predict the performance and the costs and consumption of thermal systems in buildings, for their maintenance. This model combines Thermoeconomics with data-driven Machine Learning (ML) methods. Data-driven methods extract patterns from historical process data [7], which are very useful for monitoring and model building thermal systems due to the large amount of data collected and the dynamic operation.

2. Materials and methods

This section explains the laboratory where the system has been designed, the thermoeconomics applied to the study as well as the thermoeconomics and TRNSYS software needed to carry out the case study.

2.1 Building Quality Control Laboratory of the Basque Government

The Building Quality Control Laboratory of the Basque Government (LCCE) is a laboratory prepared to carry out physical, mechanical and chemical tests on construction materials. It is divided into three areas: thermal, acoustic and materials. Thus, the thermal area has a flexible experimental plant designed to configure different installations depending on the required demand. For this purpose, the installation can be divided into different zones or islands, as can be seen in Figure 1: (1) low temperature zone, (2) high temperature zone and (3) solar collector zone. These three zones correspond to the different generation equipment. There are also (4) the distribution equipment zone, (5) the heating/DHW terminal zone and finally (6) the thermal storage zone.

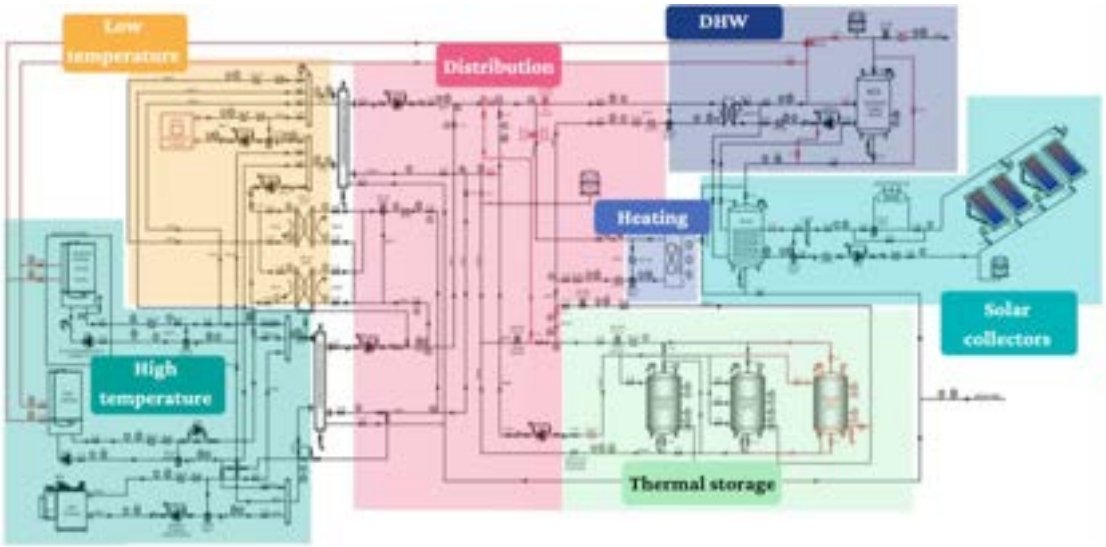

Figure 1. Experimental plant of the LCCE

The installation consists of more than 100 signals to control and monitor the variables to be evaluated. For this, 46 high precision Pt 100 class 1/10 temperature probes are used, 40 of them located in pipes and the rest in tanks, 11 SIEMENS FM electromagnetic flowmeters (MAG 3100 and 5100W sensors and MAG 6000 transmitters), 2 pressure switches, one in the general circuit and the other in the solar circuit. It also has ambient temperature, humidity and pressure sensors both inside and outside the laboratory. The boiler and the micro-cogeneration equipment have gas and electricity meters and the consumption of the heat pump is also monitored.

The entire control of the installation is managed by a Siemens IM 151-8 PN/DP CPU for ET200S and an expansion module, as well as the corresponding input and output cards for the signals, connected via Ethernet to a PC where the interface is available through which the operation is carried out and the data are collected.

2.2 TRNSYS

TRNSYS [8] is a flexible software environment for simulating the behaviour of transient thermal systems in buildings, composed of two parts:

- The first is an engine (called the kernel) that reads and processes the input file, iteratively solves the system, determines convergence and plots system variables. The core also provides utilities that determine thermophysical properties, invert matrices, perform linear regressions, interpolate external data files, etc.
- The second part consists of an extensive library of components, each of which models the performance of a part of the system. The standard library includes approximately 150 models ranging from pumps to multi-zone buildings, from wind turbines to electrolysers, from weather data processors to economics routines, and from basic HVAC equipment to the most advanced emerging technologies. The models are built in such a way that users can modify existing components or write their own, extending the capabilities of the environment.

Accordingly, TRNSYS version 18 has been used for this simulation.

2.3 THERMOECONOMICS

The Exergy Cost Theory is based on a series of Propositions, whose systematic application makes possible to unequivocally determine the value of the costs (in energy and monetary units) of each of the flows of the system under analysis [9].

The previous step for applying thermoeconomic analysis is to determine the *physical structure*, where all material and energy flows are represented. Furthermore, the approach of the structural theory of thermoeconomics goes beyond the physical structure of the system and defines its *productive structure* in a matrix form. In order to carry out a productive analysis, the flows are classified according to the function they perform in the equipment. This representation considers each equipment *i* as a black box with an input arrow, called fuel ($F_i\ [kWh]$), and an output arrow, product ($P_i\ [kWh]$). The F_i of a component *i* represents the resources (measured in exergy terms) needed to run the specific energy process and P_i contains the target of the process itself. Therefore, the difference between both terms represents the irreversibility of the process ($I_i = F_i - P_i$) and the ratio $\left(k_i = \frac{F_i}{P_i}\ \left[\frac{kWh}{kWh}\right]\right)$ reflects the unit exergy consumption of the component, which expresses the amount of fuel required to generate one unit of product. This coefficient is related to the other components through the specific $\mathbf{F}$ and $\mathbf{P}$ interrelationships, given by a matrix $\langle \mathbf{KP} \rangle$, which reflects the productive structure of the system. Likewise, a product of one component can be part of the fuel of another component, or also part of the final product, $\mathbf{P_s}$.

Consequently, the vector $\mathbf{P}$ and $\mathbf{F}$ containing the product and fuel of each team can respectively be calculated by means of the following equations [10]:

$$\mathbf{P} = \mathbf{P_s} + \langle \mathbf{KP} \rangle \cdot \mathbf{P} \tag{1}$$

$$\mathbf{F} = \mathbf{I} + \mathbf{P} = \mathbf{K_D} \cdot \mathbf{P} \tag{2}$$

where the final product vector is $\mathbf{P_s}$; $\mathbf{K_D}$ is a diagonal matrix containing the total unit exergy consumption of the components; $\mathbf{I}$ corresponds to the irreversibility vector, and the matrix $\langle \mathbf{KP} \rangle$ reflects, as mentioned before, the productive structure.

Similarly, the total fuel consumption of the system is calculated as follows:

$$F_T = I_T + P_T = \mathbf{k_e} \cdot \mathbf{P} \tag{3}$$

where I_T and P_T are the total irreseversibilities and the final product of the system respectively and $\mathbf{k_e}$ the consumption of external resources.

In relation to costs, the exergy cost $B_i^*\ [kWh]$ expresses the amount of resources used to obtain a specific flow B_i, and the unit exergy cost $k_i^*\ \left[\frac{kWh}{kWh}\right]$ expresses the ratio between the exergy cost and its exergy [11]:

$$k_i^* = \frac{B_i^*}{B_i} \tag{4}$$

Furthermore, k_i^* takes into account the resources needed to generate the flow *i* in the energy chain. It increases as the irreversibilities along the chain increase. The unit exergy costs of the equipment products $\left(\mathbf{k_P^*}\ \left[\frac{kWh}{kWh}\right]\right)$ are related to the unit exergy costs of the external resources $k_{e,i}^*$ of component *i* and to the marginal exergy consumption associated with the external resources $k_{e,i}$.

In addition, the exergoeconomic cost of *i* -flow c_i represents the economic resources required to obtain it. The economic costs of internal flows and final products depend on the thermodynamic efficiencies of the processes.

To calculate the exergoeconomic costs of fuels and products, fixed costs and variable costs have to be defined. Variable costs depend directly on the level of production, while fixed costs are the investment, maintenance and operating costs of the equipment, which are represented by the vector $\mathbf{Z}$ [€]. Because of space reasons, this paper defines only the variable costs for the exergoeconomic ones. Therefore, the exergoeconomic unit costs $c_{F,i},\ c_{P,i}\ \left[\frac{€}{kWh}\right]$ represent the unit cost of a given flow, either fuel or product.

To calculate the total cost of fuels and products, the unit exergoeconomic costs are multiplied by their exergy values:

$$C_{F,i} = c_{F,i} \cdot F_i \quad (5)$$

$$C_{P,i} = c_{P,i} \cdot P_i \quad (6)$$

2.4 THERMOECONOMICS SOFTWARE

In order to carry out this work, a software to control and diagnosis of thermal installations [12] has been used, which is based on Thermoeconomics. This software combines Matlab [13], where the calculations are performed, with Excel, where the data are recorded and the results are presented.

The software calculates the thermoeconomic costs of each of the flows of the installation, and detects the equipment with the highest irreversibilities, which are the ones that increase the cost the most along the energy chain. The costs are obtained from the productive structure that interconnects all the equipment according to (1) the distribution ratios b_{ij}, (2) the unit exergy consumption of each equipment k_i, and (3) the external resources $F_{e,i}$.

The software is able to make these calculations in a dynamic way, i.e. for a series of time stamps, so the results obtained are useful for future diagnosis analyses, given that when a parameter of an equipment varies, its unit exergy consumption varies; thus, the costs related to that component also change.

3. Case study

This work develops the previous steps to build a predictive model of a DHW installation based on the influence of climate change.

For this purpose, a simple DHW installation has been simulated in TRNSYS software emulating the installation designed in the LCCE´s experimental plant, since the final objective is to create the predictive model of real thermal facilities.

With the simulation data, thermoeconomic variables have been calculated for each instant of time, i.e. dynamic variables, such as the total cost of the installation product and, finally, the predictive model has been developed to predict the future values of these costs based on changes in the external temperature.

3.1 Design of the installation

As case study, the installation has been designed to produce DHW using a 24 kW gas boiler, as shown in Figure 2, for a residential building with 20 inhabitants in Vitoria-Gasteiz.

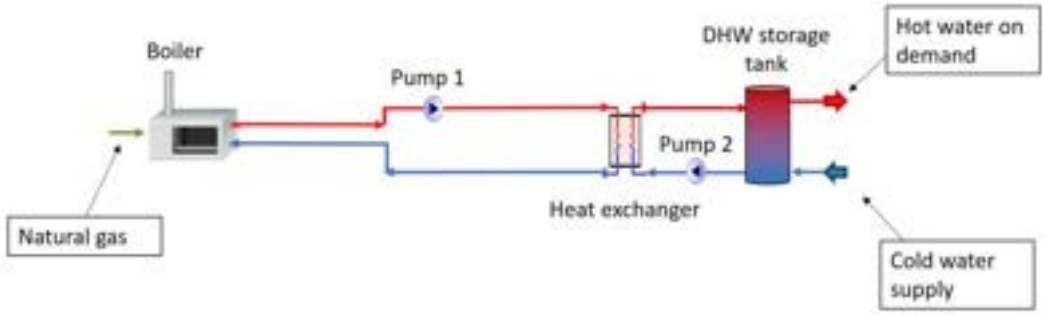

Figure 2. Installation diagram

The installation consists of:

- Generation: 24 [kW] gas boiler.
- Distribution: Hydraulic pumps, heat exchanger.
- Storage: DHW tank of 100 [l].

The parameters of the components are the ones of the LCCE´s experimental plant.

3.2 Physical configuration and productive structure

Once the installation has been designed, the physical configuration and the productive structure are determined to carry out a subsequent thermoeconomic analysis. To define the physical configuration, all material and energy flows are represented. Thus, as shown in Figure 3, 9 flows are defined:

- Energy consumption flow: 1.
- Mass flows: 2, 3, 4, 5, 8, 9.
- Virtual inertia flows: 6, 7, which represent the temperature charge and discharge of the tank.

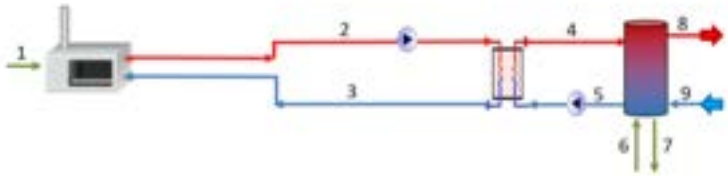

Figure 3. Physical configuration of the installation

In the productive structure, the components are defined as black boxes with interconnected input fuels and output products. In addition, virtual equipment (the green equipment in Figure 4) is added.

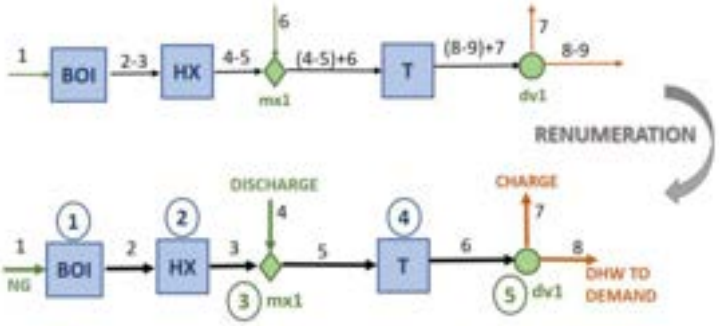

Figure 4. Productive structure of the installation

After renumbering the flows, for simplicity reasons, we have a total of 8 flows and 5 equipment: (1) BOI-boiler, (2) HX-heat-exchanger, (3) mx1-mixer 1, (4) T-tank and (5) dv1-diverter 1.

3.3 Modelling in TRNSYS

The designed installation has been modelled in TRNSYS software maintaining the parameters of the LCCE equipment (Figure 5).

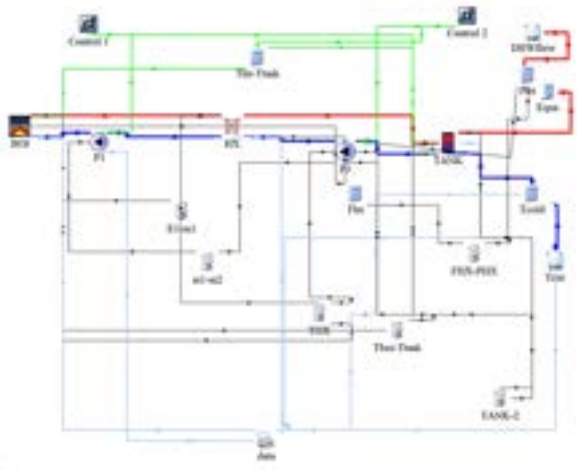

Figure 5. Simulation Studio interface in TRNSYS of the installation

3.3.1 Calculation of the DHW demand

The demand profile has been calculated according to the parameters set out in the HE4 of the CTE (Spanish Technical Code [14]) for a residential building with 20 inhabitants.

3.3.2 Implementation of the outdoor temperature

The main objective of this work is to predict the behaviour and the change in cost of the total product of the installation in future periods, when the outdoor temperature varies.

It is needed to take into account that, in order to achieve this, we have taken into account that the outdoor temperature and the cold water supply temperature are related. In this way, the temperature of the cold water supply entering the system can be calculated as a function of the outdoor temperature, which is used as a predictor variable we are going to use in the model.

Therefore, the average monthly values of the external temperatures in Vitoria-Gasteiz from the IDAE (Institute for Energy Diversification and Saving) [15] and the average monthly temperatures of the mains water in Vitoria-Gasteiz from the Spanish CTE were taken [14].

The relationship with the highest Pearson correlation (R) between these two variables is the linear one below with R=0.9795:

$$T_{cold\ water} = 0.6526 \cdot T_{ext} + 3.3462 \quad (7)$$

Thus, the cold water supply temperature is calculated for all outdoor temperatures according to the LCCE's outdoor temperature sensor.

3.3.3 Control configuration

The control has been configured as follows:

- The boiler starts when the domestic hot water storage tank is below 60.5ºC and stops when it exceeds 62ºC.
- The DHW production starts when the temperature at the primary inlet of the heat exchanger is 5ºC higher than the tank temperature and stops when it is less than 2ºC.

3.3.4 TRNSYS data

TRNSYS allows downloading an Excel file with the thermodynamic variables necessary for subsequent analysis. Specifically, each time-step it saves the following values:

- Temperatures of each flow and average temperatures of the hydraulic compensator and tank.
- Flow rates of each flow.
- Boiler fuel consumption.

The selected data coincide with the data that can be extracted from the LCCE installation and are sufficient to calculate the energy and exergy values for each flow of the productive structure as will be done later, during 168 [h] with 1-minute time-step.

3.4 Data analysis and pre-processing

From the extracted data, a "*raw database*" is obtained based on the dynamic data of temperatures, flow rates and consumption. They are used to calculate, once processed, the energies of each flow. These variables are the same as those that could be obtained from sensors installed in the LCCE.

First, in order to clean and pre-process raw data, the data are visualised to check for outliers that do not follow the normal pattern of the data series. In addition, some conditions are established to avoid intrinsic failures of TRNSYS when extracting the data.

With the pre-processed data, the corresponding energy flows in and out of each main equipment are calculated, based on the First Law of Thermodynamics, and the dynamic model is defined. Thus, an "*energy database*" is obtained that provides the global vision of the interconnections between the components.

3.5 Analysis of the active operating modes of the plant

The casuistry of the installation's behaviour is analysed on the basis of the productive structure, i.e. the active operating mode is identified at each moment, see Figure 6:

- 1st casuistry: Tank charge

The tank is below the temperature set in the control (60.5ºC), so there is a generation demand on the boiler that loads the tank.

- 2nd casuistry: Tank charge + demand

DHW demand exists and the tank is below the temperature set in the control (60.5ºC), so there are two products: tank charging and demand for DHW consumption.

- 3rd casuistry: Demand with tank discharge

DHW demand exists and the tank is above the temperature set in the control (62ºC), so the tank discharges.

- 4th casuistry: Demand without tank discharge

DHW demand exists and the tank is above the temperature set in the control (62ºC), but it does not discharge. This is physically impossible, as if there is a DHW demand, the tank must discharge, i.e. the temperature in the tank must be reduced. However, this casuistry does not cause any problem when carrying out the thermoeconomic analysis, as explained in the following section *3.6. Thermoeconomic analysis*.

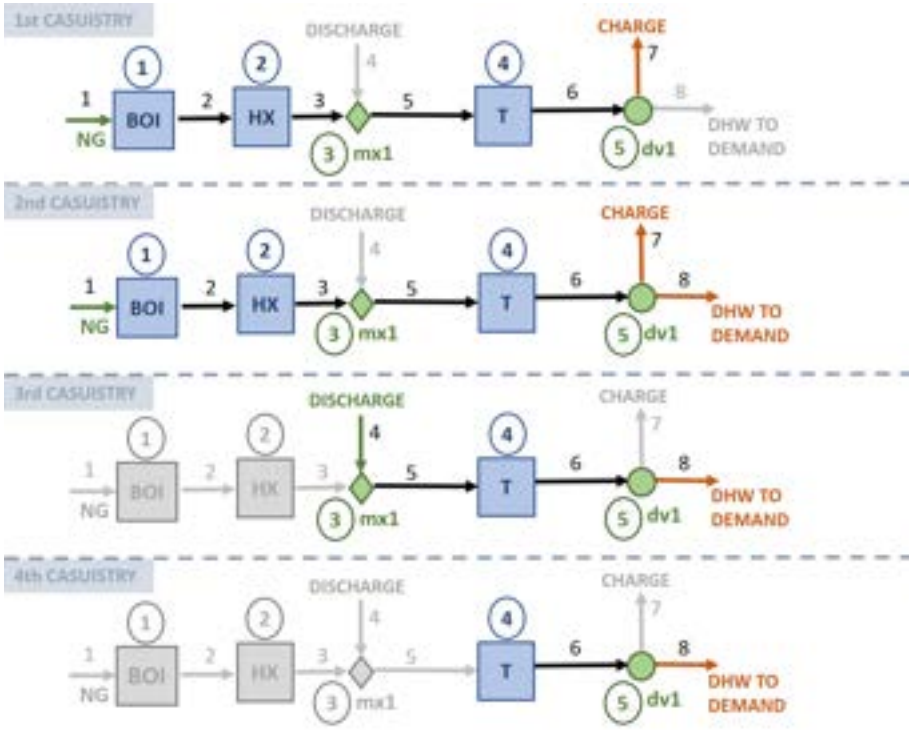

Figure 6. Casuistry of the behaviour of the installation

After analysing the operation modes, it is foreseen that in the 3rd casuistry, there is no natural gas consumption, as the boiler is off. Nevertheless, the discharge of the tank happens because in previous operation modes, gas is consumed to charge the tank. So, in order to consider the cost of charging-discharging the tank, a new methodology is developed to disregard this 3rd casuistry.

To understand the methodology, it is necessary to understand the tanks' energy-exchange formula:

$$\Delta E\ [kJ] = V_{tank}[l] \cdot \rho_w \left[\frac{kg}{l}\right] \cdot Cp_w \left[\frac{kJ}{kg \cdot K}\right] \cdot (T_{t-1} - T_t)[K] \quad (8)$$

To equal the ΔE value to 0, the tank temperature at the previous instant T_{t-1} needs to be equal to the tank temperature at the current instant, Tt.

Therefore, we only consider the Δt instants in which the tank temperature is equal to $T_t = T_{t-1} = 60.5$℃, as this is the lower temperature fixed in the control. Afterwards, we recalculate the corresponding Δt instants and energy flows in a "*new energy database*" consists of 215 lines of data, which is a 98% reduction of data lines compared to the previous data sheet extracted from TRNSYS. By means of this methodology not only the 3rd casuistry is disregarded, but also the computational burden for the thermoeconomic analysis is notably reduced.

3.6 Thermoeconomic analysis

In order to carry out the thermoeconomic analysis, the following steps are followed:

1. Calculation of the "*exergy database*": the exergy flows corresponding to all flows are calculated based on the First and Second Laws of Thermodynamics.
2. Definition of economic values: the price of natural gas is defined as the only external resource, without considering the net water price.
3. Calculation of the thermoeconomic values by means of the thermoeconomics software for the following results:
   - Unit energy consumption of the *n* equipment: k_n
   - Unit exergy costs of fuels and products: $k^*_{F_n}$, $k^*_{P_n}$
   - Unit exergoeconomic costs of fuels and products: c_{F_n}, c_{P_n}

With the unit exergoeconomic costs of the products, we calculate the total cost of the installation total product $C_{p_{DHW}}[€]$, which in this case is the DHW to demand.

3.7 Development of the predictive model

This study compares the $C_{p_{DHW}}[€]$ cost of the installation in a reference situation (calculated in this work) with the cost in a climate change condition (with an increase in the outdoor temperature). In this way, we calculate the change in the overall consumption of the system as well as the increase in the individual components Δk_n, that will indicate the effects generated by that change.

Therefore, it is needed to quantify how the outdoor temperature variable is related to the intermediate costs of the system. Therefore, the costs are modelled according to the following options:

1. Each variable to be predicted (the intermediate costs as a function of outdoor temperature) can be modelled independently, from known temperature data.
2. A stepwise process can be carried out in which, once variables are predicted, they are incorporated as predictors to infer the missing ones.
3. All variables can be predicted at once.

These three points can be implemented in two ways:

- Taking into account information from previous instants to predict the current instant. RNN (Recurrent Neural Networks) methods attempt to identify and exploit sequential information in the data. These methods retain in "memory" the information from consecutive components of the sequence. The logic is based on answering the question, "Can the information observed at the instants before the sequence be relevant to predict what happens at the current instant?" If the answer is “yes”, as is the case with time series, then the model tries to detect it and use it to predict variables.
- Considering each moment in time as an independent observation (i.e. ignoring time dependence). This can be applied if the observations of time instants are considered as independent observations; thus, any time dependence relationship between the samples is broken. In this case, other simpler models that do not take into account this temporal dependency, e.g. multi-layer perceptron, are an efficient modelling alternative.

Combining the data-driven application and thermoeconomic concepts, the effect of the change in cost due to a change in external temperature will be quantified.

4. Results and discussions

This section explains the obtained results.

4.1 Verification of the control

Figure 7 is used to check the control designed for the installation, where 2 days out of the 7 days of the test were depicted. These graphs also demonstrate the dynamism of the installation, with the following conclusions:

- On the one hand, Figure 7a shows that when the temperature difference between the primary heat exchanger inlet and the tank temperature is greater than 5ºC, DHW production starts and stops when it is below 2ºC.
- On the other hand, Figure 7b shows how the boiler starts up when the tank temperature is below 60.5ºC and stops when it is higher than 62ºC.

In other words, the control is correctly designed.

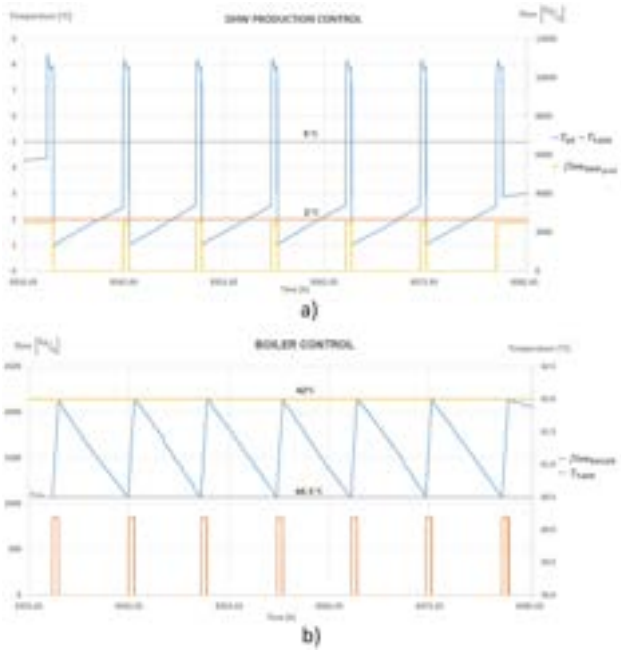

Figure 7. DHW production and boiler control verification graphs

4.2 Thermoeconomic results

Figure 8 shows the dynamic energy and exergy values of the fuel and boiler product.

- The exergy values for fuel are higher than the energy values because natural gas has a quality factor $QF_{NG} = 1.04 \left[\frac{kWh_{en}}{kWh_{ex}}\right]$
- However, exergy values of the product are lower than the energy values. This is because the exergy takes into account the quality of the energy flow, which in the case of the boiler is thermal energy. Average values show that the boiler has an energy efficiency of 89.26% compared to the exergy efficiency of 15.58%.

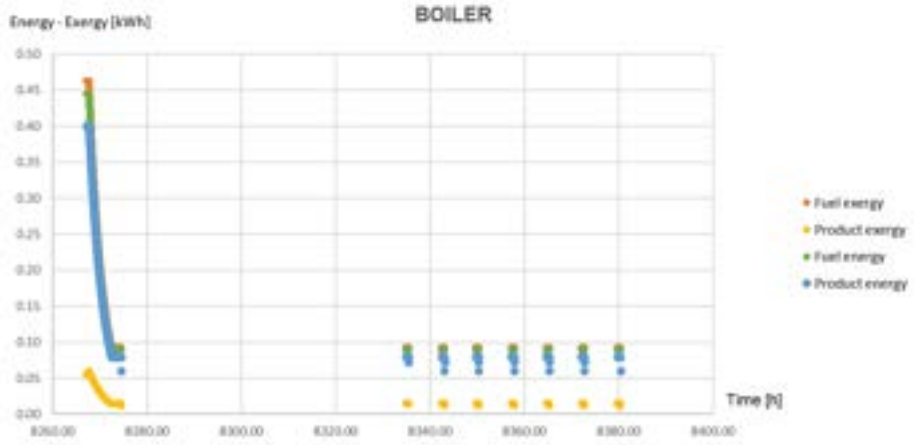

Figure 8. Energy and exergy values of fuel and boiler product

Despite having the dynamic values of the thermoeconomic results, due to space limitations, the following results show either the average values or the total sum of the values at each instant. Table 1 shows the total sums of fuels, products and equipment irreversibilities.

- On the one hand, as the energy chain progresses, the exergy values of the flows decrease. This is due to the accumulation of irreversibilities of the equipment.
- On the other hand, the equipment with the highest irreversibilities is the boiler, $I_{boiler} = 19.80\ [kWh_{ex}]$. This is due to the use of a fuel with a high exergy level (natural gas) to generate a product with a lower exergy level (hot water), in addition to the unavoidable exergy destruction intrinsic to the boiler.

Table 1. Fuel, product and irreversibilities of equipment

	EQUIPMENT	$F_{ex}\ [kWh_{ex}]$	$P_{ex}\ [kWh_{ex}]$	$I\ [kWh_{ex}]$
GENERATION	BOI	23.48	3.68	19.80
DISTRIBUTION	HX	3.68	2.16	1.52
PRODUCT	T	2.16	0.29	1.87

Table 2 shows the average values of the unit exergy consumptions of the equipment and the average values of the unit exergy costs of the fuels and products of each equipment.

- On the one hand, the unit exergy consumption of the equipment, $k_n \left[\frac{kWh_{ex}}{kWh_{ex}}\right]$, represents the amount of fuel required to produce one unit of product, showing that the equipment with the highest unit exergy consumption is the tank, $k_{TANK} = 8.87\ \frac{kWh_{ex}}{kWh_{ex}}$. This is due to the mixing of flows at very different temperatures.
- On the other hand, the unit exergy costs of the fuels $k^*_{F,i}$ of the generating equipment, (i.e. the boiler), $k^*_{F,BOILER}$ have the value of 1, since it is an external input flow. It is also observed that the ratio between the unit exergy costs of the fuels and the products of the equipment is proportional to the irreversibilities that occur.

Table 2. Unit exergy consumption of equipment and unit exergy costs of fuels and products

	EQUIPMENT	$k\ \left[\frac{kWh_{ex}}{kWh_{ex}}\right]$	$k^*_F\ \left[\frac{kWh_{ex}}{kWh_{ex}}\right]$	$k^*_P\ \left[\frac{kWh_{ex}}{kWh_{ex}}\right]$
GENERATION	BOI	6.41	1	6.41
DISTRIBUTION	HX	1.71	6.41	10.96
PRODUCT	T	8.87	10.96	96.12

Table 3 shows the average values of the exergoeconomic costs of the fuels and products of the system's equipment. For this analysis, only the exergoeconomic costs related to variable costs have been calculated, i.e. those that depend on the natural gas consumption.

- The exergoeconomic costs of fuels, c_F, take into account the irreversibilities accumulated up to that point in the energy chain; thus, moving down the energy chain, these costs increase.

- The exergoeconomic costs of the products, c_P, follow the same trend, as unit exergy costs, and increase when moving down the energy chain.

Table 3. Exergoeconomic costs of equipment fuels and products

	EQUIPMENT	$c_F \left[\frac{c€}{kWh_{ex}}\right]$	$c_P \left[\frac{c€}{kWh_{ex}}\right]$
GENERATION	BOI	5.07	32.52
DISTRIBUTION	HX	32.52	55.57
PRODUCT	T	55.57	487.43

The total cost of the DHW for the period studied is $C_P = 285.78 \ \frac{€}{7\ days}$.

4.3 Predictive model results

The Predictive model itself is not presented in this manuscript. Since we are now working in it, a coming work will contain the corresponding results

5. Conclusions

In this work a dynamic thermoeconomic analysis of a thermal installation of a building that produces DHW has been carried out and a methodology to predict the costs of the flows has been shown. This installation is designed based on the configuration of the LCCE's experimental plant and was simulated in the TRNSYS software.

During the thermoeconomic analysis, all the possible operating modes of the case study are analysed, with the following relevant conclusions:

- The equipment with the highest system irreversibilities is the boiler, $I_{boiler} = 19.80\ [kWh]$
- The equipment with the highest unit exergy consumption is the tank, $k_{TANK} = 8.87 \frac{kWh_{ex}}{kWh_{ex}}$.
- The total product cost of the installation is $C_{P,DHW} = 287.78 \left[\frac{€}{7\ days}\right]$

In addition, the first steps to develop an innovative methodology that combines Thermoeconomics and Machine Learning models is defined, in order to quantify the effects of climate change on the costs and consumption of thermal installations in buildings. This will help promoting maintenance work, which is essential for the proper functioning and for reducing GHGs.

5.1 Future lines

As said, we are working on this case study in order to develop the predictive model able to predict both the operation and the consumption and costs based on ML techniques.

Likewise, the fixed costs related to the operation, maintenance and amortisation costs of the installation will also be incorporated in the results.

The next step deals with the implementation in real systems.

In short, work will continue on a tool that combines Thermoeconomics and Machine Learning capable of predicting possible failures in thermal installations of buildings and optimising their operation.

Abstract:

Nowadays, with the constant global population growth, urbanization, pests use, climate change and resource degradation, the water-energy-food link is constantly stretched. In order to achieve water and food security, sustainable agriculture and energy production, the efforts of the next few years will be aimed to correctly balance these aspects. Therefore, it will be necessary both to improve the energy performance of traditional systems in the agricultural sector and at the same time to develop alternative and innovative ones. In this context, data from a local farm producing salad have been processed in order to relate the energy consumption of each processing phase to the produced kilogram of crop. In particular, thermal loads are attributed to the corresponding primary energy consumption. A thermo-economic analysis was carried out by considering different scenarios in terms of external ambient temperature and specific cost of electricity. Results show that the thermal load exchanged with the external ambient through the walls and the roof of the plant is about the 20% of the outgoing thermal load of the evaporator during the lighting hours whereas the thermal load of the auxiliaries (including the production lines) is about its 80%. Moreover, the variation of both the fourth range production lines operating time and the external daily temperature causes a variation in the total energy consumption related to the kilogram of processed product – up to 128%. Finally, several economic scenarios have been implemented in order to take into account the variation of the specific cost of electricity.

Keywords:

Thermo-economic analysis; Salad production.

1. Introduction

1.1. Context

Nowadays, with the constant global population growth, urbanization, pests use, climate change, resource degradation and scarcity, the water-energy-food link is constantly stretched and heavily tested. Particularly, serious and different problems affect the agricultural sector. First of all, the huge water usage accounts for 70% of the total global freshwater withdrawals [1] and it is expected that it will increase about 55% by 2050 [2]. In addition, energy consumption in the agricultural sector accounts for 3% in the European scenario and for 2% in the Italian one, respectively [3]. Moreover, the energy demand will increase about 3 times by 2050 worldwide [4]. On the other hand, it is estimated that the global population will reach 9.8 billion by 2050 and 11.2 billion by 2100 [5] in a non-uniform way worldwide. Additionally, the intense urbanization will affect more than 70% of world population. All these aspects will contribute to an intensification in the food production sector about the 60% by 2050 – it is worth noting that this sector accounts for 30% of the global energy consumption including also the cold chain and the transport sector. This scenario is exacerbated by the scarcity of arable land as well as the huge use of pesticides and chemical substances: in fact, about 1.9 Mtons of them have been employed in agricultural sector during 2019 in the EU context [6][7]. In order to achieve water and food security and at the same time sustainable agriculture and energy production, the efforts of the next few years will be aimed both to improve the energy performance of traditional systems of the agricultural sector (i.e. open fields and greenhouse systems) and at the same time to develop alternative and innovative ones by considering the ongoing energy transition – such as the indoor farming method.

As a matter of fact, several issues affect the traditional farming methods: their productivity is in fact strongly dependent on the exterior climate conditions, and they need an artificial lighting system and involve a high amount of water if greenhouse systems are installed in cold regions or hot/warm ones respectively, especially if compared to the ones of innovative and alternative agrifood systems such as vertical farms [8][9][10][11].

For the best of authors' knowledge, literature about the modelling of post cultivation phases of greenhouse systems is poor. Stanghellini et al [12] developed a model for the evaluation of evapotranspiration rate load of the plants by considering a greenhouse such it is considered one of the main energy load of those systems. The model includes the effect of the multilayers of the crop and the solar radiation is empirically evaluated as well as a careful calibration of the main parameters of interest is needed. Righini et al [13] developed and validated a greenhouse climate-crop yield model in order to correct manage those systems at high latitudes. Results show that the model is able to predict the air temperature with a very good agreement, with a relative root mean square error lower than 10%. A model for the energy optimization of greenhouses was developed by Weidner et al [14] for different climate zones in order to optimize the interior climate conditions and consequently productivity of the systems. From the abovementioned issues and lacks in literature, it is clear that in a context of energy transition regarding all the sectors and production processes, it is important to correctly model the post cultivation processes of traditional greenhouse systems in order to evaluate their energy consumption and relate it to the kilogram of processed product. The main purpose of this approach is to minimize their energy consumption as well as costs and at the same time maximize their productivity. In fact, from an economic and entrepreneurial point of view it is very useful to quantify both the rate of cost for electricity for the processed kilogram of product and the one for different scenarios by varying economic parameters (such as the specific cost of electricity) and those related to the performance of production lines, facilities and environmental conditions.

1.2. Objectives of the work

In this context the main goal of the manuscript is to model traditional agrifood system taking into account all the parameters of interest, such as external conditions, internal ones, crop type production, air conditioning and lighting systems and cost analysis. The modelling purpose is to relate the energy consumption of all the processing phases to the produced kilogram of product in order to maximize its productivity while minimizing its energy consumption and consequently its costs. In detail, data from a local farm producing salad have been processed and a thermo-economic analysis was carried out by considering different scenarios in terms of external ambient temperature and specific cost of electricity. Specifically, it is worth noting that the processing phases taken into account for the analysis are the post cultivation ones up to the final product picking for the shipping: consequently, both water and energy consumption concerning the raw materials cultivation phase are neglected.

2. Method

In order to relate the energy consumption of each processing phase (from post cultivation to final product) to the kilogram of final product intended for the market, it is fundamental to correctly evaluate all the energetic loads involved in the analysis. With this aim, in this section the implemented methodology is explained. The whole farm plant in which the entire production process takes place is reported in Figure 1 in which all the potentially thermal loads are considered.

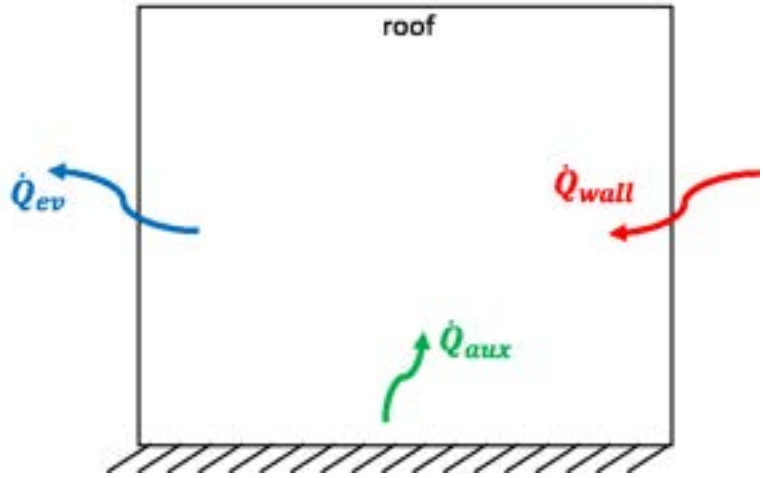

Figure 1 *- Plant schematization with the potentially energetic loads.*

In Figure 1 $\dot{Q}_{wall}$ is the thermal load exchanged with the external ambient through the walls and the roof of the plant, $\dot{Q}_{aux}$ is the thermal load caused by the auxiliaries (pumps, fans, lighting system, ecc) and the production lines; finally, $\dot{Q}_{ev}$ is the outgoing thermal load of the evaporator. It is clear that, from an energetic balance to the control volume reported in Figure 1, the sum of the thermal load exchanged with the external ambient

through the walls and the roof and the one caused by auxiliaries is counterbalanced by the outgoing thermal load of the evaporator:

$$\dot{Q}_{ev} = \dot{Q}_{tot} = \dot{Q}_{wall} + \dot{Q}_{aux} \tag{1}$$

In the energetic analysis the latent power due to the staff presence in the plant during the product's processing phases has been omitted as it is significantly lower compared to the previous ones as well as difficult to estimate. In order to evaluate the thermal load $\dot{Q}_{wall}$ through the walls and the roof of the plant it is useful to refer the analysis to the generic j-th cell in which a specific processing phase takes place as shown in **Figure 2** with both the plan and the section views reported:

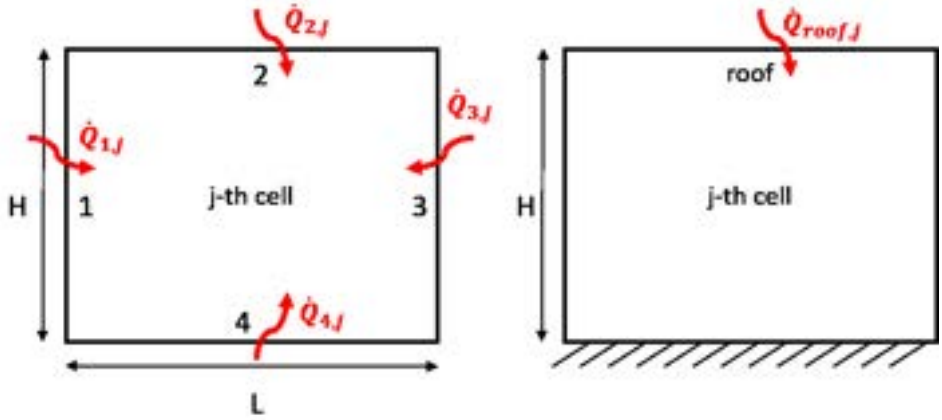

***Figure 2** - Plan and sectional view of the generic j-th cell with the indication of the thermal loads exchanged through the walls and the roof.*

The analysis was carried out by assuming that the internal temperature of the cell for the related processing phase is fixed to be T_j and by associating to each processing phase of the product a specific cell of the plant. Moreover, the whole plant is served by a refrigeration unit. The thermal load related to the j-th processing phase is defined as the sum of the thermal loads exchanged through the walls and the roof as reported in equation (1):

$$\dot{Q}_{cell,j} = \dot{Q}_{1,j} + \dot{Q}_{2,j} + \dot{Q}_{3,j} + \dot{Q}_{4,j} + \dot{Q}_{roof,j} \tag{2}$$

Thermal loads of the walls and the roof are evaluated taking into account the radiative, convective and conductive contributes to the heat transfer mechanism and they are reported in the follow equations:

$$\dot{Q}_{1,j} = \dot{Q}_{wall,1} = \dot{Q}_{c,int} \tag{3}$$

$$\dot{Q}_k = \dot{Q}_{c,int} \tag{4}$$

$$\dot{Q}_{rad} = GAa \cdot cos\vartheta \tag{5}$$

$$\dot{Q}_{c,ext} = h_{ext} A\left(T_{amb} - T_{wall,ext}\right) \tag{6}$$

$$\dot{Q}_{c,int} = h_{int} A\left(T_{wall,int} - T_j\right) \tag{7}$$

In the previous equations, A is the surface area, G is the solar radiation, ϑ is the angle of incidence of the solar radiation, h_{ext} is the external convective heat transfer coefficient, h_{int} is the internal convective heat transfer coefficient, $T_{wall,int}$ and $T_{wall,ext}$ are the internal and the external wall temperature respectively and a is the absorption coefficient. Therefore, the thermal load of the generic j-th cell $\dot{Q}_{cell,j}$ can be considered as the sum of the thermal power exchanged through the walls and the roof. Finally, the total thermal power of the considered plant $\dot{Q}_{wall}$ will be calculated as the sum of the thermal power of each cell. In detail, the total thermal power of the whole farm has been evaluated during the year by considering Naples' hourly temperature profile. Moreover, by knowing the quantity of product treated during the specific processing phase j-th (m_p^j) and its residence time inside the generic j-th cell $\left(\Delta\vartheta_j\right)$, the energy consumption of the j-th process will be evaluated and referred to the produced kilogram of raw material:

$$E_{raw\ mat.,j} = \left[\sum_{i=1}^{N_{step}} \left(\frac{\dot{Q}_{cell,j}(T_{amb,i}) + \dot{Q}_{aux,j}}{\dot{Q}_{tot}} \cdot \dot{L}_{comp,i} + \dot{L}_{aux,p,j,i}\right)\right] \Delta\vartheta_j \cdot \frac{1}{m_p^j} \quad (8)$$

In Equation (8) $\dot{Q}_{aux,j}$ is the thermal load caused by the auxiliaries (pumps, fans, lighting system, ecc) and the production lines during the j-th processing phase, $\dot{L}_{aux,p,i}$ is the mechanical power of auxiliaries (pumps, fans, lighting system, ecc) and the production lines of the considered processing phase whereas $\dot{L}_{comp,i}$ is the mechanical power of the compressor of the refrigeration unit serving the plant and $\dot{Q}_{tot}$ is the one defined in the previous Equation (1). Finally, N_{step} is the ratio between the time of the j-th process and the chosen time step. The energy consumption of the whole process for the considered raw material is the sum of the energy consumption of the j-th phases and, in order to evaluate the rate of cost for electricity – that will be defined as RCE – per kilogram of processed product, the total energy consumption of the M processes is then multiplied by the specific cost of electricity as reported in Equation (9):

$$RCE = \left(\sum_{j=1}^{M} E_{raw\ mat.,j}\right) \cdot specific\ cost\ of\ electricity \quad (9)$$

The considered case study is referred to the production of salad of a local farm and the analysis was carried out in order to include different scenarios in terms of external ambient temperature and specific cost of electricity by following the presented methodology.

3. Case study

For the present study data from a local farm near Naples have been processed in order to evaluate the rate of cost for electricity and relate it to the produced kilogram of product (salad). The identified processing phases are reported in Figure 3 in the relative flowchart:

Figure 3 *– Processing phases for the energy consumption analysis.*

In detail, the raw materials, previously grown in traditional greenhouse systems, arrive in the first cell (defined as cell 1); then the cooling process takes place and subsequently the raw materials are stored in the cell number 3. In the 4th cell both washing and drying processes occur and the semi-finished products are stored in the 5th cell from which they are bring to the cell number 6 for the subsequent phase of packaging. Finally, the products' weight control, labelling and palletizing occur in the 7th cell and then the final product is stored in the 8th cell from which it is picked for the shipping. In Table 1 the one-to-one correspondence between the specific processing phase and the nomenclature is reported:

Table 1 *- Nomenclature and relative area of the processing phases.*

Cell	*Processing phase*	$A\ [m^2]$
1	Raw materials receiving	1300
2	Vacuum cooling	310
3	Raw materials storage	2200
4	Product washing and drying	300
5	Storage of semi-finished products	450
6	Packaging of the products	750
7	Weight control, labelling and palletizing	1600
8	Storage and picking from the shipping cell	30

3.1. Operating conditions

Operating conditions of the farm in terms of quantity of product treated during the specific j-th processing phase m_p^j and its residence time inside the generic j-th cell $\Delta\vartheta_j$ as well as data about the refrigeration unit serving the whole plant and production lines with their on/off times have been processed and the rate of cost for electricity related to the processed kilogram of product was estimated. In detail, the analysis was carried out by considering several daily temperature profiles from January 9, 2023 to January 13, 2023. The thermal load $\dot{Q}_{wall}$ through the walls and the roof of the plant has been calculated by considering 0.1 as the absorption coefficient a and the value of the insulating material's thermal conductivity k has been fixed to $0.023\ W/mK$. As regard the thermal load caused by the auxiliaries $\dot{Q}_{aux}$, the first range production lines have been assumed all in operation from 4am to 8pm, whereas for the fourth range production lines data provided by the monitoring of the farm have been considered. Finally, data about the outgoing thermal load of the evaporator $\dot{Q}_{ev}$ during the second week of January 2023 have been taken into account from the monitoring of the local farm. Details about the operating conditions in which the analysis was carried out are reported in Table 2:

Table 2 *- Operating conditions for the thermo-economic analysis.*

Month	*Day*	$\dot{Q}_{wall}$	*First range production lines operating hours*	*Fourth range production lines operating hours*
January	9	$k = 0.023\ W/mK$ $a = 0.1$	16h	19h 30'
	10			16h
	11			17h
	12			16h 30'
	13			16h 30'

3.2. Thermal loads evaluation

In the operating conditions above described, all the thermal loads of interest – $\dot{Q}_{wall}$, $\dot{Q}_{aux}$ and $\dot{Q}_{ev}$ – have been calculated following the methodology presented in the previous section. Shown below the hourly dimensionless results of the thermal loads for the second week of January 2023, for the operating conditions reported in Table 2. It is worth noting that all the data shown in Figure 4(a)-(e) have been dimensionless with respect to the maximum value of the outgoing thermal load of the evaporator:

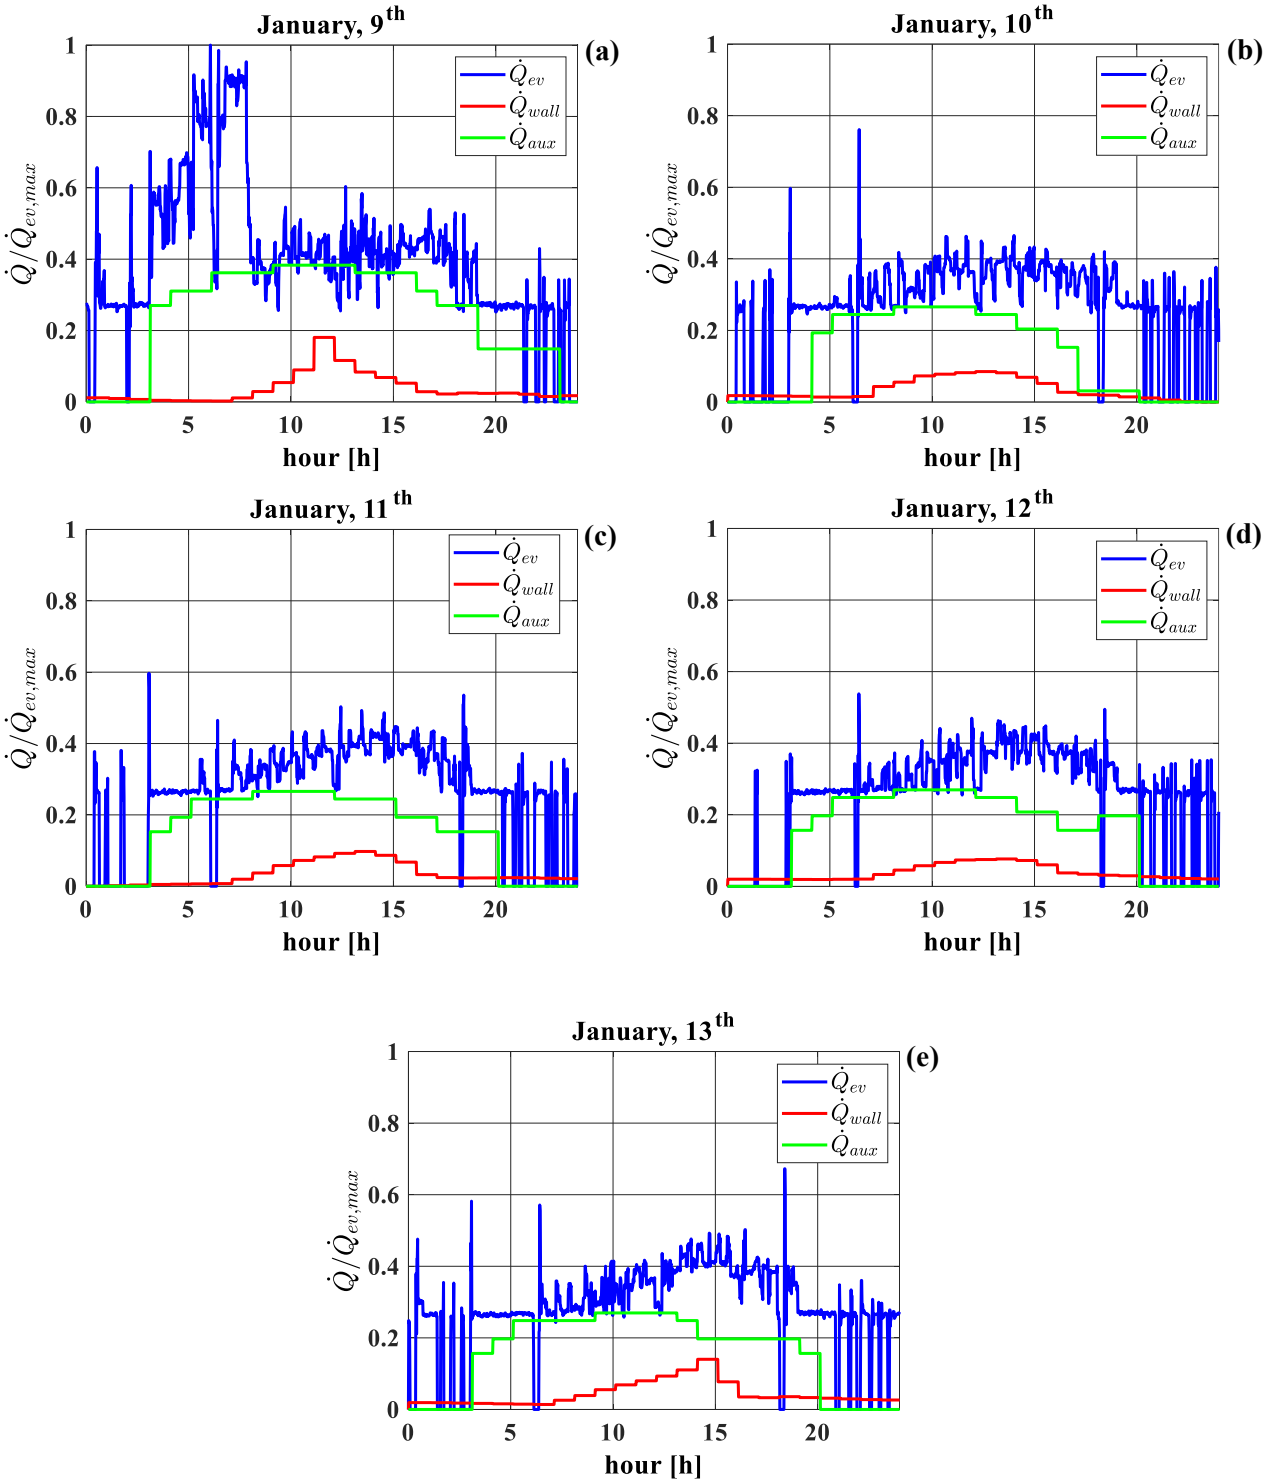

Figure 4 *- Hourly dimensionless thermal loads evaluation for the second week of January, 2023 in the operating conditions reported in Table 2. (a) January, 9th. (b) January, 10th. (c) January, 11th. (d) January, 12th. (e) January, 13th.*

It can be seen that the sum of the thermal load caused by the auxiliaries $\dot{Q}_{aux}$ and the one exchanged through the walls and the roof the plant $\dot{Q}_{wall}$ is continually counterbalanced by the outgoing thermal load of the evaporator. In detail, the thermal load exchanged with the external ambient through the walls and the roof of the plant is, at most, about the 20% of the outgoing thermal load of the evaporator during the lighting hours whereas the thermal load of the auxiliaries (pumps, fans, lighting system, ecc) and the production lines is about the 80% of it. This trend occurs for all the operating conditions considered and for all the days taken into account in the energetic analysis.

4. Results and discussion

4.1. Evaluation of the energy consumption related to the kilogram of product

Once the thermal loads of interest have been evaluated in the operating conditions reported in Table 2, the energy consumption related to the kilogram of processed product (salad) of each processing phase has been calculated by following Equation (8) for the second week of January. Data related to the quantity of product treated during the specific processing phase j-th (m_p^j) and its residence time inside the generic j-th cell $(\Delta\vartheta_j)$ have been taken into account from the monitoring of the local farm. Then, the total daily energy consumption related to the kilogram of processed product has been considered as the sum of the specific energy of each processing phase by following Equation (9). In Table 3 results in terms of total daily energy consumption related to the kilogram of processed product are reported:

Table 3 *- Daily energy consumption related to the kilogram of processed product during the second week of January.*

Month	*Day*	$\left(\sum_{j=1}^{M} E_{raw\ mat.,j}\right)\left[\frac{kWh}{kg}\right]$
January	9	4.46
	10	2.52
	11	2.37
	12	1.96
	13	2.36

It can be noted that the total energy consumption of January, 9th is significantly higher compared to the others daily total energy consumption: $+77\%$ and $+128\%$ compared to the ones of January, 10th and 12th, respectively. This trend is caused by the higher thermal load of the auxiliaries $\dot{Q}_{aux}$ during the operating hours of the farm due to the higher operating time of the fourth range production lines. It is worth noting that the energy consumption related to the kilogram of processed product shown in Table 3 is strongly dependent on the performance of the production lines, on their operating times and finally on the external conditions. Therefore values in Table 3 have not to be considered as reference ones, but they can allow to consider and compare different solutions and scenarios able to reduce the rate of cost for electricity for kilogram of processed product for the presented case study.

4.1. Economic analysis

Finally, once the thermodynamic analysis has been completed, an economic one was implemented by following Equation (9). In detail, the specific cost of electricity has been fixed to $0.22\ €/kWh$ [15] – the cost is referred to the average price during the whole year 2022 – and the daily rate of cost for electricity (RCE) related to the kilogram of processed product has been calculated for the second week of January, as shown in Figure 5.

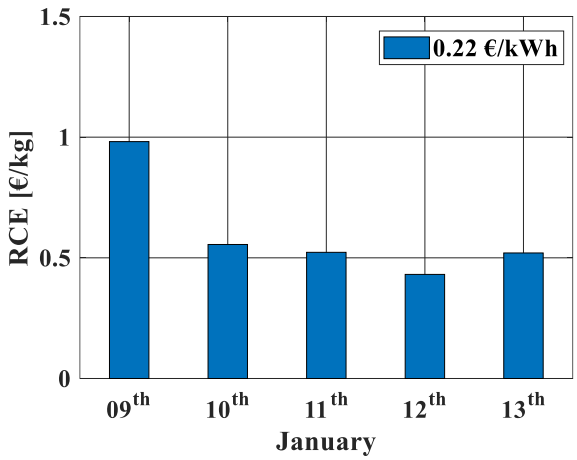

Figure 5 *- Daily rate of cost for electricity related to the kilogram of processed product for a specific cost of electricity of* $0.22\ €/kWh$ *for the second week of January.*

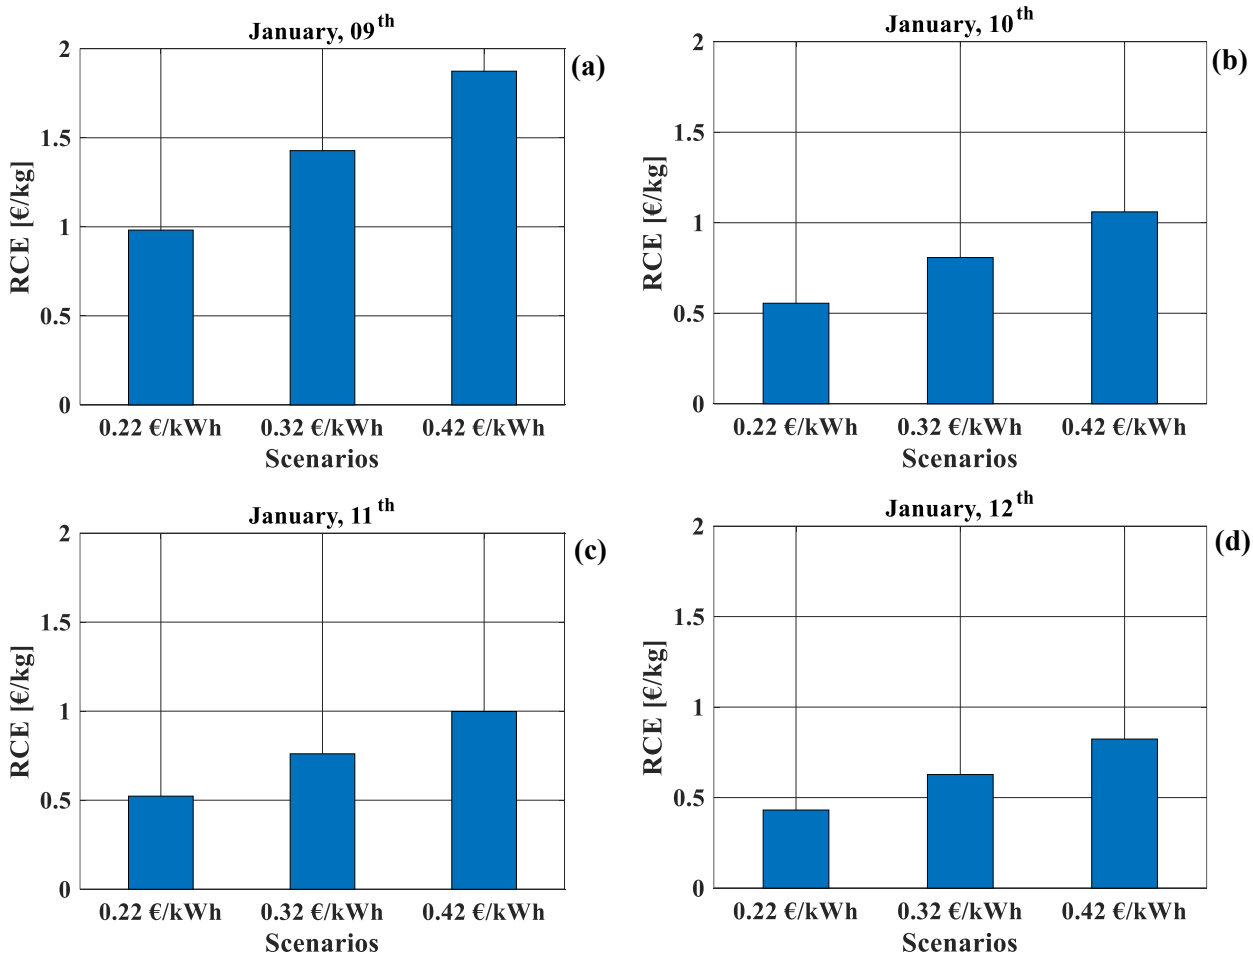
It can be noted that the daily RCE of January, 9th is significantly higher compared to the other ones, following the trend of the daily energy consumption shown in the previous sub-section (4.1): $+88\%$ and $+128\%$ compared to the ones of January 11th and 12th, respectively.

Finally, different economic scenarios have been considered by fixing the specific cost of electricity to $0.32\ €/kWh$ and $0.42\ €/kWh$, in order to take into account the variation of the specific cost of electricity. Results of the implemented scenarios are shown in Figure 6.



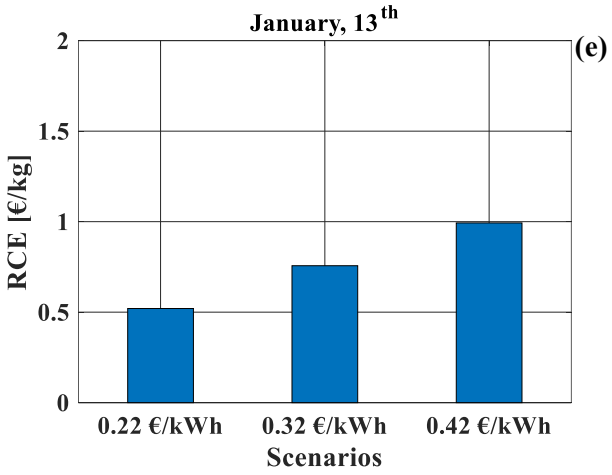


Figure 6 *– Daily rate of cost for electricity related to the kilogram of processed product for specific cost of electricity of* $0.22\ €/kWh$, $0.32\ €/kWh$ *and* $0.42\ €/kWh$. *(a) January, 9th. (b) January, 10th. (c) January, 11th. (d) January, 12th. (e) January, 13th.*

It can be noted that the increase in the specific cost of electricity involves an increase in the daily rate of cost for electricity per kilogram of processed product – $+92\%$ and $+94\%$ by passing from a specific cost of electricity of $0.22€/kWh$ to $0.42\ €/kWh$ by considering January 11th and 13th, respectively. The same trend is observed for all the operating conditions included in the analysis.

5. Conclusions

In this manuscript the modelling of a traditional agrifood system has been implemented taking into account all the parameters of interest, such as external conditions, internal ones, crop type production, air conditioning and lighting systems. In detail, data from a local farm producing salad have been processed in terms of quantity of product treated during the specific j-th processing phase m_p^j and its residence time inside the generic j-th cell $\Delta\vartheta_j$ as well as data about the refrigeration unit serving the whole plant and production lines with their on/off times. A thermo-economic analysis has been implemented by considering different operating conditions in terms of daily external temperature profile and specific cost of electricity. The main conclusions of the manuscript are reported as follow:

- For all the operating conditions considered and for all the days taken into account the thermal loads evaluation has highlighted that the thermal power exchanged with the external ambient through the walls and the roof of the plant is, at most, about the 20% of the outgoing thermal load of the evaporator during the lighting hours whereas the thermal load of the auxiliaries (including the production lines) is about the 80% of it.
- The total daily energy consumption related to the kilogram of processed product has been evaluated: for January 9th it is significantly higher compared to the others: $+77\%$ and $+128\%$ compared to the ones of January 10th and 12th, respectively.
- By considering the specific cost of electricity of January 2023 as $0.22\ €/kWh$, the daily rate of cost for electricity RCE has been evaluated. The same trend of the total daily energy consumption was found: in fact, the daily RCE of January 9th is significantly higher compared to the others, up to $+128\%$ with the one of January 12th.
- Finally, different economic scenarios in terms of specific cost of electricity have been included in the analysis. It was found that the increase in the specific cost of electricity involves an increase in the daily RCE, up to $+94\%$ for January 13th, by passing from specific cost of electricity of $0.32€/kWh$ to $0.42\ €/kWh$.

Nomenclature

a	absorption coefficient
A	surface area, m^2
G	solar radiation, W/m^2

h	heat transfer coefficient, W/(m^2 K)
H	height of the wall of the cell, m
k	thermal conductivity, W/(m K)
L	length of the wall of the cell, m
$\dot{L}$	mechanical power, kW
m	mass of processed product, kg
M	total processing phases
N	number of step integration
RCE	rate of cost for electricity, €/kg
T	temperature, K
$\dot{Q}$	thermal load, kW

Greek symbols

ϑ	angle of incidence of the solar radiation, rad
$\Delta\vartheta$	residence time of the mass during the processing phase

Subscripts and superscripts

amb	ambient
aux	auxiliaries
c	conductive
$cell$	cell
$comp$	compressor
ev	evaporator
ext	external
i	time step for the integration
int	internal
k	convective
j	specific processing phase
max	maximum
p	process
rad	radiant
$raw\ mat.$	raw material
$step$	step of integration
tot	total
$wall$	wall

Abstract:
The indoor air temperature in buildings is one of the main parameters determining both the indoor thermal comfort of inhabitants and the energy consumption of the Heating, Ventilation and Air Conditioning systems (HVAC). Clothing insulation of building residents is a key factor dramatically affecting people thermal comfort and HVAC energy demand. Indoor set point temperature, depends on clothing factor, relative humidity and mean radiant temperature. Although the clothing insulation values are selected according to well-known standards, clothing insulation depends on several factors: the metabolic heat production, activity and gender (females tend to be cooler than males in cool conditions). Therefore, users can adjust their clothing insulation according to the outdoor temperature change, suiting their own thermal comfort requirement. In this framework, a dynamic simulation model for the evaluation of the comfort conditions and the cooling energy consumption based on the variation in clothing insulation for office applications is developed in the present work. In order to calculate the space cooling demand, a suitable thermal zone was modelled by the TRNSYS Type 56 coupled to the Google SketchUp TRNSYS3d plug-in. The model was validated and applied to a suitable case study, an office room located at University of Federico II in Naples (Italy). Different sensitivity analyses were performed changing the clothing insulation and the office set-point temperature, to estimate both the comfort conditions and cooling energy demands. The model can be considered a flexible tool to suggest simple clothing adjustment behaviors which may represent a tradeoff among thermal comfort, energy saving and dressing code.

Keywords:
Dynamic simulations, Clothing insulation, Building energy saving, Thermal comfort

1. Introduction

In 2020, the global building sector accounted for 36% of energy consumption and 37% of CO_2 emissions, while the residential sector accounted for 22% of energy consumption and 17% of CO_2 emissions [1]. As a result, over the last two decades, a series of policies and regulations have been implemented in order to increase the energy efficiency and reduce carbon emissions. It is estimated that 80% of the current building stock will still be in use in 2050 and current renovations rates of 1% is too low to meet the Green Deal goals [1]. Advances in heating, ventilation, and air conditioning (HVAC) systems, energy-efficiency strategies for the building stock have been advocated to reduce energy consumption in the building sector and encouraging environmental friendly end-use behaviours [2]. These involve improved measures on the envelopes of buildings [3], such as employing innovative materials [4], advanced insulation and building structures [5], new construction and the renovation of existing buildings [6].

It is well known that, in both residential and non-residential buildings, different types of HVAC systems can be used to control the indoor air temperature, humidity and/or quality [7]. Such parameters significantly affect the indoor thermal comfort [8]. The building thermal comfort level is related to building energy consumption, therefore, a large amount of energy will be consumed while improving indoor thermal comfort [9]. Considering ongoing global warming issues and the increasing demand for cooling energy, it is also important for policy-makers and households to implement suitable strategies to reduce their cooling energy demand and resulting, consequently decreasing the related carbon emissions [10]. In this framework, energy refurbishment actions for the building envelope and HVAC systems are pivotal to reduce the building energy demand. Unfortunately, the majority of these actions are featured by high capital costs and long payback periods. However, significant energy savings can be also achieved simply modifying the users behaviour, avoiding any major refurbishment [11]. Tam et al. [12] argue that the actual occupant behaviour plays a crucial role to achieve an optimal building performance, from both energy and environmental points of view. They also suggest including occupant behaviour in the calculation procedure of the energy rating of existing buildings. A careless behaviour negatively affects the building energy demand, also affecting the thermal comfort. Energy dissipation is often due to a plurality of incorrect user habits. This is especially true in office buildings where occupants are not aware on the impact on the energy bills of their behaviours. Some previous works focused on the promotion of users behaviour change, by encouraging the adoption of positive energy management habits. These behavioural interventions include the use of interactive games to increase the user awareness regarding different energy-saving strategies [13], using monetary rewards to encourage energy conservation, introducing different forms of incentives to motivate the adoption of positive energy management habits [14].

In the framework of the user behaviour, the dress-code plays a pivotal role in the definition of the user thermal comfort [15], and therefore, of the thermal energy consumption. In many working environments (banks, universities, etc), the clothing insulation mirrors the “power” structure within the workplace, representing the symbol of credibility [16], and the dress code overrides the rational thermoregulatory behaviour. In fact, users are often expected to dress in a multi-layer wool suit, regardless of the hot outdoor climate. Corporate dress codes completely extinguish opportunities for clothing adaptation [17]. In these workspaces, the energy demand for space cooling is higher with respect to the case of more informal dressing codes. For example, a suit without the tie allows one to significantly improve the thermal comfort during the summer season. This results in a lower space cooling demand and environmental impact. Considering near-sedentary activities performed in office buildings, where the metabolic rate is approximately 1.2 met, the effect of changing clothing insulation on the optimum operative temperature is about 6 °C per clo (1 clo is equal to 0.155 m^2 K/W). Therefore, removing of a thin, long-sleeve sweater decreases clothing insulation by approximately 0.25 clo and would increase the optimum operative temperature by approximately 6 °C/clo × 0.25 clo = 1.5 °C [18]. The ASHRAE chart indicates that the clothing insulation should be reduced to 0.1-0.6 clo (ideally, 0.3) to maintain comfort at 25.6°C [19], and not at 21.5°C as in the case of 1 clo (to obtain for a standard office activity of 1.2 met, a relative humidity of 50%, an air velocity less than 0.1 m/s, and the air temperature equal to the mean radiant temperature, a Predict Mean Vote (PMV) equal to 0 and Predicted Percentage of Dissatisfied (PPD) equal to 5%). A change in clothing insulation by only 0.2 clo leads to a temperature change of about 1°C in a typical office building [20].

In civil building environments, many researchers have found that changing clothing to acclimate to different climate conditions has been an affordable and efficient method of achieving thermal comfort [21, 22]. Newsham [23] proposes a model to study the effect of different levels of clothing on thermal comfort and energy consumption. The model is applied to an office, located in Toronto, adopting high cooling set-point temperatures in summer and lower heating set-point temperatures in winter. The aim is to detect the clothing factor values suitable to guarantee a PPD index of around 5%. In case of a more flexible and adaptable clothing, the cooling set-point value of 25.55°C is detected. This decreases to 24.35°C for a value of 0.75 clo. However, both set-point temperatures are lower than the value of the dress factor corresponding to a classic formal dress (1 clo). It is worth noting that the space cooling energy demand significantly depends on the aforementioned set-point values, with an annual consumption of 218 kWh in the first case, 275 kWh in the second one, realizing an energy saving of 21%. Wu et al. [24] present a study dealing with an office building in Guangzhou, featured by a hot summer and a warm winter. To perform the study, once a week the office workers carried out a questionnaire regarding the thermal comfort, whereas physical environmental parameters were continuously recorded. For each season, different clothing factors were considered. They conclude that for the investigated weather zone, increasing the set-point temperature in office buildings from 26°C to 29°C would save about 60% cooling energy without thermal discomfort. Schiavon and Lee [25] developed two multivariable linear mixed models considering the clothing as a function of outdoor air temperature measured at 6 o'clock and of indoor operative temperature. These models allow more accurate thermal comfort calculation and HVAC sizing with respect to the common practice of keeping the clothing insulation equal to 0.5 clo in the summer and 1 clo in the winter. For example, the winter median clothing

insulation in Canada was 0.8 clo when the median winter outdoor air temperature measured at 6 o'clock was−7.5°C. Lakeridou et al. [26] suggest increasing the set-point temperature of the offices of the United Kingdom by 2°C with respect the current set-point values of 22 ± 2°C. They changedthe set-point temperature only for one floor of the building and measured the indoor air temperatures at various locations across the floors. The results of the statistical analysis for all 129 participants suggest that the increase led to the occupants feeling significantly warmer in comparison with the group at lower temperature settings. However, increasing the floor set-point of open-plan areas to 24°C appears not to cause substantial discomfort, even if the actual percentage dissatisfied (APD) in some offices was near its maximum acceptable value equal to 20%. De Dear [22] examines the influence of clothing for two different cases study located in Sydney (Australia), a suburban shopping mall and a call center. The company that operates the call center is based on a strict working dress code from Monday to Thursday, but employees were free to wear casual clothes on Fridays. The daily mean values for all workers of the clothing factors on Friday were significantly higher than values for other weekdays in winter and lower in summer. On Friday, in the Sydney office case study, workers showed their marked preference for clothing not imposed by codes of formality.

1.1. Aim of the work

Although this topic was widely studied in literature, a lack of knowledge regarding the analysis using dynamic simulations is detected. This kind of analysis allows one to control, for each time step of the simulations, the key variables affecting the thermal comfort, considering the users within a whole building-plant simulation system. Considering that the building is a complex system, the energy phenomena occurring are different and continuously correlated: these phenomena concern the features of the building envelope (walls, roofs, windows), the plants for the production of space heating and cooling, the intended use of the zones of the building (residential, offices, hotels), the presence of a large number of people or machines that produce heat. Avoiding experimental investigations, the dynamic simulation analyzes the energy performance of a building with precision and reliability, obtaining consistent estimates. For this reason, the present study is performed using the TRNSYS software, analyzing the actual influence of the relaxation of the dress code on the cooling energy demand and the thermal comfort of occupants. The developed model was applied to a typical office located in Naples (South of Italy) of the University Federico II. The proposal for an extreme relaxation of the dress code will give the opportunity to remove the jacket and tie from the classic formal dress. As a limit case study, the so-called "tropical" dress, consisting of a short-sleeved shirt and shorts, was also analyzed. Note that the hourly dynamic simulation allows one to evaluate the hours of discomfort of the users as a function of the cooling set-point temperature and clothing factor for any day of the summer season. The dynamic simulation model demonstrated its ability to accurately predict the thermal comfort perceptions. In addition, using the dynamic simulation tool, it is possible to properly design the HVAC systems capacity (oversized to respect specific and rigid thermal comfort conditions), and to determine their lower energy demand.

2. Method

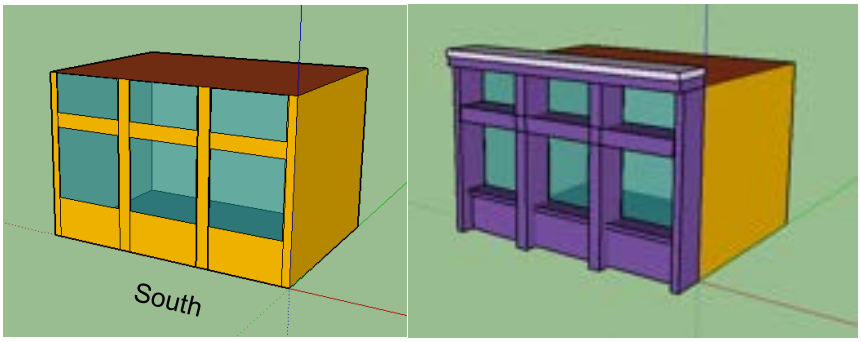
In this section the method used to develop the calculations is presented. In particular, section 2.1 shows the model developed to perform the dynamic simulations and the economic, energy and economic analyses; section 2.2 reports the case study considered to run the simulations.

2.1. Model

The simulation model of the office is developed using the well-known tool TRNSYS. It includes a large library of components, which are able to accurately simulate the energy performance of the energy components included in the investigated system. The types included in TRNSYS environment are considered reliable and validated [27]. TRNSYS software is very reliable and accurate for the evaluation of building energy demand [28] and is considered by the scientific community as a benchmark tool to validate the in-house building simulation models [29-31].

Type 56 was selected to model the office. The validation of the whole Type 56 is presented in reference [32]. This component calculates the dynamic energy demand, by considering its 3D geometry (defined in the Google SketchUp TRNSYS3d plug-in [33], the effects of the environmental conditions (i.e. ambient temperature and humidity, solar radiation, etc.) the envelope thermophysical proprieties, as well as all the internal gains (people, lights, machineries), the ventilation and infiltration rate. The office geometry analyzed in this work is represented in

Figure ***1***. Details about the geometry are provided in the case study section. To simulate the external overhangs, the tool "Trnsys3d Shading Group" was used. In Type 56 a number of parameters can be set: material thermophysical properties of walls and layers, ventilation and infiltration profiles, heat gains, heating and cooling scheduling, etc. Note that the mathematical model of Type 56 allows one to evaluate the building user comfort according to the ASHRAE Standard 55-2013 [34]. It is also worth noting that Type 56, included in TRNSYS 18 release, includes a detailed model for the calculation of radiation in the building, taking into account a complex model for the calculation of view factors and considering the radiative properties of the surfaces as a function of the wavelength. As a consequence, the model returns the wall temperatures and the radiate flows emitted by the walls and transmitted by the glazing surfaces. Thus, the model can also calculate important comfort parameters such mean radiant temperature and operative temperature which directly affect the comfort indexes. The most relevant comfort parameters are calculated according to the Fanger theory [35]. In particular, according to the UNI EN ISO 7730 regulation [36], the calculated comfort indexes are Predicted Percentage of Dissatisfied (PPD) and Predicted Mean Vote (PMV). Therefore, the model allows one to detect the number of operating hours where the comfort parameters are outside the acceptability range (discomfort hours).



(a) *(b)*

Figure 1. Sketchup 3D model of the office, without (a) and with (b) external overhangs

Type 15 and 109 were used to simulate the weather conditions of the city where the selected office is located providing the hourly weather data files obtained by Meteonorm database. The cooling energy needed to cool the office at the desired set-point temperature is produced by a fan coil unit, simulated by the TRNSYS Type 600. The fan coil is supplied by chilled water by a suitable variable speed pump, simulated by Type 110. A suitable control strategy, managed by the proportional controller Type 1669, is implemented in the model to manage the water flow rate flowing through the pump. The controller manages the flow of water to be supplied to the fan coil according to the indoor air temperature of the office. When the indoor air temperature is higher than a fixed threshold value, the pump supplies the fan coil with the highest value of flow rate, which is proportionally reduced when the indoor air temperature decreases. The fan coil air flow is assumed to be constant, and it depends on the nominal cooling capacity of the fan coil.

2.2. Case study

The case study is a 22.3 m^2 office located at 10th floor of the building of University of Federico II, in Naples, South of Italy, see

Figure **2**. The office consists of one external vertical wall and three adjacent vertical walls, bordering other internal areas (offices and hallway). The building. On the external wall there are six double-glazed windows with aluminium frame and air gap.

(a) *(b)*

Figure 2. University of Federico II, Piazzale Tecchio, Naples, Italy (a), Investigated Office (b)

In particular, three windows (1.52m x 1.56m) are located on the lower side of the wall and three windows (skylights, 1.52m x 0.85m) are located on the upper side of the wall. The aluminium frame covers 35% of the whole glazed area for lower side windows and 40% of the whole glazed area for upper side windows. A venetian blind is also considered for all lower side windows, device that plays a fundamental role in calculating of the incoming solar radiation. To control the opening and closing of the shading device, a suitable control strategy of the solar radiation is implemented. In particular, if the total horizontal radiation is lower than a certain treshold, the shading device is completely opened. Conversely, the shading device is completely closed.

The building envelope was defined according to the period of construction of the building. The features of the typical buildings constructed during the years from 1955 and 1970 were assumed and reported in Table 1.

Table 1. Thermophysical proprieties of the office

Component	Thickness [mm]	U [W/m^{2}K]
Internal floor/ceiling	350	0.347
External wall	340	0.326
Outer pillar	470	1.899
Window glass (lower and upper wall)	4/16(air)/4	2.89

The heat gains due to the people, lighting systems and machineries were summarized in Table 2. The considered values were fixed according to the ASHRAE Handbook Fundamentals [37]. The infiltration rate was set equal to 0.6 1/h. The office is occupied by users from 9:00 am to 6:00 pm on weekdays. The closure of the office during the summer holidays was assumed from August 8th to 22nd. The cooling season was assumed from May 1st to September 30th. The cooling system operates only during the occupation hours.

A control strategy related to the switching on and off of the artificial lights was implemented. Easily, the lights are switched on when the total horizontal radiation is lower than a fixes value defined equal to 120 W/m^2.and switched off when it is higher than 200 W/m^2.

Table 2. Heat Gains

Mode	Total heat [W]	Radiative heat [W]	Convective heat [W]
	Two computers		
Continuous operating	65	6.5	58.5
Energy saving	25	2.5	22.5
	Four Monitors, 48 cm each one		
Continuous operating	80	8	72
Energy saving		0	
	Lights: 2 LED panels [60cmx60cm] 48W		
Switching on	31.2	8.4	22.8
	Two women	Activity: Light office work	
Total heat [W]	Sensible heat [W]	Latent heat [W]	Radiative Sensible heat [%]
115	70	45	60

For the comfort analysis of the office occupants, three different combinations of the main variables affecting on the thermal comfort condition were simulated.

In particular, the metabolic activity and air velocity values were set constant and equal respectively to 1.2 met (representative of the light metabolic activity for sedentary office work) and 0.1 m/s. Such values are consistent with the type of simulated indoor environment. As for the clothing factor, three different values were defined, each corresponding to a specific outfit. In particular, according to the EN ISO 7730:

- For the comfort condition C1, the value of 1 clo was associated, representative of the classic formal dress (trousers, long-sleeved shirt, jacket and tie);
- For the comfort condition C2, the value of 0.5 clo was associated, representative of a generic light summer clothing (light trousers and unbuttoned short-sleeved shirt);
- For the comfort condition C3, the value of 0.3 clo was associated, corresponding to a "tropical" outfit, consisting of shorts, a short-sleeved shirt, socks and sandals.

Concerning the energy, environmental and economic analysis, the following assumptions were considered. To convert the cooling energy demand of the office in electric energy, a constant coefficient of performance equal to 3 [38] and an electric efficiency of the national power plants equal to 0.46 [39], were assumed. The operating cost evaluation is carried out assuming a specific electric unit cost equal to 0.53 €/kWh_{el}. The total CO_2 emissions due to the electric energy demand were evaluated considering an equivalent emission factor equal to 0.48 $kgCO_2$/ kWh_{el} [40].

3. Results

In this section, the main results obtained by the dynamic simulations are discussed. The results are presented considering the hourly trends over a single day of the summer season as well as the energy trends obtained for each month of the summer season. The results obtaiened by a sensitivity analysis, performed by varying both the set-point temperature of the cooling plant as well as the clothing factor of the users are presented, considering their effect on the thermal comfort of the users itself. Note that for the comfort analysis, it was assumed that the user perceives a comfort condition according to the values assumed by PMV. If -1 <PMV<+1, the user perceives a comfort condition.

In

Figure ***3***, the hourly trends of the main physical parameters (relative humidity and radiant mean temperature) affecting the thermal comfort of the users (according to the UNI EN ISO 7730) are reported for a typical summer day. The air velocity was assumed constant at the value of 0.1 m/s, considering that in the investigated office no significant inflitration occurs. Note that both graphs of

Figure ***3*** report such trends for all the considered set-point temperatures of the cooling plant (from 24°C to 28°C).

For all the set-point temperatures similar trends of the mean radiant temperature can be observed. In particular, the mean radiant temperature decreases from 00:00 to 06:00 am following the trend of the outdoor air temperaure and it starts to increase from 06:00 and 09:00 am, when the sun rises and the solar radiation is directed on the external wall of the office. When the cooling plant is switched on (from 09:00 am to 6:00 pm), the radiant mean temperature decreases. The drop is more significant for the set-point temperature of 24°C Note that the office consists of one external wall and its windows all facing south. Therefore, although the indoor air temperature reaches the set-point value, the radiant mean temperatures increase reaching the maximum values at 12:30 pm, due to the high solar radiation incident on the office. For the set-point temperature of 28°C and 24°C, the radiant mean temperatures reach the values of 29°C and 26.5°C, respectively, although the cooling plant is switched on. The lowest peak values achieved at 06:00 pm occur at the closing time of the office and the switching off of the cooling plant. After that, the radiant mean temperature shows again an increase, due both to the solar heat which is absorbed during the day and released during the evening hours, and to the radiative and convective fluxes emitted by the computers which continue to be active in the energy saving mode. A slight reduction of radiant mean temperatures is verified during the late afternoon and evening hours when the solar radiation is zero and the outdoor air temperature starts to decrease. For all the set-point temperatures similar trends of the relative humidity can be observed. In particular, it is about lower than 70% during the office opening time, while it shows significant increases in the first and last hours of the day. Note that the cooling plant reduces the relative humidity of the investigated office but it is not designed to constantly control the relative humidity of the room. Therefore, for a typical sunny and humid day as the reported one, the relative humidity is high during the operation hours. However, the values fall within the range 30%-70%, suggested by the UNI EN ISO 7730.

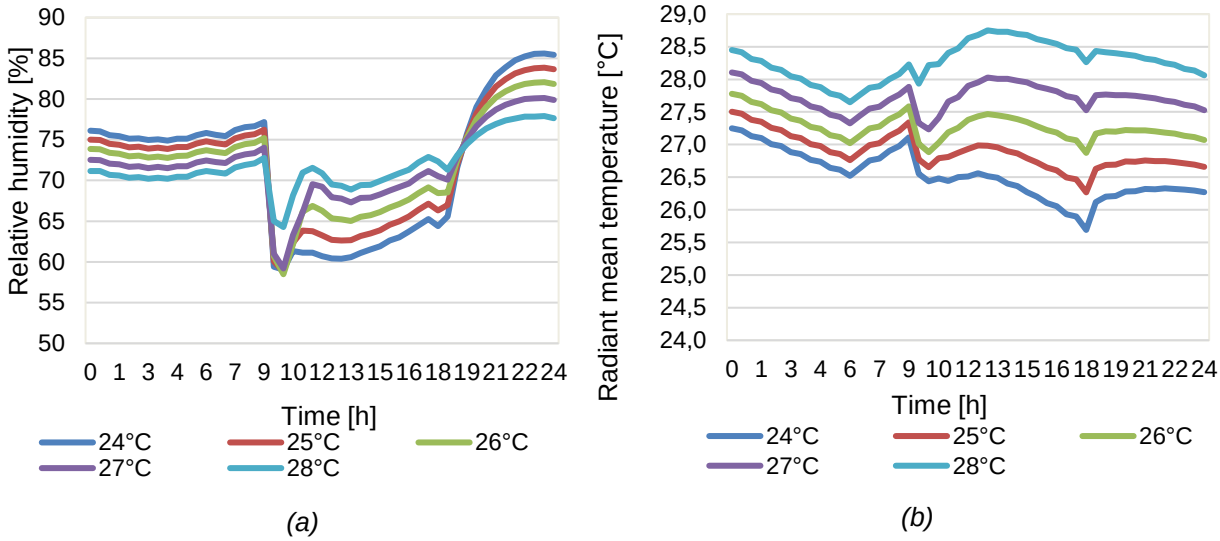


Figure 3. Hourly relative humidity (a) and radiant mean temperature (b)

In Figure 4, the monthly cooling energies from the cooling season (May-Sept) for all the investigated cooling set-point temperatures were reported. Considering the weather data of Naples, the hottest month is July. In this month the highest consumption for space cooling purpose is equal to 18 kWh/m^{2}month for the set-point temperature of 24°C. The lowest one is equal to 12 kWh/m^{2}month for the set-point temperature of 28°C, 33% lower than the previous case. Note that the low peak values occur in August are due to the two closing weeks of the university for the summer vacation.

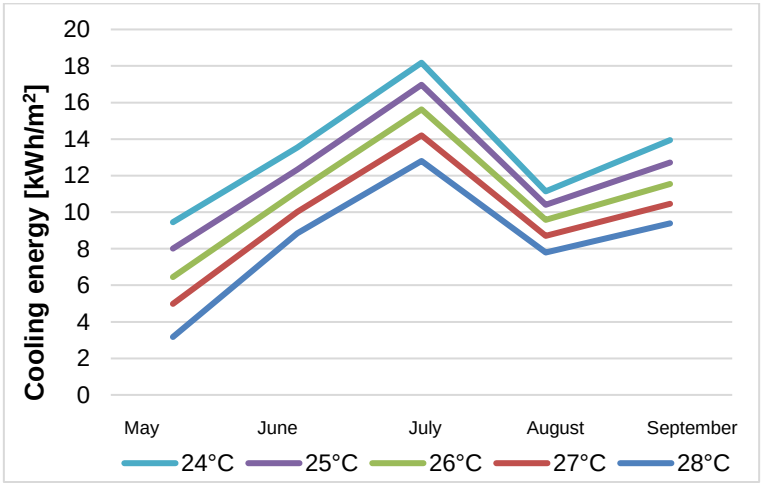

Figure 4. Monthly cooling energy vs cooling set-point temperatures

	Hours number of system operation	Comfort hours Clo 1	Comfort hours Clo 0.5	Comfort hours Clo 0.3
24°C	865	833	862	864
25°C	834	687	828	834
26°C	800	157	792	799
27°C	768	24	758	766
28°C	713	0	308	707

Figure 5. Comparison between hours of plant operation and hours of comfort

Figure 5 shows the comparison between the hours of plant operation and hours of comfort for the three considered scenarios of clothing factor, equal to 0.3 clo, 0.5 clo and 1 clo. As the set-point temperature value increases, the number of operating hours of the plant progressively decreases from 865 to 713. In the case of the classic formal dress, see CLO 1 scenario, the number of operating hours of the plant is high only at 24°C, whereas it is equal to 0 and 24 at 28°C and 27°C, respectively. With light summer dress, see CLO 2 scenario, the number of operating hours of the plant is high up to 27°C. With a tropical outfit, see CLO 3 scenario, also the cooling set-point temperature of 28°C becomes tolerable, considering that the number of operating hours of the plant is 707. The cooling set-point temperature of 28°C is not suitable for clothing factors equal to 1 and 0.5.

In Figure 6 the frequency distribution of PMV related to the number of plant operation for different cooling set-point temperatures were reported. Considering a clothing factor equal to 0.3 and a set-point temperature of 24°C, the PMVs are for about 850 hours lower than 0. For about 100 hours, a cooling perception, corresponding to -0.75<PMV<-1 was observed. Considering a clothing factor equal to 1, only a very low number of hours corresponds to PMVs higher than 1. For a set-point temperature of 25°C and a clothing factor of 1, for more than 150 hours, the obtained PMVs are higher than 1. For the same clothing factor, an increase of the set-point temperature of only 1°C determines a very significant increase of the discomfort hours, passing from about 150 to 650 hours. For a set-point temperature of 27°C and a clothing factor of 0.5, related to the summer light dress, almost all the PMVs are lower than 1 for all the operation hours. However, if the set-point temperature is raised to 28°C, for about 400 hours the PMVs are higher than 1. Conversely, if a summer light dress is adopted, i.e. a clothing factor equal to 0.3, all the PMVs are lower than 1 for all the operation hours. This means that the relaxation of the dress code is functional for the reduction of the cooling energy consumption, considering that the users will set a high cooling temperature due to the cooling perception due to the adoption of summer light dresses.

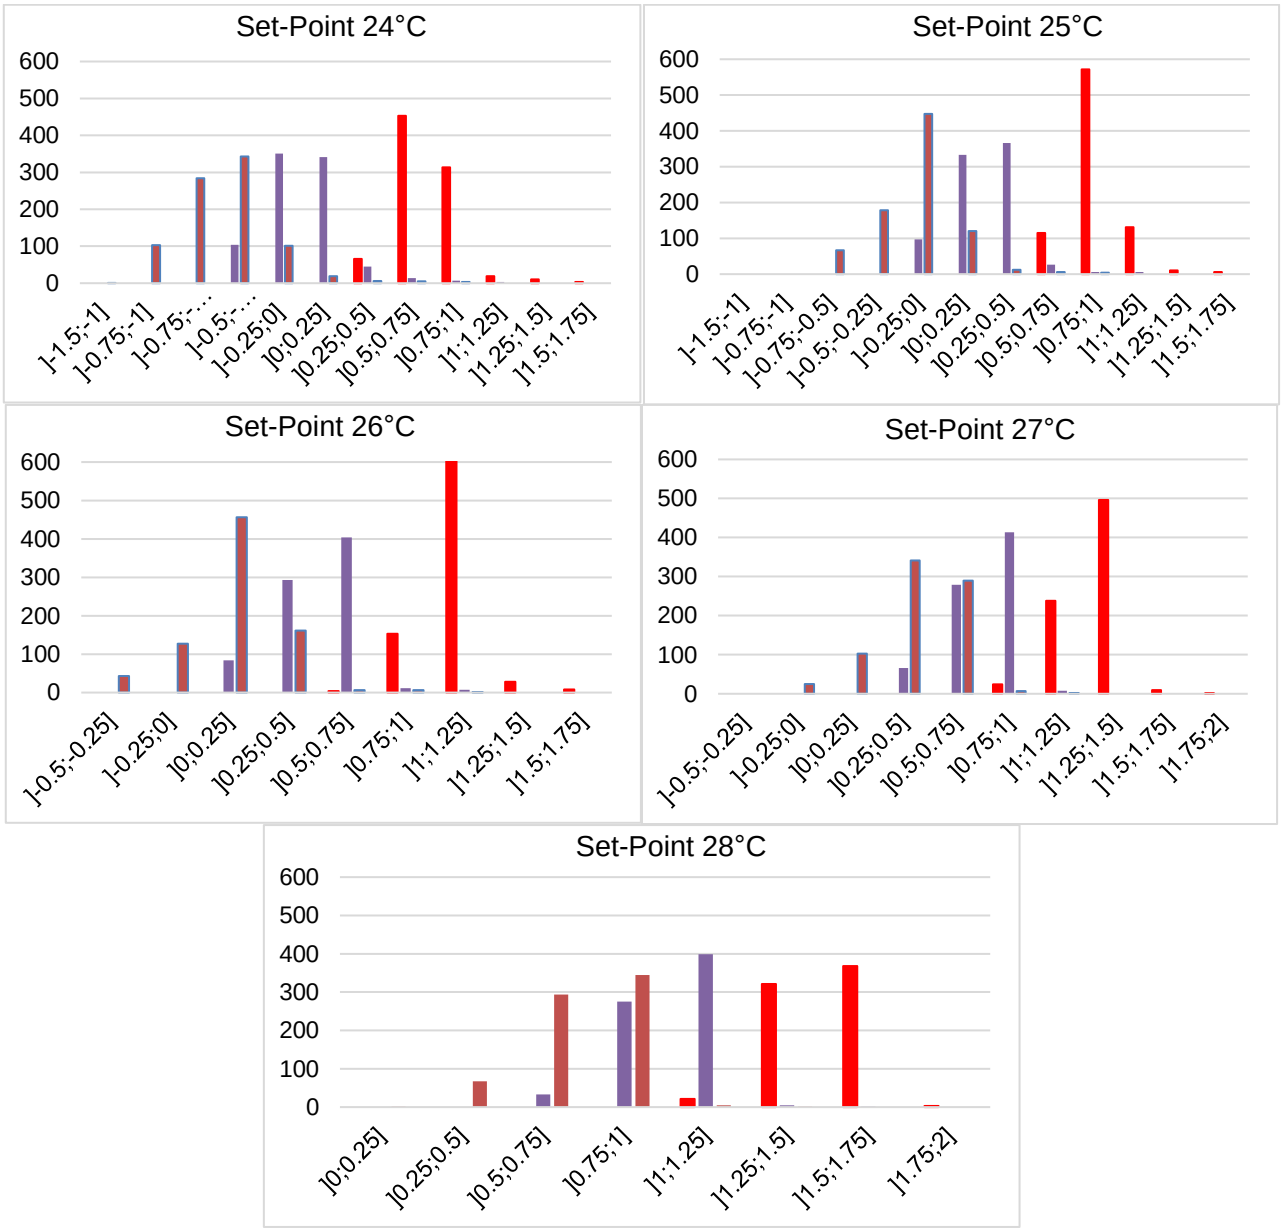

Figure 6. Frequency distribution of PMV indices for different cooling set-point temperatures

In Table 3, the results of the energy, economic and environmental analyses for all the set-point temperatures investigated, from 24°C to 28°C were reported. A set-point temperature of 24°C involves a cooling energy demand of 66 kWh/m^2 higher than the energy demand related to the set-point of 28°C, equal to 42 kWh/m^2 and higher than the demand related to the value of 26°C, equal to 54 kWh/m^2. The set-point temperature of 28°C and 27°C, determines primary energy savings over 32%, when compared with the set-point temperature of 24°C. The set-point temperature of 28°C corresponds to a reduction in the total CO_2 emissions of 108 kgCO_2/year when compared with the set-point temperature of 24°C. Concerning the operating cost for space cooling, for the set-point temperature of 24°C, the obtained value is 376 €/y, which reduces to 252 €/y for the set-point temperature of 28°C. Therefore, without any capital cost, this energy measure, simply wearing a tropical or light summers dresses, can be useful for reaching important energy, economic and environmental savings. Note that this energy measure was evaluated only considering one office of 22 m^2. Therefore, the results could be of course more advantageous and significative if the analysis will be extended to other offices of the university.

Table 3. Energy, economic and environmental analysis

Set-point temperature [°C]	Cooling energy [kWh/m^{2}y]	Primary energy [kWh/m^2 y]	Cost for space cooling [€/y]	Total CO_2 emissions [kgCO_2/y]	Increase of cooling energy [%]
24	66.24	67.60	376	332	57.80
25	60.41	62.34	347	306	43.92
26	54.35	56.81	316	297	29.47
27	48.36	51.24	285	252	15.21
28	41.98	45.32	252	224	-

4. Conclusion

This study evaluated the influence of classic formal dress-codes on the cooling energy demand and the perceived comfort, in office users during the summer season. A typical university office was selected to evaluate which effective consumption reduction could be obtained through a significant relaxation of the dress-code, when an increase of the air set-point temperature occurs. Several clothing factors were considered related to the classic, tropical and light summer clothing. The investigation was performed in TRNSYS environment by a dynamic simulation model evaluating both the common comfort indexes and the cooling energy demand of the office. The model was applied to a suitable case study, the office room located at the University of Naples Federico II, where authors of the presented study work. The results of the simulations showed that the clothing factor and the set-point temperature dramatically affect both energy consumption and the comfort indexes values. Furthermore, these results proved that the use of a more flexible dress-code, considering higher set-point temperatures, significant energy, economic and CO_2 emissions savings can be obtained. The increase of the summer air conditioning set-point temperature up to 28°C, is acceptable only for the dress code consisting of shorts and short-sleeved shirts. If this clothing is extreme and unacceptable for the type of office considered, a more formal dress-code, consisting of trousers, a short-sleeved shirt and closed shoes, can be adopted. However, in this case the increase in the air set-point temperature up to 27°C can be settled. If any relaxation of the dress-code can be accepted due to the fact that the classic formal dress is essential for the users, acceptable comfort index values can be obtained only if the air set-point temperature is decreased at least 24°C. This value not only is lower than the threshold set by the Italian normative (DL 1 March 2022, N. 17) regarding the summer air conditioning temperature, but also implies energy, economic and environmental impact increases. A set-point temperature of 24°C is the only value compatible with the classic dress, although this involves intolerable cooling energy demand. The set-point temperature of 27°C, compatible with light summer dress determines cooling energy savings over 37%. The set-point temperature of 28°C is compatible only with the tropical dress. and corresponds to a reduction in the consumption of cooling and primary energy by over 50%.

The analysis of the case study allowed, albeit on a small scale, to test the high potential of the increase of the cooling set-point temperature in the offices during the summer season, on the significant reductions in terms of energy, economic and environmental impacts. However, there are critical issues, which risk limiting the implementation of the initiative.

- Workers that may not feel adequate with a more flexible type of clothing and are still anchored to the choice of a formal outfit because it is coherent with the company policy.
- The difficulty of implementation within working contexts that require the interfacing with the public, considering the common idea that the dress worn reflects the degree of seriousness, reliability of employ, of professionalism and competence within a working context.

Abstract:

Hard-to-abate industries require significant amounts of hydrogen, which is mainly used as feedstock, reducing agent and gas carrier. Currently, most of this demand is met by fossil-based hydrogen produced on-site or delivered by trailers. There is therefore huge potential to decarbonize these industries by replacing conventional grey hydrogen supply with sustainable power-to-hydrogen systems that exploit renewable energy to produce green hydrogen through electrolysis. In this work, a semiconductors production plant was considered as a case study. Hydrogen is used as gas carrier in epitaxial silicon growth and the demand is about 110 tons per year. The goal is to explore the cost-effectiveness of on-site green hydrogen production. The power-to-hydrogen system includes a photovoltaic plant, a PEM electrolyzer, a compressor, a hydrogen tank, a grey hydrogen back-up system and the electrical grid connection. The optimal system sizing was carried out by adopting the Particle Swarm Optimization (PSO) algorithm able to identify the configuration that minimizes the Levelized Cost of Hydrogen (LCOH) while ensuring the coverage of the hydrogen demand over the entire year. For a detailed techno-economic assessment, size-dependent cost functions were applied, and the lifetime of the electrochemical component was estimated based on its operating hours during the year.
Results show that the cost-optimal solution is the current scenario, where only grey hydrogen is employed (LCOH equal to 4 €/kg). Different decarbonization targets (i.e., grey hydrogen share constraint in the range 0-100%) were also investigated and the resulting LCOH ranges from 4 €/kg (full grey hydrogen scenario) to 10.85 €/kg (full green hydrogen scenario). The resulting Pareto front shows two distinct regions: the reduction of grey hydrogen share from 100% (current scenario) to 30% - corresponding to a decarbonization rate of 0% to 70% – follows a smooth trend with an LCOH increase from 4 to 6.2 €/kg (first region). Higher decarbonization rates (> 70%, second region) instead lead to a steeper increase in the LCOH, reaching 10.85 €/kg in the completely decarbonized scenario (0% grey hydrogen).

Keywords

Hydrogen, Electrolysis, Optimal sizing, Hard-to-abate, CO_2 savings

1. Introduction

Electronics manufacturing currently represents a niche industrial application of hydrogen. Specifically, high purity hydrogen (i.e., higher than 99.999%) is used as a gas carrier in the semiconductor industry for the epitaxial growth of the silicon wafers.

According to Rochlitz et al. [1], 16.5 million Nm^3 of hydrogen are consumed annually by the around 500 epitaxy reactors across Europe. This demand is largely met by fossil-based hydrogen (i.e., grey hydrogen) that is delivered – either compressed or liquid – by trailers to the industrial plants, or alternatively produced on-site through Steam Methane Reforming (SMR). Thus, renewable power-to-hydrogen (P-t-H) systems can represent a promising low-carbon strategy for the hydrogen supply of the semiconductor industries. In fact, using green hydrogen in hard-to-abate sectors can effectively reduce CO_2 emissions in a cost-effective way. Gärtner et al. [2] investigated the integration of a power-to-hydrogen system in a German glass industry and found out that CO_2 emissions can be reduced by up to 60% through the use of renewable hydrogen. Marocco et al. [3] investigated the role of hydrogen in decarbonizing the high-temperature heat production in the steel sector. Moreover, they highlighted that lower Levelized Cost of Hydrogen (LCOH) values can be achieved by exploiting cheaper electricity, such as that generated by on-site Renewable Energy Sources (RES). Röben et al. [4] assessed the techno-economic feasibility of reducing direct CO_2 emissions in copper production by

installing a power-to-hydrogen system. They confirmed that the electricity price is a crucial parameter to achieve a cost-efficient decarbonization. In addition, they pointed out that exploiting the by-product oxygen can boost the profitability of this solution. Gu et al. [5] carried out a techno-economic analysis of a green methanol production plant and the results emphasized the impact of the carbon price on reaching the breakeven with the conventional process. However, no studies that specifically assess the cost-effectiveness of exploiting green hydrogen in the silicon wafers manufacturing were found in the literature. Thus, the present work aims at filling this gap by proposing a detailed techno-economic optimization study for a power-to-hydrogen application in the semiconductor industry. The optimal sizing of the RES-based hydrogen production system was performed by adopting the Particle Swarm Optimization (PSO) algorithm and the effects of different decarbonization targets on the LCOH were investigated by applying the ε-constrain method. The PSO algorithm was chosen because its robustness and good convergence speed make it ideal for the design of energy systems [6].

The structure of this works is as follows: Section 2 describes the design methodology and reports the main techno-economic input data, Section 3 outlines the case study, Section 4 shows the results and Section 5 summarizes the conclusions.

2. Methodology

2.1. System layout

The renewable power-to-hydrogen system consists of the following components: the photovoltaic panels (PV), the electrolyzer (EL), the compressor (CP), the pressurized hydrogen tank (HT), the grey hydrogen back-up system (HBS) and the national electrical grid (GR). The schematic layout of the system is shown in Figure 1.

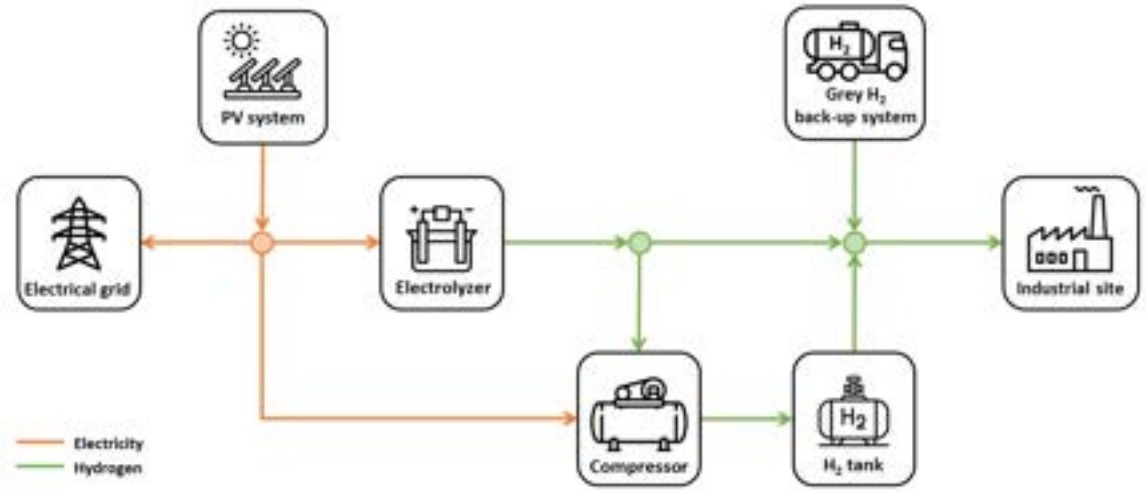

Figure 1. Schematic layout of the power-to-hydrogen system.

2.2. Modelling of the components

The modelling of the components of the power-to-hydrogen system is described below.

PV system

The PV power production was evaluated as follows [6]:

$$P_{PV}(t) = f_{PV} \cdot P_{PV,rated} \cdot \left(\frac{G_T(t)}{G_{STC}}\right) \cdot \left[1 + \alpha_P \cdot \left(T_c(t) - T_{c,STC}\right)\right] \quad (1)$$

where P_{PV} (in kW) is the output power of the PV system, $P_{PV,rated}$ (in kW) is the rated power of the PV system, G_T (in kW/m^2) is the incident solar radiation evaluated for the optimal configuration of tilt and azimuth angles, G_{STC} (in kW/m^2) is the solar irradiance at Standard Test Conditions (STC), T_c (in °C) is the actual PV cell temperature during operation, $T_{c,STC}$ (in °C) is the cell temperature at standard test conditions, α_P (in 1/K) is the temperature coefficient of power, and f_{PV} is the derating factor.

The meteorological data for the estimation of the PV power production were extracted from the Photovoltaic Geographical Information System (PVGIS) tool considering the dataset for the Typical Meteorological Year (TMY) [7].

Electrolyzer

The Proton Exchange Membrane (PEM) technology was considered for the electrolyzer since it offers faster dynamic response and wider operating range than the alkaline technology, which results in better

performances when coupled with variable RES. The nominal efficiency of the PEM electrolyzer was assumed equal to 55% and the operating pressure was set to 30 bar. Moreover, a specific modulation range (10-100% of the rated power) was imposed to ensure safe and efficient operation of the electrolyzer [6]:

$$P_{EL,min} \leq P_{EL}(t) \leq P_{EL,rated} \quad (2)$$

where P_{EL} (in kW) is the electrolyzer operating power, $P_{EL,min}$ (in kW) is the minimum electrolyzer operating power and $P_{EL,rated}$ (in kW) is the electrolyzer rated power.

Hydrogen tank

A pressurized storage tank is required to cope with the fluctuations in hydrogen production and demand throughout the year. A Type-I tank (i.e., made of seamless aluminium or steel) with a maximum storage pressure of 200 bar was chosen. In addition, the minimum pressure of the tank was set to 20 bar according to the specific requirements of the industrial process.

The Level of Hydrogen (LOH) in the tank, which is defined as the ratio between the amount of hydrogen stored in the tank and its maximum capacity, was evaluated as follows:

$$LOH(t) = LOH(t-1) + \frac{P_{EL}(t-1) \cdot \Delta t \cdot \eta_{EL}}{LHV_{H_2} \cdot Cap_{H_2}} - \frac{\dot{m}_{H_2}(t-1) \cdot \Delta t}{Cap_{H_2}} \quad (3)$$

where Δt is the time resolution (i.e., 1 hour in this study), η_{EL} is the efficiency of the electrolyzer, LHV_{H_2} (in kWh/kg) is the lower heating value of hydrogen, Cap_{H_2} (in kg) is the rated capacity of the hydrogen tank, and $\dot{m}_{H_2}$ (in kg/h) is the hydrogen flowrate sent to the industrial plant.

In order to guarantee the correct hydrogen supply to the industrial plant, at any time interval, the following constrain has to be met:

$$LOH_{min} \leq LOH(t) \leq LOH_{max} \quad (4)$$

The LOH_{min} can be evaluated as the ratio between the minimum and the maximum pressure storage, while LOH_{max} is set equal to 1.

Hydrogen compressor

A three-stage intercooled compressor was selected to increase the hydrogen pressure up to the storage tank value. The specific energy consumption to pressurize hydrogen from the operating condition of the electrolyzer (i.e., 30 bar) up to the maximum storage pressure (i.e., 200 bar) was assumed equal to 4 MJ/kg [8].

Grey hydrogen back-up system

A fossil-based back-up solution was also included in the system. Specifically, a tube trailer with pressurized grey hydrogen was considered.

2.3. Energy management strategy

In order to model the hourly operation of the power-to-hydrogen system over a reference year, an Energy Management Strategy (EMS) was implemented. The adopted control strategy sets the operating conditions of the system based on the hydrogen demand of the industrial plant and the availability of RES production.

The EMS starts with the evaluation of the hydrogen demand profile:

- If the hydrogen demand is higher than zero, the supply intervention has the following priority: first hydrogen from the electrolyzer (if electricity is available from RES), then green hydrogen from the pressurized storage tank and finally grey hydrogen from the fossil-based back-up system. Specifically, two sub-cases can occur:
    - In case of hydrogen demand higher than zero and sufficient electricity from the PV, the electrolyzer can be switched on and operated within its modulation range, while the excess power – if any – can be exported to the electrical grid. The electrolyzer production can be fed directly to the industrial plant or, if the hydrogen demand is exceeded, it can be compressed and stored.
    - In case of hydrogen demand higher than zero and power from the PV not available or not sufficient, the deficit must be covered first resorting to the green hydrogen storage and then to the grey hydrogen back-up system.
- If the hydrogen demand is zero, renewable electricity from the PV – if available – is converted into hydrogen, which is entirely stored. The excess power, if any, is then sold to the electrical grid.

2.4. Optimal design

The optimal design of the power-to-hydrogen system was performed by adopting the PSO algorithm and implementing a two-layer approach. According to this methodology, the sizing and dispatch problems are decoupled: in the outer loop a potential design solution (i.e., the sizes of the components) is iteratively generated by the PSO algorithm, while the operation of the power-to-hydrogen system is managed in the inner loop according to the rule-based EMS described in Section 2.2. The optimal design problem was formulated and solved in Matlab (r2022b) with a year-long time horizon and an hourly time-step resolution.

In the PSO algorithm, a population size of 100 was used and both the cognitive and social parameters were set to 1.9. The optimization procedure aims to identify the system configuration that minimizes the LCOH while satisfying the following constrains on the unmet hydrogen demand (UH_2) and the maximum share of grey hydrogen in the annual demand (GH_2):

$$UH_2 \leq UH_{2,target} \tag{5}$$

$$GH_2 \leq GH_{2,target} \tag{6}$$

Equation (5) represents the constraint on the system reliability and the target of unmet hydrogen demand ($UH_{2,target}$) was imposed to zero. Equation (6) defines the maximum share of grey hydrogen ($GH_{2,target}$) that can be used in the plant. The $GH_{2,target}$ term was varied between 100% and 0% to build up a Pareto front according to the ε-constrain method [6].

The LCOH (in €/kg), which represents the objective function to be minimized, is defined as follows:

$$LCOH = \frac{C_{NPC,tot}}{\sum_{n=1}^{N} \frac{M_{H_2}}{(1+d)^n}} \tag{7}$$

where $C_{NPC,tot}$ (in €) is the total Net Present Cost (NPC) of the system, M_{H_2} (in kg) is the annual hydrogen demand of the industrial site, d is the real interest rate (that includes both the nominal interest rate and the annual inflation rate) and N is the system lifetime (set equal to 20 years).

The NPC includes the capital expenditure, the operation and maintenance (O&M) costs and the replacement costs incurred over the whole lifetime of the system. The NPC was evaluated as (with i = PV, EL, HT, CP):

$$C_{NPC,tot} = \sum_i C_{inv,i} + \sum_{n=1}^{N} \left(\frac{\sum_i C_{O\&M,i,n} + \sum_i C_{rep,i,n} + C_{greyH_2,n} - C_{GR,sell,n}}{(1+d)^n} \right) \tag{8}$$

where $C_{inv,i}$ (in €) is the investment cost (i.e., CAPEX) of the i-th component incurred at the beginning of the project, $C_{O\&M,i,n}$ (in €) is the operation and maintenance cost of the i-th component during the n-th year, $C_{rep,i,n}$ (in €) is the replacement cost of the i-th component incurred at the n-th year (if required), $C_{greyH_2,n}$ (in €) is the annual cost due to the purchase of the fossil-based hydrogen and $C_{GR,sell,n}$ (in €) is the annual revenue for selling the surplus electricity to the grid.

The specific CAPEX of the PV system was assumed equal to 800 €/kW which is in line with the cost of the utility-scale projects in Europe [9].

The specific investment cost $c_{inv,EL}$ (in €/kW) of the PEM electrolyzer was estimated by using a modified power law that considers both the plant capacity and the maturity of the technology [10]:

$$c_{inv,EL} = \left(k_0 + \frac{k}{P_{EL,rated}} \cdot \left(P_{EL,rated}\right)^{\alpha} \right) \cdot \left(\frac{V}{V_0}\right)^{\beta} \tag{9}$$

where k_0 and k are the fitting parameters, $P_{EL,rated}$ (in kW) is the rated power of the electrolyzer, α is the scaling factor, β is the learning factor, V and V_0 are the plant installation year and the reference year, respectively. For a more detailed techno-economic assessment, the lifetime of the electrolyzer stack was evaluated based on the actual number of operating hours during the year.

The specific CAPEX of the pressurized tank was set at 500 €/kg, which is in good agreement with the costs of Type-I tanks with storage pressure below 250 bar [11]. The specific investment cost of the compressor was assumed equal to 1600 €/kW [8]. Finally, a cost of 4 €/kg was considered for the fossil-based back-up solution [1]. The main techno-economic input data are summarized in Table 1.

Table 1. Techno-economic input data.

Parameter	Value	Ref.
PV		
f_{PV}	86%	[6]
α_P	-0.003 1/K	[6]
CAPEX	800 €/kW	[9]
O&M (annual)	2% (of the CAPEX)	
Lifetime	20 yr

Grey hydrogen		
Emission factor for SMR	9.5 kgCO_2/kgH_2	[12]
Cost	4 €/kg	[1]
Other assumptions		
Discount rate	4.9%	
Revenue for exported electricity	0.0363 €/kWh	
System lifetime	20 yr	

3. Case-study

A semiconductor production plant located in Southern Europe was considered as a case study. The real hourly demand profile over one reference year was used in this analysis. The plant operates continuously throughout the year with an average hydrogen demand of about 12.5 kg/h (which is in agreement with other literature

sources [1]) and a maximum consumption of around 15.5 kg/h. Further details on the demand profile are omitted for confidentiality reasons. The total annual hydrogen demand amounts to 110 tons and is currently met by a conventional fossil-based solution (i.e., grey hydrogen purchased externally and delivered by trailer).

4. Results and discussion

The optimal sizing was first performed without imposing any constraint on the $GH_{2,target}$ and the LCOH resulted in 4 €/kg, confirming that fossil-based hydrogen is currently the cheapest solution. However, adopting this strategy exhibits severe environmental drawbacks since the production of 110 tons of grey hydrogen generates 1045 tons of CO_2 emissions per year.

In order to assess the effect of the different decarbonization targets on the LCOH, the design of the energy system was then carried out by imposing a constraint on the annual grey hydrogen share, which was gradually reduced from 100% to 0%. The main sizing results and economic performance indicators are summarized in Table 2.

By reducing the amount of grey hydrogen that can be used by the industrial plant, the sizes of PV and electrolyzer increase significantly. Specifically, the rated capacities of PV and EL rise respectively from 0.68 MW and 0.27 MW (with 90% grey hydrogen share) to 11.96 MW and 3.3 MW (in the 100% RES-based configuration with 0% grey hydrogen share). Despite the considerable increase in the PV size (up to 11.96 MW), the corresponding footprint is consistent with the available space in the industrial site and the surrounding areas.

Furthermore, the results clearly show that the installation of a hydrogen storage (including hydrogen tank and compressor) is not economically convenient for scenarios with a grey hydrogen share higher than 70%. The size of the pressurized tank is relatively small (between 19 and 644 kg) when the grey hydrogen share is between 70% and 10%, and then sharply increases to 4930 kg when only green hydrogen is considered (0% grey hydrogen share).

Table 2. Main sizing results and economic performance indicators.

Grey H_2 share [%]	PV [MW]	EL [MW]	HT [kg]	CP [kW]	LCOH [€/kg]	CO_2 emissions [ton/y]
100%	0	0	0	0	4.00	1045
90%	0.68	0.27	0	0	4.46	940
80%	1.32	0.55	0	0	4.77	836
70%	1.98	0.83	19	7	5.07	731
60%	2.62	1.10	59	12	5.37	627
50%	3.23	1.39	101	22	5.66	522
40%	3.87	1.66	153	30	5.94	418
30%	4.62	1.94	201	35	6.23	313
20%	5.63	2.25	369	41	6.67	209
10%	7.29	2.75	644	50	7.50	104
0%	11.96	3.30	4930	60	10.85	0

As shown by the Pareto front in Figure 2, the cost of hydrogen ranges from 4 to 10.85 €/kg. Green hydrogen appears to be more expensive than fossil-based alternatives, but this solution can be beneficial from an environmental perspective since it allows the CO_2 emissions to be considerably reduced (up to 1045 ton/y of CO_2 emissions can be avoided).

It is worth noting that the LCOH increases evenly up to a grey hydrogen share of 30% – which corresponds to a decarbonization rate of 70% – with an LCOH of 6.2 €/kg (Figure 2). In this region, reducing the annual consumption of grey hydrogen by e.g., 50%, leads to a saving of 522 tons of CO_2 per year and an increase in the LCOH (compared to the 100% grey hydrogen scenario) of 41%. At higher decarbonization rates (> 70%), the Pareto front shows a steeper slope and increase in LCOH: the transition to a complete decarbonization of the energy system (0% grey hydrogen share) indeed leads to an increase in the LCOH of about 170%.

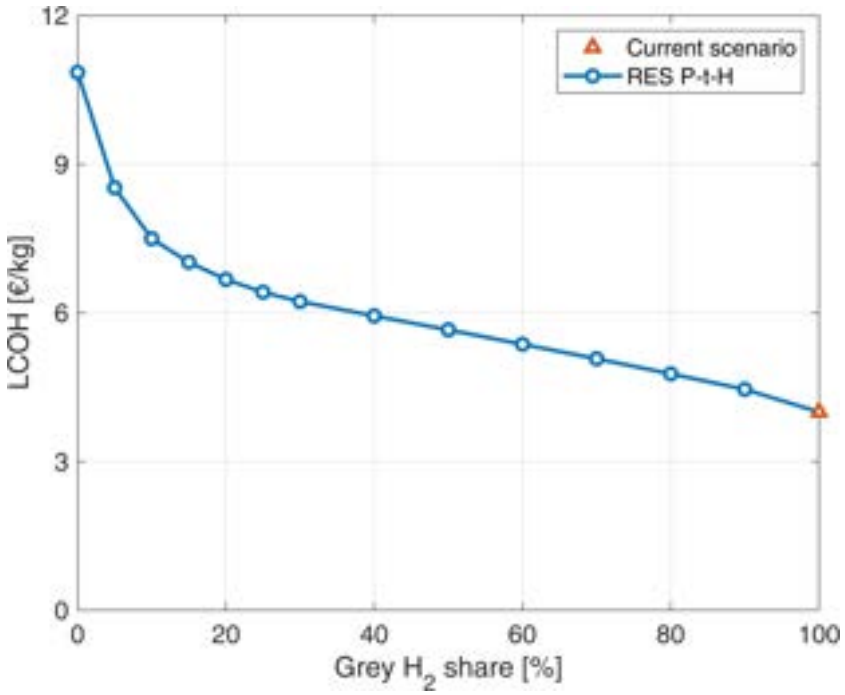

Figure 2. Pareto front between the levelized cost of hydrogen and the grey hydrogen share.

Figure 3 shows the breakdown of the NPC for different values of grey hydrogen share. For values above 50%, the purchase of fossil-based hydrogen represents the largest cost contribution (yellow area in Figure 3), while for the other scenarios the PV and EL costs have the largest impact. Moreover, it is evident that with the transition to lower values of grey hydrogen share, the revenues associated with the surplus electricity exported to the grid increase significantly ("Grid export" area in Figure 3) because of the sharp increase in the PV size. Finally, it is noteworthy that the storage system is an important cost contribution (20%) in the fully decarbonized scenario (0% grey hydrogen share), in which a large tank (4930 kg) is required to ensure a reliable supply of green hydrogen throughout the year.

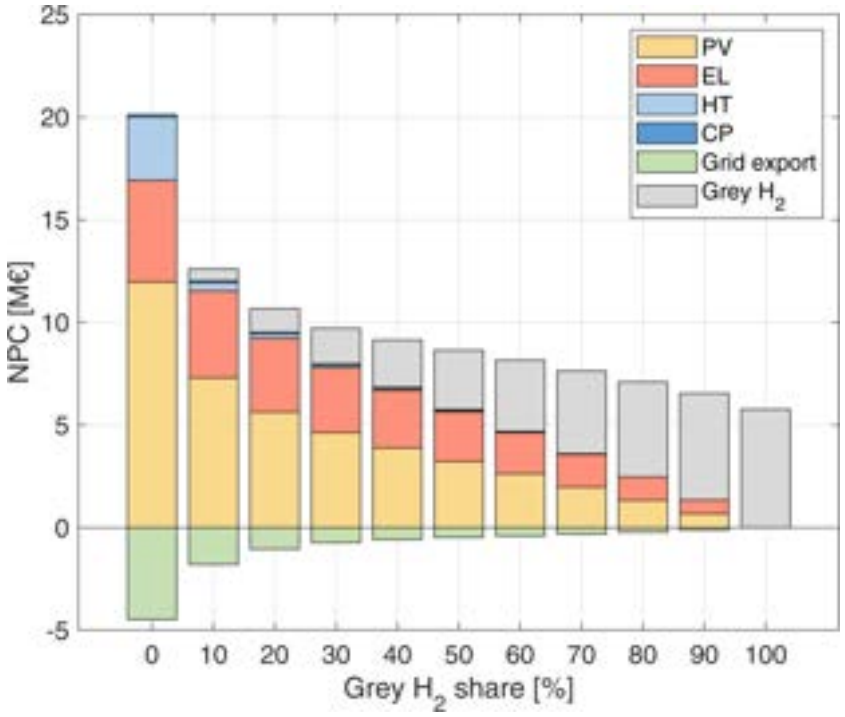

Figure 3. NPC breakdown for different annual grey hydrogen share.

5. Conclusions

This study aimed at assessing the techno-economic feasibility of decarbonizing a semiconductor industry by exploiting green hydrogen. The optimal sizing of the renewable power-to-hydrogen system was carried out by adopting the PSO algorithm in a two-layer optimization approach. Different decarbonization targets (i.e., 0% to 100%) were investigated and the LCOH resulted in the range between 4 and 10.85 €/kg. Producing green hydrogen proved to be more expensive than conventional fossil-based solutions but it can effectively reduce CO_2 emissions. The resulting LCOH-$GH_{2,target}$ Pareto front shows two distinct regions: the reduction of grey hydrogen share from 100% (current scenario) to 30% - corresponding to a decarbonization rate of 0% to 70% – follows a smooth trend with an LCOH increase from 4 to 6.2 €/kg (first region). Higher decarbonization rates (> 70%, second region) instead lead to a steeper increase in the LCOH, reaching 10.85 €/kg in the completely decarbonized scenario (0% grey hydrogen). In the scenarios with a grey hydrogen share above 50%, the purchase of grey hydrogen represents the main contribution of the NPC, while in the other scenarios PV and EL provide the largest shares. In the fully decarbonized configuration, the size of the storage system increases significantly, as it has to ensure the supply of green hydrogen throughout the entire year and reaches a share of 20% share of the overall NPC.

In conclusion, renewable power-to-hydrogen system does not represent the most cost-competitive solution, from an economic point of view, to provide hydrogen to the industrial plant. However, the profitability of the RES-based configuration can be significantly boosted when considering also the environmental benefits (i.e., CO_2 emission savings) generated by replacing the conventional grey hydrogen supply with the low carbon one. In addition, both the costs of photovoltaic and electrolyzer technologies are expected to decrease in the coming years, and this reduction could enhance the competitiveness of green hydrogen for industrial applications. In a future work, a sensitivity analysis on the main economic parameters will be carried out in order to identify the conditions in which green hydrogen can achieve the cost-parity with the current fossil-based supply.

Nomenclature

CAPEX	Capital Expenditures
CP	Compressor
EL	Electrolyzer
EMS	Energy Management Strategy
GR	Grid
HBS	Hydrogen Back-up System
HT	Hydrogen Tank
LCOH	Levelized Cost Of Hydrogen
LOH	Level of Hydrogen
NPC	Net Present Cost
O&M	Operation and Maintenance
PEM	Proton Exchange Membrane
PSO	Particle Swarm Optimization
P-t-H	Power-to-Hydrogen
PV	Photovoltaic
RES	Renewable Energy Sources
SMR	Steam Methane Reforming
TMY	Typical Meteorological Year

Abstract:

This article proposes a methodology to quantify the flexibility potential of a district heating network. By "flexibility potential" is meant here the degree of freedom in combining and controlling the energy units of a district heating network in order to meet a target demand. This potential has been modelled as the logarithm of the available combinations (or configurations), like the Shannon/Boltzmann entropy in statistical mechanics. The methodology produces a set of four entropy-inspired indicators. The first two, called "structural" and "operational" flexibility, are proportional to the number of available combinations of energy units and their input and output thermal powers, respectively. The other two indicators are the "effective" counterparts of structural and operational flexibility, and indicate the extent to which a given demand profile exploits the overall flexibility potential of a district heating network. The methodology takes into account the different sources of flexibility related to heat production, (de)storage, dissipation or diversion, as well as load adjustment techniques (demand management). Given its scaleless and dimensionless formulation, the methodology can be applied to energy systems of any size or energy type. The methodology is presented with the open-source tool used for the calculations and an illustrative example.

Keywords:

District heating, District heating networks, Energy flexibility, Operational flexibility, Thermodynamics, Entropy.

1. Introduction

The phenomenon of flexibility has been a source of many definitions and ambiguity in many fields of research. With respect to energy networks in the broadest sense, the International Energy Agency gave a first formal definition of "flexibility" in 2011: the ability of an energy system to react to temporal changes in energy production and demand [1].

The first active research on the subject of energy flexibility focused on power systems. The trigger for such issues was the decarbonization of these networks [2], which often leads to the inclusion of renewable sources in the energy mix [3], e.g., solar or wind power. Thus, possible sources of flexibility in electricity networks have been identified for a long time [4].

Although the question of flexibility in heat networks came later, several sources of flexibility have already been identified in the past, often with the intention of bringing flexibility to electricity networks [5]. The classical approach is to implement thermal energy storage, which can consist of centralized [6] or decentralized [7] collective physical storage units, or the use of the thermal inertia of the network itself [8], although the latter approach has its limitations in new generation (low temperature) networks [9]. Other approaches consist in controlling water flows [10] or their temperatures [7].

Thermal networks are generally considered as a way to increase the flexibility of electrical networks. For example, power-to-heat (P2H) systems increase flexibility because they allow excess electricity generated by PV panels to be converted into heat [11]. It is perhaps because of this "grid support" role that research on their intrinsic flexibility is less advanced. In addition, it is often evaluated indirectly, through a host of indicators that are related to flexibility: the ratio of renewables in the energy mix [12]; operational maps expressing the relationship between active and reactive power in an electrical network [13]; operational maps linking combined heat and power production in CHP units to the interface between electrical and thermal networks (see Fig. 5 in [9]); or the economic cost of improving flexibility, e.g., through better control devices [14].

While all the above approaches are useful and interesting, the authors of this paper believe that the field of heat networks lacks explicit and quantitative flexibility indicators. Similarly, the diversity of available energy units is an important source of flexibility, both for the design and the management of networks, yet it is not well known [15] and apparently lacks quantitative indicators. Finally, the authors also believe that efforts are needed to propose indicators that are decoupled from annual simulations and other indicators such as economic ones,

as these two factors prejudge the control strategy. Only when dedicated flexibility indicators with their own formulation and magnitude (or even units) are available, can network flexibility be accurately analyzed.

This article proposes an interpretation of flexibility inspired by the notion of entropy in statistical mechanics. That is, flexibility is understood as the logarithm of the possible combinations between the different energy units of a network. This notion is broken down into combinations of units (so-called "structural" flexibility) and combinations in the management of units (so-called "operational" flexibility). An explicit and non-dimensional indicator, proportional to the number of combinations, is proposed for each declination. The analysis allows to take into account controllable or non-controllable production units (renewables), thermal storage (physical unit or grid inertia), consumption or thermal dissipation, or demand-side management (DSM).

The paper is structured as follows: Section 2 describes in detail the method and the calculation of the indicators; Section 3 presents an illustrative case with its results and analysis; Section 4 discusses several aspects of the method that could be improved; and Section 5 summarizes the most relevant insights about the method and the illustrative case.

2. Materials and method

2.1. Hypotheses and data pre-treatment

This methodology is based on the first order thermodynamic analysis, and thus on the following assumptions and postulates:

- The system is in pseudo-permanent regime. Dynamic considerations are not taken into account. When the user declares a thermal unit, they must make sure that it can deliver heat at the exact moment required by the end-users. Any temporal mismatch due to ramp-up or ramp-down times, or inertia in general, must be ruled out before supplying a unit's thermal power range to the method. Taking into account temporal variability is a perspective for the authors, that will be treated in later researches.
- All units considered in the analysis are capable of producing heat at the temperature required by the demand profile. Issues related to temperature mismatch are not modelled. When the user declares a thermal unit, they must make sure that it can deliver heat at the temperature required by the end-users. Any decrease in temperature due to transport losses or heat exchange must be discounted from the unit's thermal output before supplying this information to the method.
- Spatial considerations are not taken into account. When the user declares a thermal unit with a power range, they must make sure it is the power range that the unit can deliver on the end-user side. Therefore, any heat losses due to transport must be discounted from a unit's power output before supplying this information to the method.
- Head loss along pipes is neglected.

The different sources of flexibility in a network are modelled as thermal power ranges. Table 1 shows how equivalence can be established for different flexibility sources.

Table 1. Equivalent thermal units considered by the method, with their interpretations and some examples.

Equivalent Thermal Unit	Interpretation	Example of a real unit
Adjustable production	A production unit whose thermal power output can be adjusted by its operator.	Biomass boiler
Non-adjustable production	A production unit whose thermal power output cannot be controlled by its operator.	Solar thermal collector field
Storage/de-storage	Any means of accumulating heat. It can be a physical unit or a management technique.	Thermal storage tank
Dissipation/Diversion	To displace heat outside of the system's boundaries.	Heat dissipation by aerothermal units. Heat exports to another aggregator.
Demand-Side Management	To act upon the demand profile in order to modify it for a better matching with the available thermal productions.	Using reward mechanisms in order to direct users' energy consumption to target periods of the day.

2.2. Underlying concept of the method

The indicators proposed in this article are inspired by the notion of entropy. In thermodynamics, if all possible configurations of a thermodynamic system have the same probability of existing, entropy is determined through Boltzmann's formula: $S = \ln(\Omega)$. The authors of this article took inspiration on that approach, and suggest the concept of 'combinatorial multiplicity' in order to analyze the flexibility of district heating networks.

Combinatorial multiplicity (Ω), an analogy to thermodynamic multiplicity, is understood as the number of possible ways to operate the units of energy in a district heating network given an external constraint. In this article, the external constraint is a thermal power demand.

The authors implemented this concept of flexibility through two approaches. One, called "structural flexibility", relates to the number of possible combinations of energy units that satisfy the demand. The other, called "operational flexibility", is related to the number of combinations of thermal energy outputs within the combined energy units. Figure 1 summarizes the two approaches visually, and the following subsection explains the calculation procedure in a formal and detailed manner.

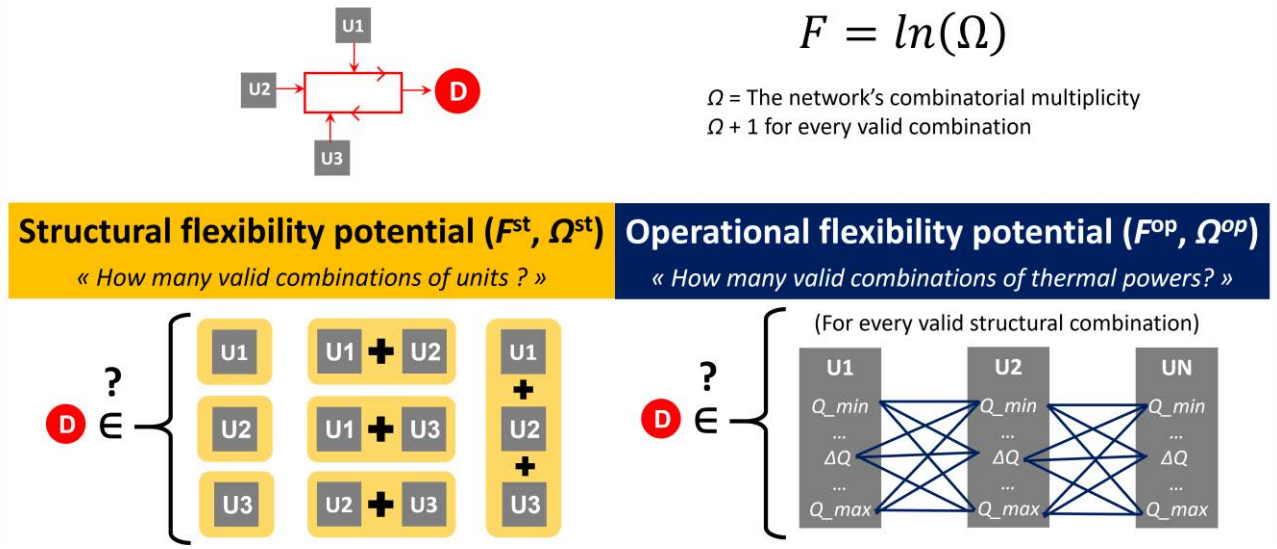

Figure 1. Flexibility potential assessment with a combinatorial approach inspired by the concept of entropy: structural flexibility (down, left) and operational flexibility (down, right).

2.2. Structural flexibility

Let us consider a heating network equipped with *N* equivalent units from the list provided in Table 1. The minimum and maximum heat outputs of the network are the sum of the minimum and maximum specific heat outputs of all units (1).

$$\dot{Q}_N^{\dagger} = \sum_{n=1}^{N} \dot{Q}_n^{\dagger} \qquad \langle \dagger = min, max \rangle \tag{1}$$

For the flexibility analysis, the global control step of the network has been defined as the greatest common divisor of the control steps of all units (2). This global control step, together with the global minimum and maximum power, determines the operating range of the network (3).

$$\Delta\dot{Q}_N = gcd\left(\Delta\dot{Q}_{j=1}, \dots, \Delta\dot{Q}_{j=J}\right) \tag{2}$$

$$Q_N \in \left[\dot{Q}_N^{min} : \Delta\dot{Q}_N : \dot{Q}_N^{max}\right] \tag{3}$$

The structural flexibility is evaluated over this operating range, power by power. All possible combinations of units are considered, from 1 to N selected units. For each combination of units, if the requested power is well within the combined operating range, the number of local configurations at that power (Ω_q^{st}) increases (4).

$$\forall\, Q \in Q_N \; and \; \forall\, st \in C^{st} \qquad if\; Q \in Q^{st} \implies \Omega_q^{st} = \Omega_q^{st} + 1 \tag{4}$$

The overall structural configuration number (Ωst) is the sum of all local structural configuration numbers over the operating range of the network (5). Because all combinations are assumed to be equiprobable, the structural flexibility is determined by a parallelism of the Boltzmann equation (6).

$$\Omega^{st} = \sum_q \Omega_q^{st} \tag{5}$$

$$F^{st} = ln(\Omega^{st}) \tag{6}$$

A value of $F^{st} = 0$ indicates a choke point, i.e., a thermal power demand that no structural combination of energy units can satisfy. An F^{st} of one indicates a structurally rigid point, i.e., only one structural combination can satisfy the demand. Note that a combination does not necessarily mean a single unit; it can be a combination of several units. An F^{st} greater than one means that the network is structurally flexible, i.e., several

combinations of units can meet the demand. The higher the F^{st} value, the more flexible the network is. These considerations apply to both local and global flexibilities.

2.3. Operational flexibility

Operational flexibility is concerned with the combinations of driving units, rather than the combinations of units. Indeed, often the same combination of units can be driven in different ways to satisfy the same demand. The number of operational configurations is determined in a similar way to the structural one, with one difference: each valid combination of thermal outputs counts (7).

$$\forall\, q \in Q_N \wedge \forall\, c^{st} \in C^{st} \qquad \forall\, q^{st} = q \implies \Omega_q^{op} = \Omega_q^{op} + 1 \tag{7}$$

A valid combination is one that satisfies the power demand even with overproduction, provided that the overproduction can be managed (i.e. stored or dissipated). It is important that there is no unmanaged overproduction. Operational flexibility is the logarithm of the number of operational configurations (8 and 9).

$$\Omega^{op} = \sum_q \Omega_q^{op} \tag{8}$$

$$F^{op} = ln(\Omega^{op}) \tag{9}$$

The structural and operational analyses, applied over the entire operating range of a network as defined by (4), lead to two distributions of flexibilities (structural and operational). Structural flexibility and operational flexibility provide non-redundant information with respect to each other. Structural flexibility does not take into account whether the units operate at their limits (upper or lower). Hence the need to define operational flexibility. Both give rise to different distributions of multiplicity, and their maximum will often be reached at different thermal powers. When combined, they make it easier to forecast choke points in the operation of a district heating system.

For clarity, a calculation example of both flexibilities is offered in Fig. 2. Let a district heating network feature three different thermal units. Each one has its own adjustable operating range. Then, the network is faced to a thermal power demand that falls within its production range. It is probable that the demand can be covered by combining the production units in different ways. Here, the term ‘combination’ is understood as ‘operating one or multiple thermal units simultaneously’. Following this logic, structural flexibility considers how many combinations of units can cover the demand *at least once*. Operational flexibility considers how many different ways of operating the units exist in order to cover a demand. In operational flexibility, every valid combination counts. In structural flexibility, every valid combination of units counts only once, independently of its number of valid operational combinations (see Fig. 2).

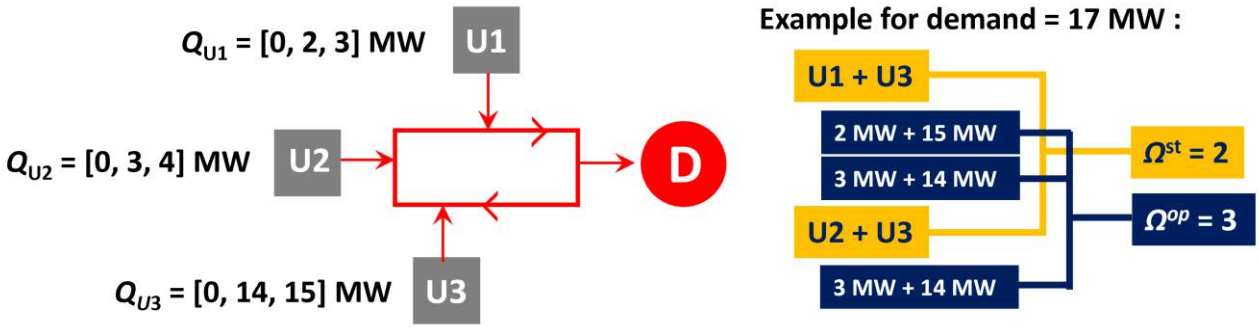

Figure 2. Calculation example of structural and operational multiplicities.

Let readers note that in order to count as a valid solution, a combination must satisfy the demand exactly. This logic applies in both structural and operational flexibility analyses. Therefore, in structural analysis, it is not sufficient that the demand be within a combination’s aggregated operating range. The structural combination must have at least one operating point where the thermal power output equals the demand exactly. This means that the discretization of thermal power ranges is an important point of the methodology. This aspect is discussed in section 4.

2.3. Dedicated open-source Python tool for the calculations

An open-source tool has been written in Python 3.9 for the implementation of the methodology and the calculation of the illustrative case presented in section 3. The tool allows to introduce a series of lists to declare the equivalent energy units in the system (adjustable production, non-adjustable production, storage, dissipation or DSM). Lists are used to declare unit names, operating ranges, and operating steps. Prohibited combinations of units may also be declared, in case the practical constraints of the case study do not allow the simultaneous operation of certain units. Then the tool starts with a routine to check the correctness of the input data (for example, that the operating steps are consistent with the operating ranges). After this check, a

dictionary of unit combinations is created and purged of all user-defined forbidden combinations. Then, the tool uses several "for" loops and "if" statements to analyze each combination and check if it complies with the energy balance and if it corresponds to a target demand value. If so, this combination is considered flexibility. The target value can be 1) either a user-defined request; 2) or each stage of operation of the neighborhood network as a whole, if the user requires a complete distribution of flexibility. After this process, the tool creates a dictionary of valid combinations and calculates flexibility indicators. After the whole process, the tool returns the numerical values of the flexibility for the network and plots the distributions of the structural and operational flexibilities (i.e., the figures presented in section 3). The tool is encoded in UTF-8 and requires the "itertools", "matplotlib" and "numpy" packages.

3. Results for an illustrative case

The previous section described innovative indicators of structural and operational flexibilities and how to evaluate them. This section shows how to apply the methodology and perform a detailed flexibility analysis of a heat network. For this purpose, a simple illustrative example has been developed to show all important information in the flexibility analyses. Readers are reminded that the actual output of this article is the methodology itself, not this illustrative example.

3.1. System description and input data

The illustrative example consists of a heat network with 6 units (Table 2). As a reminder, these are equivalent units, which can represent physical devices, a complete process/machine or an energy management technique.

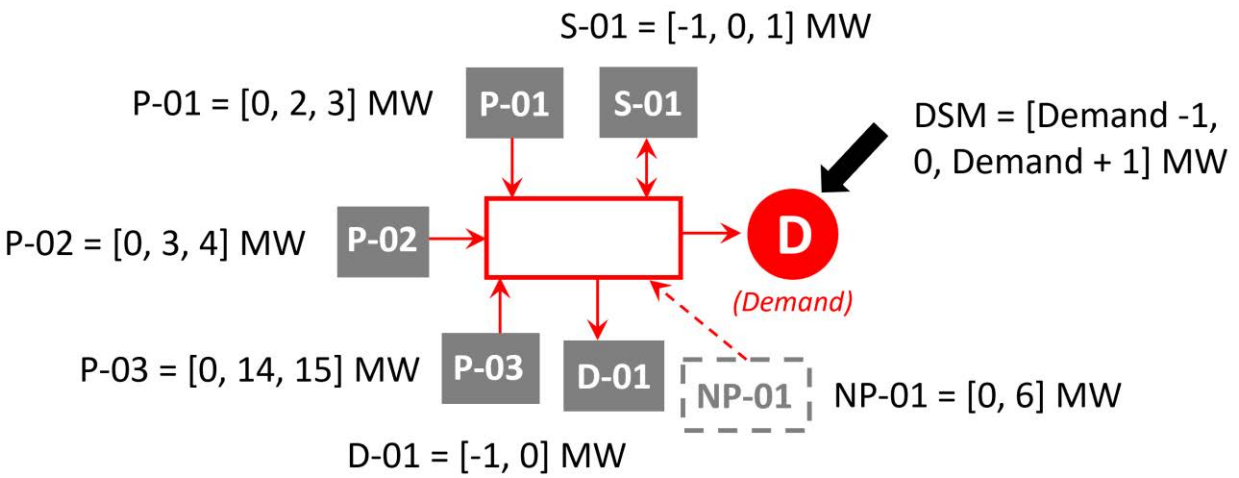

Figure 3. Schematical representation of the illustrative case.

Table 2. Equivalent thermal units considered in the illustrative case.

Unit name	Real unit	Equivalent thermal unit	Operating range
P-01	Biomass boiler	Adjustable production	[0, 2, 3] MW
P-02	Heat pump	Adjustable production	[0, 3, 4] MW
P-03	Heat import	Adjustable production	[0, 14, 15] MW
NP-01	Solar collector field	Non-adjustable production	[0, 6] MW
D-01	Aerothermal dissipation	Dissipation/Diversion	[-1, 0] MW
S-01	Thermocline storage unit	Storage/De-storage	[-1, 0, 1] MW
DSM	Tariff-incentivized modification of users' consumption patterns	Demand Side Management	[Demand -1, 0, Demand +1] MW

3.2. Analysis of structural and operational flexibility

Figures 4 and 5 show the so-called structural and operational flexibilities distributions, respectively. Both are to be represented on the aggregated power range of the network (x-axis). In this example, the lower bound (-3 MW) corresponds to 0 MW generated (P-01, P-02, P-03), 1 MW stored (S-01), 1 MW dissipated (D-01) and 1 MW shed (DSM). The upper bound (+24 MW) corresponds to 22 MW generated (P-01 = +3 MW, P-02 = +4 MW, P-03 = +15 MW), 1 MW de-stored (S-01) and 1 MW anticipated (DSM).

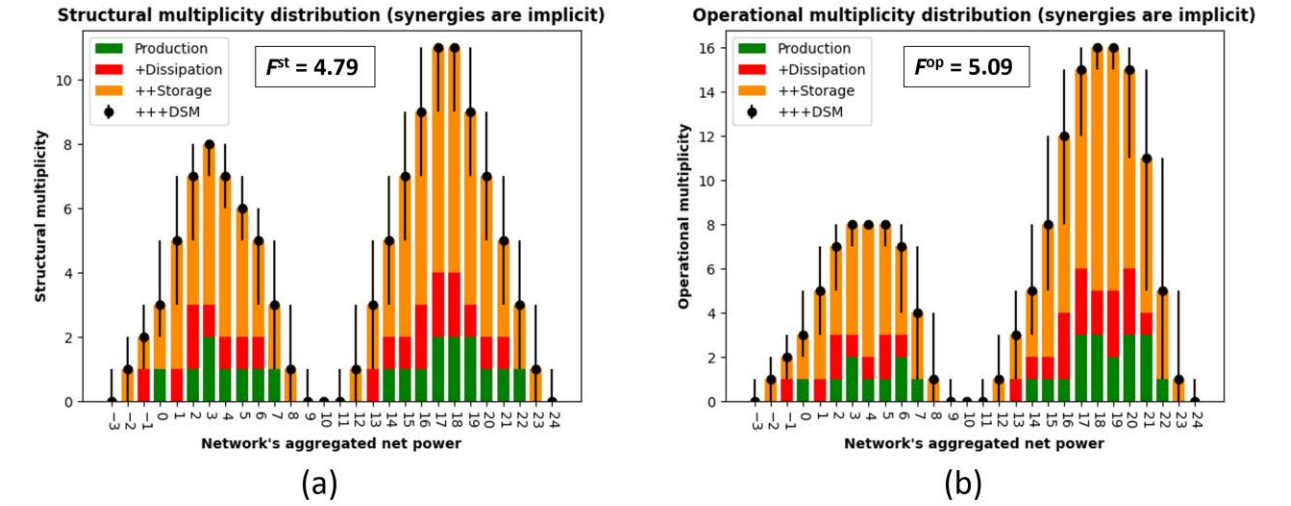

Figure 4. Flexibility distributions over full demand range: a) Structural flexibility, b) Operational flexibility.

The y-axis represents local flexibility at each power, determined by the methods described in Sections 2.2 (structural) and 2.3 (operational). The contribution of the generation units (green bars) is represented at the base of the distribution because it does not depend on the other unit types. Then, the dissipation units are represented in combination with the production (red bars), because they can only remove from the system heat already contributed by other units. The contribution of the storage units is shown in combination with the productions and dissipations (orange bars). It depends on a previous production (which could be partially dissipated), but also on the state of charge of the storage units. The asymmetric error bars represent the effects of the DSM techniques, once the other units are considered.

Thus, it turns out that the controllable generation units will determine the overall flexibility range to a large extent; the other units only expand the flexibility range implemented by the productions. Dissipation widens it only to the left, while (de-)storage widens it to the left and to the right. The DSM, rather than providing flexibility, shifts demand to other powers, which will be advantageous or not depending on the local flexibility of neighbouring powers.

In this illustrative case, the outputs allow two ranges of flexibility: [2 - 7] MW and [14 - 22] MW, which result from all possible combinations between P-01, P-02 and P-03. Then, adding dissipation widens them to 1 MW and 13 MW respectively, and allows to reach -1 MW if only dissipation is used. Storage extends the ranges further, to -2 MW or 12 MW under load, or to 8 MW or 23 MW under discharge. In addition, the storage load would have allowed -1 MW, 1 MW, and 13 MW even with no dissipation. And of course, dissipation and storage increase the local flexibility on the powers already covered by the productions. In fact, they include cumulative synergies. Quantifying and locating precisely the different synergies is an interesting perspective foreseen by the authors.

The potential effects of DSM (error bars on the y-axis) represent the largest possible change in F in the DSM range from a specific power. DSM can shift demand to powers where the local flexibility of the grid would be different. For example, the local structural flexibility at 4MW may switch between 1.79 and 2.08, as the DSM of +/- 1MW would shift demand to 5MW or 3MW respectively. Both the increase and decrease in flexibility are displayed, as the DSM is not always controllable. For example, time-shifted heating requirements often have to be made up later. The DSM can give flexibility to certain power demands that are not accessible by other units (-3 MW, 9 MW, 11 MW and 24 MW in this example). If a power unit is in a flexibility plateau (e.g., 10 MW), DSM will have no effect on its flexibility. DSM will not cause flexibility to rise above its overall maximum, nor will it cause it to fall below zero.

Any power that may fall to zero flexibility due to a poorly managed DSM is a potential choke point. Any power slice that has zero flexibility, but can be increased by DSM, is a bypassable choke point. Any slice of power with zero flexibility without a solution is a hard choke point.

The effects of non-drivable power generation (e.g., renewables) are displayed in Figures 3 and 4. A non-drivable generation of 6 MWth has been assumed. This could symbolize, for example, the installation of a solar thermal collector field with a peak generation of 6 MWth. The new flexibility distributions are given in Fig. 5.

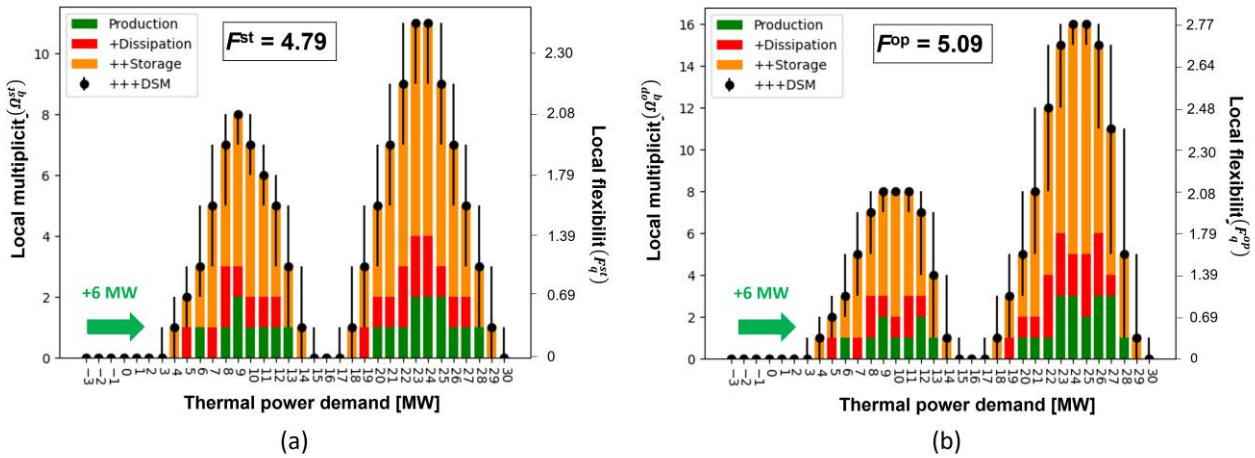

Figure 5. Flexibility distributions after consideration of renewables (non-adjustable production): a) Structural flexibility, b) Operational flexibility.

As a reminder: non-modulable generation is modeled as a heat input to the network that cannot be modulated in power. It must be either used, stored or dissipated. As a result, the two flexibility distributions are shifted to the right on the x-axis (see Figures 4a and 4b). While the old distributions went from -3 MW to 24 MW (Fig. 1), the new ones go from 3 MW to 30 MW. The old lower bound of -3 MW has been retained in the figure for illustrative purposes, but note that there is no flexibility before 3 MW.

Since non-adjustable heat generation is a "must" unit, there is no freedom to (not) select it. Therefore, this does not change the number of possible combinations. Note that there are still 32 combinations of units and 160 combinations of input/output heat outputs (see Appendix A), as in the previous scenario. The only change is that now all possible combinations include non-adjustable generation, and thus have +6 MW of heat output.

The effect of non-controllable productions may seem harmless, but it is not. When the district network is confronted to a demand profile, it will be forced to operate at certain regions of its flexibility distribution. The integration of new, non-adjustable thermal productions (like renewables) may completely unbalance the flexibility matching of the network. In other words, the effects of renewables on flexibility are difficult to forecast even if the network had been well-designed for a demand profile. The methodology presented in this paper (and its calculation tool) may be used for early detection of flexibility issues due to changes in the energy mix of a territory.

4. Discussion on the method

4.1. On the combinatorial approach

The main advantage of a combinatorial approach is that all possible configurations of the system are taken into account. This is the reason why the authors speak of "flexibility potential", instead of "flexibility". A dynamic simulation can only give a "circumstantial" idea of the flexibility of a network, because it prejudges the control strategy, and therefore may encounter difficulties not necessarily due to the configuration of the network at the base. On the other hand, the computation time is the weak point of a combinatorial approach, especially if the number of units is higher than 15.

4.2. On disregarding other performance criteria

This methodology and its indicators are free of preconceived ideas about optimal management or control strategies. Criteria such as energy efficiency, exergy efficiency, economic performance, environmental effects... are totally ignored. The methodology does not give less importance to a specific choice of technical units according to their abundant need of primary energy, or high implementation costs, or high CO2 emissions, or long start-up/shutdown times... In fact, none of these parameters are needed as input to the model. Any combination that satisfies the demand while respecting the energy balance is an equally valid solution.

Heat quality (temperature) considerations are also very limited. Any solution that meets the final heat demand at the requested temperature is valid, regardless of the upstream temperatures. For example, two generating units producing heat at 120°C and 50°C respectively, and both meeting heat requirements at 35°C, are also valid and important under this methodology. Although higher production temperature may indicate higher transmission losses or lower energy efficiencies in substations. In any case, the user must ensure that any generation, storage, dissipation or load control unit included in the analysis can satisfy the heat demands at the requested temperature.

The methodology does not rule out solutions that may seem counter-intuitive or unreasonable from the perspective of first-order thermodynamic analysis. This concerns in particular the overproduction of heat followed by the dissipation of the excess. For example, assume a generating unit and a dissipating unit with thermal power ranges Q_prod = [0, 1, 2, 3] MW and Q_diss = [-1, 0], respectively. If the demand is Q_dem = 2 MW, it is equally valid to produce Q_prod = 2 MW or to produce Q_prod = 3 MW and then to dissipate Q_diss = -1 MW. The methodology gives equal weight to both possibilities. Any arrangement of units that exactly matches the demand is considered flexibility.

All of these are deliberate choices by the authors, in order to create indicators that focus solely on combinatorial flexibility. There are also many methods and tools for multi-criteria analysis of heating networks, with a wide variety of criteria. As for counter-intuitive solutions, it is precisely the variety of criteria that justifies not discarding them. The optimality of a solution largely depends on the context and the decision criteria. Overproduction followed by partial dissipation may seem unreasonable, but it can allow the purchase of primary energy at better rates, for example. In this case, it can become economically optimal. If an exploitation decision is possible, it can become optimal under certain specific conditions and must therefore be taken into account.

4.3. On discretizing continuous ranges of thermal production

The discretization of continuous ranges of thermal power is probably the most debatable aspect of this methodology. Any thermodynamic system is indeed continuous, and trying to analyze it on finite increments may seem too reductionist an approach. The best answer of the authors to this remark at the moment is: control. District heating networks are equipped with demand-oriented energy systems and often subject to some type of control, often discrete. The thermal powers in this method should be considered as control steps.

4.4. On applying the method to other types of energy networks

The methodology, as presented in this article, is intended and more suitable for district heating networks with sources of flexibility from this list: thermal energy production (including partial load operation); storage and retrieval of thermal energy; dissipation (or diversion) of thermal energy; and any demand management techniques that impact thermal energy demand profiles. Only sources of flexibility that can be "translated" into thermal power can be modelled.

Nevertheless, with some data pre-treatment by the user, its applicability can be extended slightly. First, the methodology (and the corresponding Python tool) allows to the user to set the parameters. Thermal power was used in this article, but electrical power could be used to replicate the analysis for electrical networks. Since the methodology is based on balance sheets, the analysis remains consistent as long as the input data is consistent. The same could be done with district cooling networks, as long as their sources of flexibility can be routed as cooling powers. It could even be applied to gas networks, choosing mass flow rates as units.

Also, the methodology is not necessarily limited to the district level. As the notion of spatiality is not modelled, the methodology can be applied to micro-grids (mW) as well as very large-scale (GW) grids, provided that the sources of flexibility are modeled accordingly.

Furthermore, the sources of flexibility taken into account by the methodology are described in such a generic way that they can represent many types of real units/techniques. For example, a conversion unit can be modeled as equivalent production and dissipation units.

The authors are aware that the aforementioned adaptations, although feasible, represent a burden for the user. Their future work is to integrate as many of them as possible into the methodology (and by extension, into the open-source tool), as new features.

Using natural logarithms for quantifying these indicators becomes very useful when expanding/connecting networks. For example, let us assume that a district heating network is connected upstream with the electric grid via electrically-driven mechanical-compression heat pumps. When the heat pumps are implemented, the combinatorial multiplicity of the whole system is the product of the combinatorial multiplicities of the grid and the district heating network. At the same time, the authors would like the indicator of flexibility to be the sum of the flexibilities from the grid and the heating network. Using logarithms allows both addition properties.

5. Conclusions and perspectives

The district heating domain lacks explicit and quantitative indicators to describe the flexibility potential apart from other performance criteria. In this paper, the authors provide an answer to this deficiency through a combinatorial approach. It understands the flexibility potential as the degree of freedom in the selection and control (separately or simultaneously) of the energy units of a network in the face of various demands. The following findings and perspectives can be highlighted:

- The method can help in the energy planning of urban energy networks. Namely, it can help anticipate potential choke points, or the possible effects of renewable energy deployment on existing networks.
- It is planned to study the possibility of working with continuous distributions of flexibilities, rather than discrete ones.

- It is planned to study the applicability of the method to other energy networks, such as electricity networks, district cooling or gas networks. The dimensionless formulation of the method allows (in theory) to extend its application.
- It is planned to define additional indicators, for example an "effective" flexibility that would evaluate to what extent a given demand profile exploits the flexibility potential of the requested network.

The objective is to make the methodology as applicable as possible without putting the burden of data pre-treatment on the user.

Acknowledgments

The authors wish to express their gratitude to the Institut Carnot Energies du Futur for their support through the funding granted to the FlexENR project. The authors wish to express their gratitude to the Région Auvergne Rhône-Alpes for their support through the funding granted by the AXELERA program.

Appendix A

Table A.1 shows the detailed analysis of all possible combinations of units and their thermal powers for the illustrative case shown in Section 3 of the main part of the manuscript. DSM was not processed in the combinatorics because it is represented on the final distributions of flexibility.

Abstract:
Decarbonizing high temperature heat in industrial processes is challenging as there are only few alternative fuels to reach the necessary temperatures. In steel mills the material must be heated up to 1250 °C before hot rolling of steel. Currently, this energy-intensive step is done in steel reheating furnaces fueled with natural gas. Synthetic fuels such as green hydrogen, synthetic methane and green ammonia are possible alternatives for substituting the current polluting energy carrier and in many future climate strategies considered as a crucial component for achieving greenhouse gas neutrality. In this paper, we present options for on-site production of synthetic fuels for steel mills and discuss them by a qualitative approach. Specifically, we investigate hydrogen, synthetic methane and ammonia. We consider state of the art technologies and apply them to a real-world use case from the steel processing industry in Austria. We point out the benefits of on-site generation of synthetic fuels as opposed to external supply in the case of steel mills. Depending on technology, we discuss possibilities for heat integration, implementation of carbon dioxide looping and efficiencies of the systems. We highlight the significant increase in the demand for electrical energy. Further, we discuss challenges of combustion in relation to nitrogen emissions, combustion behavior and effects on steel quality. Our results show hydrogen to be advantageous in many aspects when considering a fuel switch in steel mills with on-site generation. But also we identify synthetic methane as an interesting option that should be further examined.

Keywords:
steel processing industry, on-site synthetic fuel production, hydrogen, synthetic methane, ammonia.

1. Introduction

The use of alternative fuels such as hydrogen, synthetic natural gas (SNG) and ammonia offers significant potential for decarbonizing industrial energy systems. These fuels can serve as an energy source for power plants or be utilized to produce heat directly for industrial processes. The first stage in generating synthetic fuels via the green route involves producing hydrogen from renewable electricity. The conversion of electricity into hydrogen is energy- and cost-intensive. Given that the demand for electricity in general will increase strongly in the future and given that the availability of renewable electricity is finite, it is crucial to carefully evaluate the most appropriate applications for these fuels. For high temperature processes exceeding 1200 °C, where electrification is not always a viable option, synthetic fuels can provide a suitable alternative and should be prioritized for these applications.

In Austria, the metal industry, particularly steel production, accounted for 61 % of the greenhouse gas emissions generated by the entire industrial sector [1]. Hot rolling of steel is one of the major energy consumers in the iron and steel production process chain, with energy consumption of around 1.5 to 3 gigajoules per ton of crude steel [2]. The main function of the hot rolling mill is to reheat steel blanks, called billets, above the recrystallization temperature and roll them thinner and longer through successive rolling stands. The billets are heated to about 1250 °C in industrial furnaces, mainly using natural gas as the primary energy source for heating [3]. The furnace for heating the billets is the major energy consumer in the rolling process and has a big impact on costs and emissions of the product. [2]

To date, only little literature is available concerning alternative fuels for steel reheating furnaces. Schmitz et al. [4] conducted a study on the reduction of CO_2 emissions from hydrogen-fired reheating furnaces, which considered the electricity generation mix. Their findings indicated a substantial potential for lower CO_2 emissions when compared to natural gas-fired furnaces. Similarly, Johansson [5] examined the economic feasibility of using bio-synthetic natural gas (bio-SNG) derived from biomass instead of LPG as a fuel source

for reheating furnaces. The results of this study indicated that the use of bio-SNG was not economically viable. Niska et al. [6] investigated solid biofuels from forest products and found problems arising from ash deposition.

Potentials and challenges of alternative fuels with on-site generation are not explored. To determine the feasibility of on-site synthetic fuel production for steel mills, an evaluation must consider not only quantitative results obtained from simulations, but also qualitative factors such as combustion, safety concerns, technical feasibility or heat integration. This study seeks to assess the most suitable technologies for different alternative fuel productions, specifically hydrogen, SNG and ammonia, based on the aforementioned factors, and to identify the factors that influence the suitability of each option. It highlights the potentials and challenges associated with on-site generation of synthetic fuels and demonstrates the circumstances under which on-site generation is viable.

2. Use Case

A company from the steel processing industry located in Styria, Austria, serves as a use case. The steel mill processes delivered steel billets through hot-rolling, heat-treatment and mechanical processing. The main product is peeled bar steel for the automotive industry. The billets are heated to a rolling temperature of about 1250 °C using a walking hearth furnace powered by natural gas. The furnace is heated by numerous top and side burners, which enable homogeneous heat transfer along the length and width of the furnace.

The steel mill typically operates for one or two eight-hour shifts during weekdays, Monday through Friday. During idle times, the walking hearth furnace is ramped down to a user-defined temperature. The energy demand for the steel reheating is about 360 kWh per tonne steel. Detailed process control data of the furnace are available. The steel mill is located in a residential area and due to the presence of an outdated electric arc furnace, the maximum power connection to the steel mill is 30 MW.

3. Concepts for on-site generation of synthetic fuels

In this section, we investigate various options for on-site generation of synthetic fuels such as hydrogen, SNG and ammonia, and provide an in-depth analysis of the associated technologies, storage methods, combustion processes, influence on steel quality, safety considerations, costs and efficiencies. By presenting a comprehensive overview of these important factors, we aim to explore the potentials and challenges of on-site generation of these alternative fuels for steel mills.

3.1. Option 1: Hydrogen

The production of green hydrogen involves the electrolysis of water to split it into hydrogen and oxygen gases. Renewable electricity is used to power the electrolysis unit. There are three main electrolysis technologies available: alkaline water electrolysis (AWE), polymer electrolyte membrane (PEM) electrolysis and solid oxide electrolyzer cell (SOEC). These technologies differ in various aspects, such as their dynamics, efficiency, temperature and pressure levels, technological advancements, and lifetime. AWE are the most advanced electrolysis technology, but they cannot respond well to load changes. Response to load changes are the main advantage of PEM. SOEC is a high temperature electrolysis which can be coupled with an excess heat source. This results in a high efficiency; however, SOEC technology is still in development stage. [8] [9]

Storage of hydrogen is crucial for on-site generation and mainly serves to decouple the operation of electrolysis and steel reheating. Storage of hydrogen presents challenging problems due to its light weight and gaseous nature. Several hydrogen storage options are available, including compressed gas storage, liquefaction, absorption (metal hydrides) and adsorption storage. Liquefaction of hydrogen demands a high amount of energy, approximately 30 to 40 percent of the energy content of hydrogen [9], and is mostly used for high-purity applications in the chemical industry and aerospace applications [10]. Absorption storage have low sorption and desorption kinetics and cannot be operated very dynamically. Adsorption storage operate at very low temperatures and require a lot of energy. [9] Therefore, compressed gas storage is considered the most suitable for our specific use case.

Compressed hydrogen storage systems can operate at pressures up to 700 bar, which requires the use of compressors to attain the required ultimate pressure. The process of compressing hydrogen also causes a significant amount of energy consumption, equivalent to 13-18 percent of the lower heating value of hydrogen. [9]. Furthermore, the negative Joule Thomson effect of hydrogen must be taken into account. During compression, hydrogen undergoes a cooling effect, which raises concerns regarding the potential for pressure vessel materials to be damaged if the temperature drops too low. Conversely, when hydrogen is relaxed, it undergoes a warming effect [11].

Figure 1 shows the layout of an on-site hydrogen generation system. The setup includes an electrolysis unit, a compressor, hydrogen and oxygen storage and a reheating furnace. The oxygen produced as a byproduct

during electrolysis is also stored and can be utilized for combustion. Moreover, the steel reheating furnace produces excess heat.

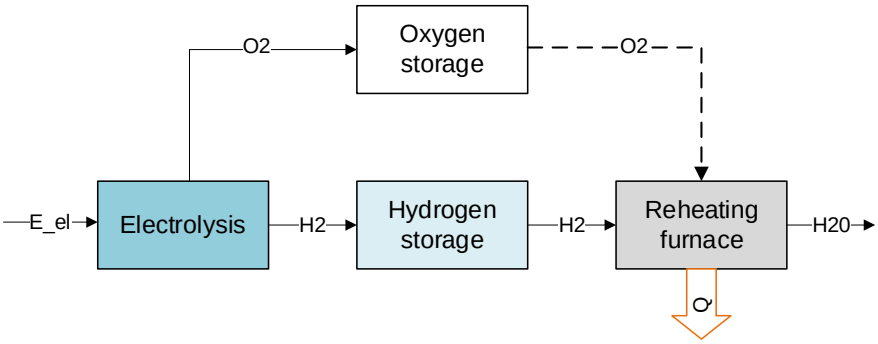

Figure 1. System hydrogen.

Hydrogen is well suited for generating high temperature heat due to a high flame temperature. However, there are significant differences between the combustion of hydrogen and natural gas. Due to its higher flame temperature, less fuel is required to generate the same amount of heat, resulting in less combustion air needed and lower convection within the combustion chamber. This must be considered in the process control when operating the furnace. [12]

Hydrogen can be burned with either air or oxygen. Combustion with air results in higher NOx emissions compared to natural gas combustion because the higher flame temperature (~2000 °C) produces more thermal NOx. Combustion with oxygen leads to lower energy input (approximately 30 %) and no NOx emissions; however, safety concerns regarding explosions and even lower convection due to the higher flame temperature (~2700 °C) make it challenging. Moreover, adaptation of the furnace is more expensive. [13] [12] [14]

Safe use and handling of hydrogen poses some unique challenges. Easy leaking, low ignition energy and possible damaging influence of equipment materials must be taken into account [10]. Scale formation on steel billets increases by 12 percent [15].

3.2. Option 2: Synthetic natural gas

Two main processes to produce synthetic natural gas (SNG) are catalytic methanation (CM) and biological methanation (BM). Methanation is a chemical reaction in which hydrogen and carbon dioxide and/or carbon monoxide, are converted into methane and steam with the aid of a catalyst or microorganisms. Catalytic methanation uses various metals as catalysts while biological methanation uses microorganisms as catalysts. Equation (1) shows the reaction equation for the synthesis of SNG:

$$CO_2 + 4\,H_2 \leftrightarrow CH_4 + 2\,H_2O \quad (1)$$

The CM unit typically operates within the temperature range of 300 to 550 °C and at a pressure of approximately 10 bar. The exothermic reaction involved in catalytic methanation generates a substantial amount of heat. The fixed-bed regenerator is the most commonly used reactor type for this process. In contrast, the biological methanation process operates at lower temperatures of 30 to 70 °C and at pressures ranging from 1 to 10 bar. Generally, larger reactor sizes are required to achieve high conversion efficiency. Both CM and BM units have good load response characteristics, although CM has a minimum load requirement of 40 percent and must maintain a standby temperature of 200 °C. The efficiency of the CM unit can be improved through heat integration. The catalyst used in CM is sensitive to impurities, whereas microorganisms utilized in BM are generally less sensitive. [16]

Figure 2 illustrates the arrangement of the system for SNG production. The SNG system consists of several components, including electrolysis, hydrogen and oxygen storage, methanation unit, and SNG storage. In addition, a carbon capture system is installed, which consists of an absorber and desorber. The CO2 separated from the flue gas is utilized for the methanation unit. Prior to absorption, the flue gas must undergo cooling through a heat exchanger, which generates excess heat. Oxygen can also be stored and utilized for combustion.

As previously mentioned, catalytic methanation produces excess heat, which can be employed for high-temperature electrolysis. The excess heat generated from the furnace can be utilized for the standby mode of the catalytic methanation unit or for high-temperature electrolysis utilizing SOECs. The excess heat produced during the operation mode of catalytic methanation can be also used for high-temperature electrolysis. Overall, the SNG system with carbon capture has the potential to utilize excess heat generated during various stages of the process to improve its overall efficiency. However, due to the two conversion steps involved, the process efficiency is lower, and additional space is required for the extra unit.

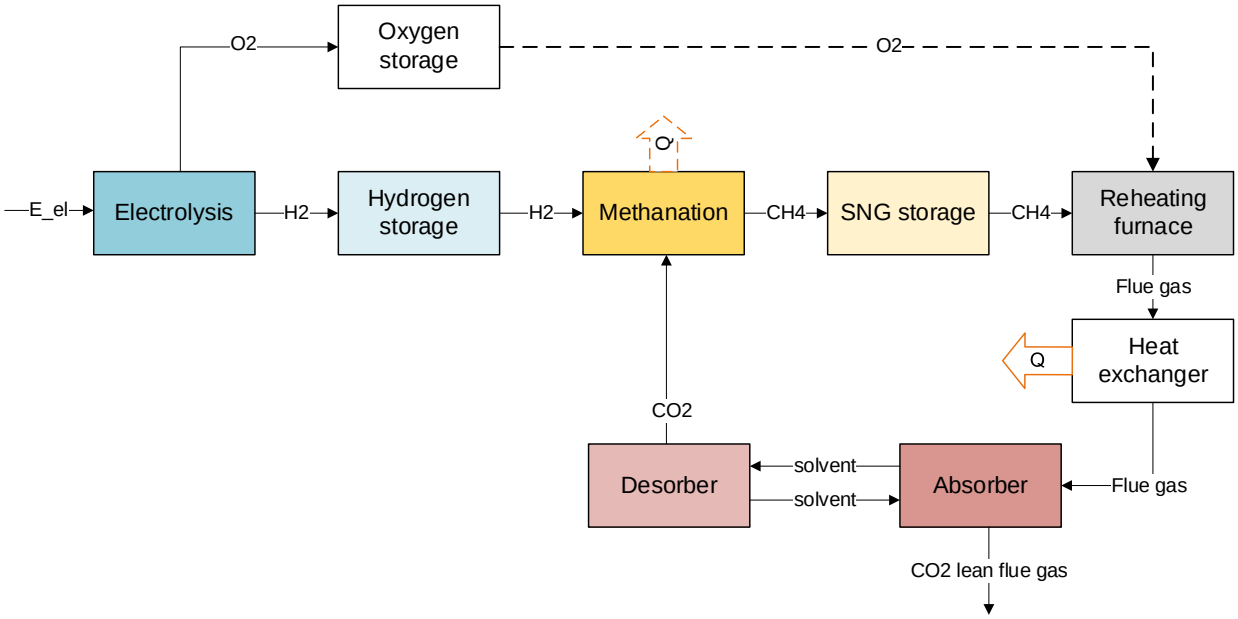

Figure 2. System SNG.

It is assumed that the combustion of SNG is similar to combustion of natural gas, and therefore no modifications to the furnace or process control are necessary.

SNG storage is less challenging than hydrogen storage due to the higher energy content per unit volume. Existing infrastructure for storage and pipeline transportation can be used for SNG. The pressures required for storage are significantly lower, resulting in negligible energy demands for storing SNG. Furthermore, lower storage pressures imply less strict safety requirements. The quality of steel and scale formation is not expected to differ significantly between natural gas and SNG.

3.3. Option 3: Ammonia

Ammonia today is mainly used for fertilizer, but is it an interesting option as an energy source for the future. Due to the high flame temperature, it is practicable to generate high temperature heat. Its main advantage is the easier storage of ammonia compared to hydrogen. For green ammonia, firstly hydrogen is produced through an electrolysis, additionally nitrogen is produced through an air separation unit and then hydrogen and nitrogen are processed into ammonia with the Haber Bosch process, according to Eq. (2): [17]

$$N_2 + 3\,H_2 \leftrightarrow 2\,NH_3 \tag{2}$$

More recently, ammonia is discussed as a fuel for generating heat for industrial applications. In the shipping sector it is seen as a promising alternative due to its stability and low transportation costs. However, ammonia combustion has disadvantages, including low burning velocity and high fuel nitrogen oxides production. To mitigate these issues, a blend of hydrogen or methane with ammonia can be used. Increased hydrogen proportion in the fuel mix leads to an increase in burning velocity, but also more NOx emissions. However, adding methane to the mix not only increases the burning velocity but also reduces the NOx emissions, making it a viable alternative.[18] [12]

Figure 3 shows the layout of the system ammonia. It consist of an electrolysis unit, hydrogen and oxygen storage, Air separation unit, Haber Bosch plant, ammonia storage and a reheating furnace. Excess heat is

generated by the Haber Bosch unit as well as by the reheating furnace. As combustion of ammonia with pure oxygen is not performed, the obtained oxygen is not used within the system.

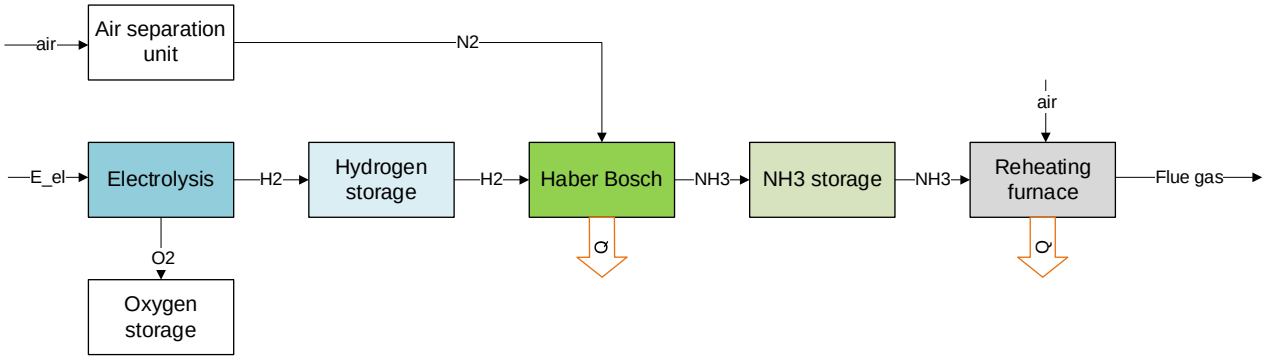

Figure 3. System Ammonia.

3.4. System specifications

While the focus of this paper is on qualitative comparison and analysis, basic evaluations of efficiencies, investment costs, and specific energy demand were also performed to provide a comprehensive overview of the subject and provide valuable insights. Consequently, Table 1 presents the summarized values for investment costs and efficiencies, which were utilized in further calculations.

Table 1. Investment costs and efficiencies of all components of the systems. [19]–[23]

Component	CAPEX	Efficiency, %
AWE	1400 €/kW_{el}	0.65
PEM	1800 €/kW_{el}	0.63
SOEC	2700 €/kW_{el}	0.81
Compressor + H2 storage	33 €/kWh_{H2}	0.85
Hydrogen burner	63.32 €/kW_{therm}	-
Catalytic methanation	750 €/kW_{SNG}	0.75*, 0.8**
Biological methanation	1050 €/kW_{SNG}	0.78*, 0.9**
SNG storage	33 €/kWh_{SNG}	1
CO2 storage	33 €/kWh	1
Carbon capture system	40 €/t_{CO2}	
Ammonia plant (ASU, Haber Bosch, NH3 storage)	850 €/t_{NH3}	0.85

*in relation to the calorific value, **conversion efficiency

For calculations of the investment costs, the approximate capacities of the plants were determined through a small optimization problem (MILP) using data from our use case. These capacity sizes are summarized in the Table 2 were used for further calculations. In the case of SNG and ammonia, the hydrogen storage serves as a buffer between electrolysis and methanation unit and is smaller than the storage of the hydrogen system.

Table 2. Capacities of the plants.

Plant	System hydrogen	System SNG	System ammonia
Electrolysis output	7 MW	8.75 MW	8.25 MW
Hydrogen storage size	35 MWh	10 MWh	10 MWh
Methanation output	-	7 MW	-
SNG storage size	-	35 MWh	-
Haber Bosch output	-	-	7 MW
NH3 storage size	-	-	35 MWh

4. Evaluation of concepts for alternative-fuel production

4.1. Qualitative discussion

There is no one-size-fits-it-all solution for substituting natural gas in steel mills. The suitability of the different alternative options depends on various factors. Important factors are space availability, location of the steel mill, environmental regulations, maximum power connection, integration of renewable energies, production schedule and energy demand for production. All these aspects will be discussed in the following.

The preconditions for on-site generation concepts include the sufficient space, a power connection capable of providing at least the same amount of power as the electrolysis unit, and the infrastructure to store hydrogen safely on premise. Additionally, integration with the company's renewable energy sources is advantageous.

For all alternative fuel options, out of the three electrolysis concepts, the Solid Oxide Electrolysis Cell (SOEC) exhibits the highest theoretical efficiency due to the availability of excess heat from the reheating furnace, which is at approximately 800°C without air preheating. However, the technology readiness level of SOEC remains below that of Proton Exchange Membrane (PEM) and Alkaline Water Electrolysis (AWE). Furthermore, SOEC typically operates at a constant level, so it depends on the scheduling of the rolling mill and energy prices. The suitability of PEM electrolysis depends on the operation of the electrolyzer, which may require dynamic operation due to fluctuating renewable energies, energy prices or irregular production schedules. AWE, even though the most advanced electrolysis technology, is likely unsuitable for this particular application due to a lower efficiency and static operation.

Hydrogen: When considering hydrogen as a fuel for steel reheating furnaces, on-site generation presents several advantages. First, it eliminates the challenges associated with hydrogen transport. Additionally, the production of oxygen as a byproduct of the electrolysis process prevents the need for costly external oxygen supply. Oxygen use enables more energy-efficient production and reduces the required capacities for electrolysis and hydrogen storage. However, utilizing oxygen for combustion requires more extensive modifications to the furnace compared to air combustion. Nevertheless, existing steel reheating furnaces can be retrofitted for the use of hydrogen. Further, additional adaptations for process control and investigations of scale formation and steel quality are required. Using hydrogen as a fuel in steel reheating furnaces does not produce CO_2 emissions, as long as electricity is obtained from renewable sources.

SNG: Due to the two conversion steps involved, the process efficiency is lower, and additional space is required for the extra methanation unit. Nevertheless, the easier handling of the fuel and its combustion behavior, which is very similar to natural gas, represent the main benefits of this approach. The SNG system does not necessitate any modifications to the furnace or process control, and the quality of the steel and scale formation remain the same.

The SNG system, coupled with carbon capture, has the potential to utilize excess heat generated during various process stages to improve its overall efficiency. To evaluate the performance of the SNG concept, simulations that take heat integration into account are necessary. The performance of the SNG system primarily depends on production capacity and schedule, which enables efficient heat integration. In addition, the oxygen produced by the electrolysis can be utilized for combustion, representing another advantage of the on-site generation concept. When comparing catalytic and biological methanation, the latter method has the advantage of being less sensitive to CO_2 source impurities; however, the reactor needs more space.

Ammonia: The use of ammonia combustion for industrial applications, including steel reheating furnaces, remains largely unexplored. Also, there is a lack of research investigating the effects of ammonia combustion on steel. The use of ammonia as a fuel presents significant challenges in relation to NOx emissions and burning velocity, making it a less viable option compared to hydrogen. Moreover, as the primary advantage of ammonia over hydrogen is its ease of transport, and small-scale Haber Bosch plants are not common, on-site generation may not be advantageous. Additionally, the generation of nitrogen from an additional air separation unit, and the oxygen obtained from electrolysis that is not used pose further disadvantages. While ammonia combustion remains an interesting option for industrial applications, extensive research and development is required before its widespread use. Generally, it may be better suited for external supply.

4.2. Quantitative results

In this section, results of some basic calculations are presented. Figure 4 shows the efficiencies of the systems with all possible combinations of technologies. It is evident that the hydrogen system achieves the highest efficiency. The SNG system shows the lowest efficiencies, with no significant difference between catalytic and biological methanation. The system ammonia lies in between.

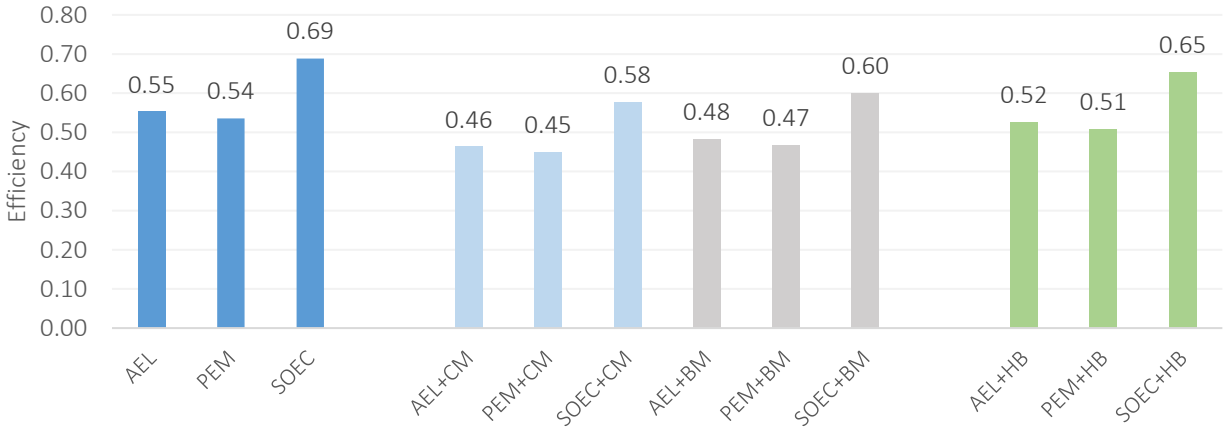

Figure 4. Efficiencies for the considered system configurations.

Figure 5 illustrates the total energy demand of the process chain for reheating of one tonne steel, for the different systems and depending on the combustion type (air/oxygen). Using oxygen for combustion can significantly lower the energy demand.

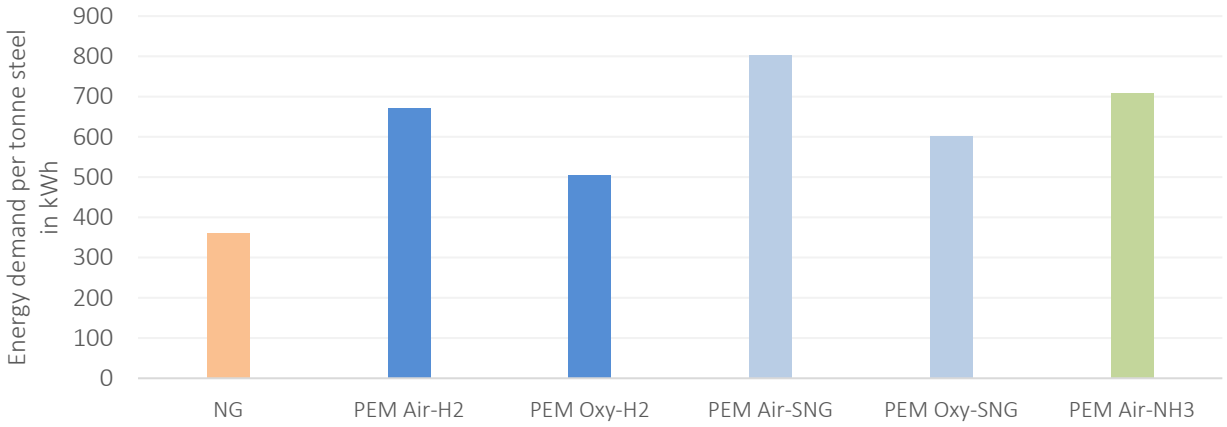

Figure 5. Energy demand per tonne steel reheated for air and oxygen combustion of different energy carriers.

Figure 6 gives an overview of investment costs for the different systems. The SNG system has the highest investment costs, primarily because of the additional costs for the carbon capture plant. Main investment costs in all systems are associated with the electrolysis unit, with SOEC being the most expensive one.

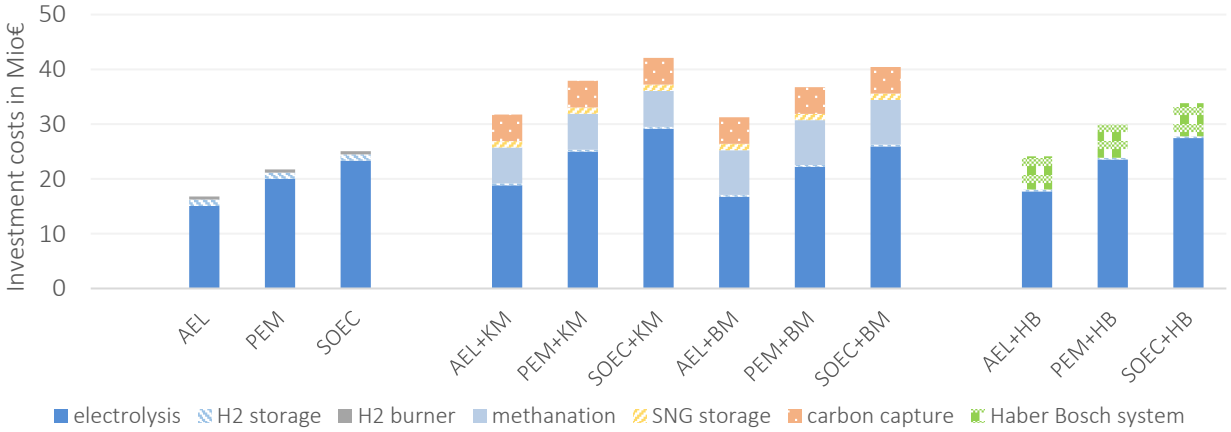

Figure 6. Investment costs for the considered system configuration.

5. Conclusion

In this paper, we presented concepts for on-site generation of hydrogen, synthetic natural gas (SNG) and ammonia, and conducted a qualitative comparison underpinned by basic estimates regarding investment costs and efficiencies. We discussed factors like combustion behaviour, heat integration, effects on steel quality. Our analysis revealed that on-site generation of hydrogen offers benefits related to transport, use of oxygen and low CO_2 emissions. For SNG, easy handling of the fuel and numerous possibilities of heat integration were identified as advantages. We found ammonia not to be suitable for an on-site generation concept. Also there are several challenges in combustion of ammonia, mainly related to low burning velocity and high NOx emissions. Overall, the production of synthetic fuels leads to a significant increase in electricity demand, requiring the company to have a sufficiently high power connection. If on-site generation will ever be economically viable will heavily depend of future natural gas prices and emission regulations.

Acknowledgments

The research presented is part of the research project LEOPOLD, funded by the Austrian research promotion agency (FFG) (Project number 35833857). The authors would like to thank all project partners for their contributions.

Abstract:

Despite the current push for full electrification of the transportation sector, the utilization of IC engines (either on their own or hybrid guise) will continue for the foreseeable future. This is even more evident in the freight industry and with construction equipment. Therefore, the use of alternative fuels is a vital stepping stone toward low-carbon transportation. Environmental regulations have been developing enormous interest in biodiesel as an alternating fuel, with the main objective of reducing emissions associated with the transportation sector. Biodiesel is a renewable fuel that is mainly produced from vegetable oils and animal fats. At an industrial scale, its production is an energy-intensive operation that contributes to the overall carbon footprint.
The present paper describes the energy and exergy analysis of an existing biodiesel plant. The facility applies used cooking oils and vegetable oils as raw materials and has an annual consumption of over 1,100 toe (as of 2021). The analysis identified the possibility of using biomass as a primary energy source for heat. Furthermore, the detailed analysis of the plant operation enables the identification of energy conservation measures that can reduce the electricity consumption and the pellet consumption by 29 tons a year.

Keywords:

Biodiesel; Energy; Exergy; Irreversibility; Thermodynamics.

1. Introduction

In recent decades, several concerns have arisen regarding the balance between energy consumption and sustainable, environmentally friendly, economically viable, and socially fair development. In this context, renewable energies started to play a leading role in order to reverse the worrying scenario of the possible depletion of fossil fuels (1). The energy consumption of society has contributed to the reduction of the existing reserves of coal, natural gas, and oil, and the ratio between consumption and production does not allow the continuous replenishment of these reserves, so depletion is inevitable (2). On the other hand, climate change is undoubtedly the greatest socio-environmental concern that the planet is facing today. Although burning fossil fuels is the main problem, it is also true that the increase in the volume of road traffic created by the world's dependence on transportation, particularly in large urban centers, has contributed on a large scale to the increase in pollutant emissions and energy consumption (3). In 2020, the total emissions of pollution gases emitted in Portugal (57.6 Mton CO_2) are estimated that 25% come from national transport, being the sector that consumed the largest amount of energy by year, around 32.6%, followed by industry (31.2%), domestic (19.5%), services (13.4%) and agriculture and fisheries (3.3%) (4).

To comply with the international goals to achieve carbon neutrality by 2050, renewable energy technologies have been at the top of the international discussion and several signs of progress have been conducted in this sector (5). However, no effective solution was implemented regarding the transportation sector and environmental regulations have been developing a huge interest in biodiesel as an alternating fuel, with the main objective of reducing hazardous emissions. In this context, it is believed that the replacement of fossil fuels by biofuels, such as biodiesel, can be a major contributor to the transportation sector (6). Currently, emphasis has been given to the study of bioethanol and biodiesel to replace gasoline and diesel respectively, since to use these biofuels it is not necessary to make major changes in road transportation (7). Biodiesel in particular is a biodegradable, non-toxic energy source synthesized from various raw materials, including man-made waste such as used oils and animal fats, which in contact with nature can cause major environmental

imbalances (8). According to the international energy agency (IEA) (7) biodiesel production has been gradually increasing, as shown in Figure 1 (a). Although insignificant, this increase tends to remain until 2025 with an estimated world production of 46 billion liters. Regarding the countries that lead the biodiesel production sector, data presented in Figure 1 (b) shows that in 2021, Indonesia was the world's largest producer of biodiesel with a total of 9.5 billion liters, followed by Brazil with 6.9 billion liters of biodiesel produced (6).

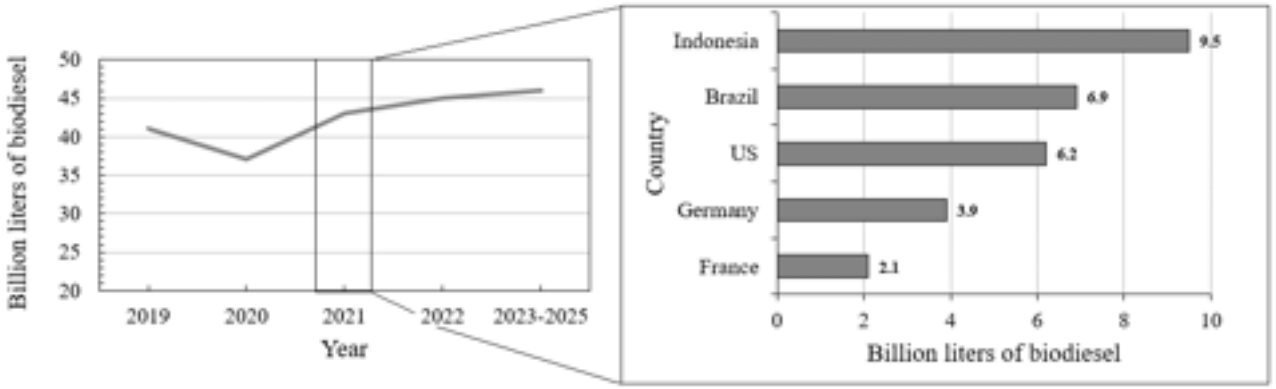

Figure 1. (a) World production of biodiesel; (b) Worldwide leading countries in biodiesel production in 2021.

Although biodiesel is pointed out as a solution for the transportation sector, the increased production worldwide has also led to an increase in the production of vegetable oils, as they are the main raw materials used for biodiesel production on an industrial scale. However, the high cost of biodiesel production, as a consequence of the high price of vegetable oils, is the biggest problem for its implementation and commercialization on a large scale, making biodiesel less economically competitive compared to diesel derived from petroleum [1]. To create alternatives, many methods have been explored to reduce this cost, one of which involves replacing vegetable oil with used cooking oils. Recycling frying oil as a biofuel not only removes a hazardous compound that is most of the time released to the environment but also allows the production of a renewable and less polluting source of energy (8,9).

From an industrial point of view, the biodiesel and conventional diesel production processes have almost equivalent efficiencies, with regard to the conversion of their raw materials into fuels (10). The opportunity to reduce the energy consumption in industrial plants, and therefore decrease the overall energy consumption of the process, allows for an intensification of the integration of biodiesel production on a large scale which could be very important for the dissemination of this fuel worldwide. In this context, this work focuses on an energy analysis carried out on a company in the biofuels sector in Portugal, more precisely, a company dedicated to the industrial production of biodiesel. Since the company is characterized by being an energy-intensive consumer, having consumed throughout 2021, 1120.46 toe, it is important to conduct an energy and exergy analysis of the plant in order to identify energy optimization solutions that can reduce the electrical and thermal energy consumption. Based on the identification of the processes involved in biodiesel production and the related products used for its production, the energy consumed and produced is estimated in this work. This allows to determine the efficiency of the process. However, energy analysis does not provide all the information needed to characterize the performance of the production process. Therefore, exergy analysis is useful to pinpoint the thermodynamic losses and inefficiencies (11). This study presents a methodology to determine energy and exergy efficiencies of biodiesel process production, which include both biodiesel and energy production. Moreover, solutions are presented to increase the energy performance of the biodiesel production process, highlighting the need to conduct a detailed thermodynamic analysis of biodiesel production plants to disseminate the use of this fuel in the transportation sector.

2. Theoretical Background

2.1. Biodiesel

Biodiesel is considered a biofuel, whose composition and properties comply with the European standard EN 14214 or the American standard ASTM D6751. It consists of a mixture of methyl esters of fatty acids formed by transesterification or esterification of vegetable oils (e.g. soybean, rapeseed, sunflower, and palm oils) or animal fats with methanol or ethanol, from various chemical or biological processes (12). From the chemical reaction between these raw materials, two products are obtained, an ester (biodiesel) and glycerol (also known as glycerin), which can be used, for example, by the pharmaceutical industry. The reaction is catalyzed by an acid or a base, depending on the characteristics of the oil and/or fat used. The reaction mechanism can be divided into three stages, where the triglyceride is sequentially converted to diglyceride, monoglyceride, and glycerol, in a sequence of three reversible reactions (12), as shown in Figure 2.

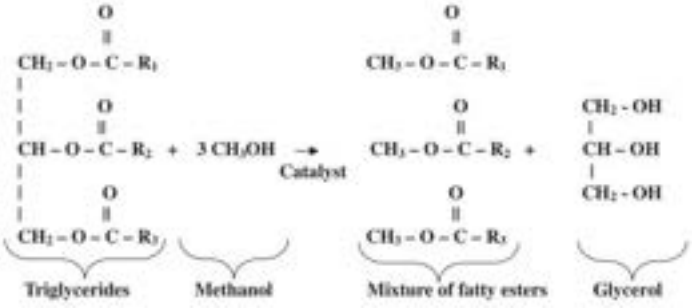

Figure 2. Methanolysis of triglyceride.

2.2. Mass and Energy Balance

The first law of thermodynamics is the main principle that governs the energy conservation principle of any system. The conservation of energy is closely linked to the mass conservation principle, stated by (13). In a steady state, the mass balance model of the biodiesel production process is expressed by Eq. (1).

$$\dot{m}_{in} = \dot{m}_{out} \tag{1}$$

Analogously, the energy balance results from the difference between the energy produced by a fuel and the energy required to obtain it (14), as expressed in Eq. (2) (15,16):

$$\dot{E}_{in} + \dot{Q} = \dot{E}_{out} \tag{2}$$

Except for the electrical energy, that was measured, the remaining forms of energy were calculated according to Eq. (3), as they do not contain any other form of energy other than the chemical energy of each compound.

$$\dot{E} = \dot{m}\, LHV \tag{3}$$

The heat supplied to the system comes from the burning of pellets, being $\dot{Q}$ expressed by Eq. (4).

$$\dot{Q} = \dot{m}\, LHV \tag{4}$$

2.3. Exergy Balance

While the majority of the chemical industry uses energy analysis to optimize their processes, this does not indicate that the energy is efficiently used (11). To determine if a process is thermodynamically efficient, entropy generation must be analyzed, the higher the entropy generation, the higher energy is degraded (17). This property can be estimated by exergy, which represents the useful amount of work that can be extracted from a system when taken into thermodynamic equilibrium with the environment. Exergy changes account for the irreversibility of a process that depends on entropy production. Consequently, this irreversibility can be obtained by the exergy analysis of the system. In this context, the exergy balance can be expressed in Eq. (5) (10).

$$\dot{\varepsilon}_{in} + \dot{\varepsilon}^{Q} = \dot{\varepsilon}_{out} + \dot{W} + \dot{I} \tag{5}$$

where subscripts *in* and *out* apply the same flows as the ones applied in the energy balance an $\dot{I}$ is the system's irreversibility.

The exergy of a system is composed of several elements, as presented in Eq. (6).

$$\dot{\varepsilon} = \dot{\varepsilon}^{ph} + \dot{\varepsilon}^{0} + \dot{\varepsilon}^{k} + \dot{\varepsilon}^{po} \tag{6}$$

where $\dot{\varepsilon}^{ph}$, $\dot{e}^{0}$ $\dot{\varepsilon}^{k}$ and $\dot{\varepsilon}^{po}$ are the physical, chemical, kinetic, and potential exergy, respectively.

In this study, only fluids with chemical energy (Eq. 7) are considered and all other forms of exergy are therefore neglected.

$$\dot{\varepsilon}^{0} = \dot{m}\, \varphi\, LHV \tag{7}$$

In Eq. (7), φ depends upon the chemical composition of the fuel, being considered approximately equal to 0.975 for liquids and gases and 1.07 for biomass (18,19).

2.4. Efficiency

In this study, two energy efficiencies are considered, the efficiency of the production of biodiesel, presented in Eq. (8), and the total energy efficiency of the process, expressed in Eq. (9).

$$\eta_{Bio} = \frac{\dot{E}_{Bio}}{(\dot{E}_{in} + \dot{P})} \quad (8)$$

$$\eta = \frac{\dot{E}_{Bio} + \dot{E}_{Gly}}{(\dot{E}_{in} + \dot{P})} \quad (9)$$

where $\dot{P}$ represents the pumping power. While the efficiency of biodiesel production, η_{Bio}, is obtained by the ratio between the biodiesel energy and the total energy consumed for its production, the efficiency of the process, η, takes into account the products that are collected from this process, biodiesel, and glycerine.

Regarding the exergetic efficiency, one can consider the rational efficiency for biodiesel production, expressed in Eq. (10), and the rational efficiency of the process, presented in Eq. (11).

$$\psi_{Bio} = \frac{\dot{\varepsilon}_{Bio}}{\dot{\varepsilon}_{in} + \dot{P}} \quad (10)$$

$$\psi = \frac{\dot{\varepsilon}_{Bio} + \dot{\varepsilon}_{Gly}}{(\dot{\varepsilon}_{in} + \dot{P})} \quad (11)$$

The rational efficiency of the production process is a measure of the process performance, being defined by the ratio between useful exergy output and the maximum input exergy. While ψ_{Bio} focuses on the biodiesel production process, ψ considers all the products obtained from this process.

3. Materials and Methods

3.1. Biodiesel Production Line

As previously mentioned, biodiesel is a product resulting from the transesterification of oils with an alcohol in the presence of an acid or alkaline catalyst. The biodiesel production process implemented in the industry where this study was conducted can be summarized in the flowchart shown in Figure 3.

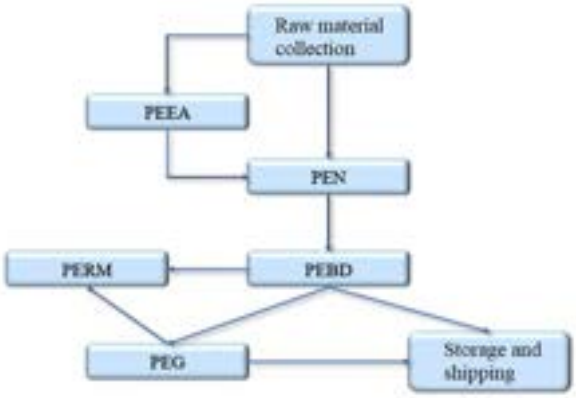

Figure 3. Biodiesel production process.

To ensure that the final product (biodiesel) meets the requirements, several process variables need to be controlled. The biodiesel to be shipped must have the parameters within the specifications, according to the European standard EN 14214. Some of the process parameters to be considered are the acid number (IA) and the percentage of free fatty acids (FFA) in the raw materials, residual raw materials (MPR), the degree of mixing between alcohol and triglycerides in the transesterification process as well as all operating temperatures and pressures.

The process begins with the collection of raw material that consists of waste oils. These oils are mainly wastes from the food industry (restaurants) or resulting from the oil refining industry. The incorporation of this type of waste as a raw material promotes industrial symbiosis and enhances the circular economy. The second stage begins with PEEA (Specific Acid Esterification Production Unit). The raw materials have characteristics that prevent them from being incorporated directly into PEBD (Specific Production of Biodiesel Unit), namely a high acidity index and high content of water, phosphorus, and other contamination. The high-acid MPR (IA > 10 mg/g and FFA > 5%) then need to go through an acid esterification process to be able to be incorporated into the PEN (Specific Neutralization Production Unit). The third phase consists of the pre-treatment of the low-acid MPR (IA < 10 mg/g and FFA < 5%) together with the MPR after the acid esterification process, which occurs in the PEN, to be ready to be incorporated into the PEBD. In the PEBD, biodiesel results from the transesterification of oils with methanol in the presence of a catalyst, sodium methylate. During this process, three reversible reactions take place. From the triglycerides (*TG*) of the oils, two intermediate components are formed, the diglycerides (*DG*) and the monoglycerides (*MG*). The reactions are as follows (12)-(14):

$$TG + CH_3OH \leftrightarrow DG + R_1COOCH_3 \quad (12)$$

$$DG + CH_3OH \leftrightarrow MG + R_2COOCH_3 \quad (13)$$

$$MG + CH_3OH \leftrightarrow GL + R_3COOCH_3 \quad (14)$$

where $R_{1,2,3}$ are organic radicals.

The global reaction, which characterizes the production of glycerol (*GL*) and biodiesel (R_3COOCH_3), is expressed by reaction (15).

$$TG + 3CH_3OH \leftrightarrow GL + 3R_3COOCH_3 \quad (15)$$

The crude glycerine produced in PEBD needs to be treated in order to be able to be exported. PEG is the glycerine treatment process that guarantees a minimum glycerol content of 75-80%. The methanol recovered from the PEBD and PEG (Specific Production of Glycerine Unit) processes needs to be purified (PERM - Specific Production of Methanol Rectification Unit) in order to be used again (> 98 %). Finally, both biodiesel and glycerine are stored in tanks to be later exported.

3.2. Specific Production of Biodiesel Unit

The biodiesel production unit is schematically represented in Figure 4. The process begins with the heating of neutral oils from the PEN (D-03) together with virgin vegetable oils from the D-05 by a plate heat exchanger and a tubular heat exchanger to a desired temperature. Then the raw material is mixed with methanol and sodium methylate, the catalyst. The mixture enters the R-3001 reactor (cavitation reactor) and the reaction takes place up to a percentage of methyl esters close to 85%. The products resulting from this reaction (biodiesel and glycerine) are sent to the D-06 decanter, where the glycerine is decanted and separated, going to the D-08. To simplify this operation, recirculation of the glycerine is conducted, i.e., part of the glycerine that leaves the D-06 goes back in to maintain the temperature and help with its separation (the greater the amount of glycerine, the greater the tendency for deposition). Biodiesel (light phase of D-06) is mixed again with the reagents and passes through the cavitation reactor R-3002 where the formation of esters is completed. The products go to the D-07 and the glycerine is decanted into the D-09 accumulator.

In the production of biodiesel, using an alkaline catalyst, some amount of soap is always produced. Thus, once the transesterification reaction is completed, the excess catalyst and soap tend to be concentrated in the glycerine phase. However, there is always some amount of these constituents that remain in the biodiesel stage. This fact can cause problems in the follow-up of the process: the soaps remain in the process and can cause the clogging of the resins. To solve the problem, when the mixture reaches the D-10 accumulator, phosphoric acid is added keeping the pH controlled (close to neutral). Acidification aims to create conditions less favorable to the formation of soaps and to end the transesterification reaction. This is followed by Flash 1 at approximately 75 ºC and a pressure of 130 mbar, the methanol in the biodiesel is dried to 5000 ppm. Methanol is recovered to D-11 while biodiesel goes to D-15. In the resin basins (R-3003 and R-3004) occurs the final adsorption of glycerine which has sodium, methanol, and some impurities. Biodiesel leaves the resins for Flash 2 where, under more severe conditions of pressure and temperature, methanol drops to values within the European standard, EN 14214, below 2000 ppm. After physical filtration, the biodiesel goes to D-01/D-02. Subsequently, an antioxidant is added to the biodiesel, and this is transferred to the shipping tanks.

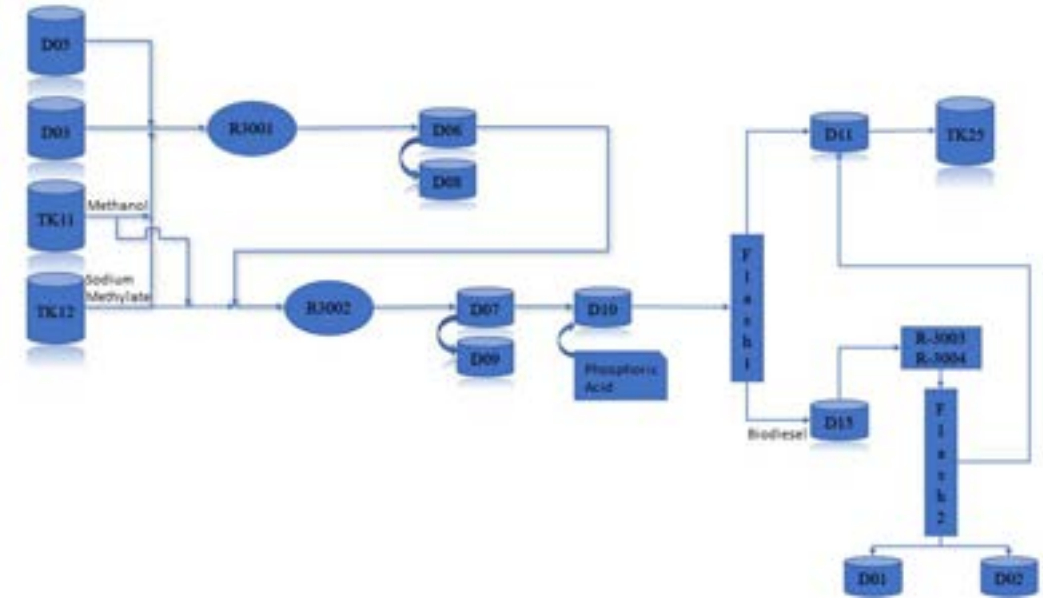

Figure 4. Scheme of the Specific Production of Biodiesel Unit.

4. Results and Discussion

4.1. Energy consumption and biodiesel production

Because of fluctuations in biodiesel production, energy consumption is not constant throughout the year. However, since biofuel production requires temperature control, the highest energy consumption is due to the heating and cooling operations. To better understand the energy needs in biodiesel production, it is essential to carry out an analysis of the history of energy consumption of the processes, which is divided into electricity consumption (electric motors for the pumps and chiller) and consumption of pellets (boiler). For this, the data referring to the year 2021 were used, as presented in Table 1.

Table 1. Typical energy consumption and biodiesel production in a year (2021).

Month	Pellets (ton)	Electricity (kWh)	Production of biodiesel (ton)
January	131.90	155,882.00	1,252.60
February	125.56	108,908.00	876.00
March	154.84	183,094.00	1,787.70
April	135.44	157,979.00	1,491.20
May	160.86	177,861.00	2,104.40
June	132.98	168,588.00	1,740.90
July	127.20	154,309.00	1,572.60
August	100.98	134,481.00	1,227.70
September	160.92	192,194.00	2,064.70
October	157.58	173,891.00	1,706.40
November	157.04	174,555.00	1,780.40
December	106.02	127,698.00	899.40
Total	**1,651.32**	**1,909,440.00**	**18,504.00**

To determine the energy consumption per ton of biodiesel produced, the consumption values are converted into toe to obtain a reference value in toe /ton of biodiesel, taking into account the thermodynamic and electrical conversion factors (1 toe = 41,868 MJ and 1 kWh = 215 $\times 10^{-6}$ toe) presented in Dispatch nº 17313/2008 (20). For calculation purposes, the lower heat value (LHV) of the pellets is considered equal to 18.0 MJ/kg. To determine the consumption of pellets in toe, Eq. (16) is used. On the other hand, the conversion of electrical energy consumption into toe is given by Eq. (17).

$$E_{\text{toe}} = \frac{m.\,\text{LHV}}{41.868} \tag{16}$$

$$E_{\text{toe}} = ec\,.\,215 \times 10^{-6} \tag{17}$$

where *m* is the mass in ton, the LHV is in MJ/kg and the *ec* corresponds to the electric consumption in kWh.

Regarding the energy consumption and using the values for 2021, it appears that the company is covered by the SGCIE (Portuguese Management System of Intensive Energy Consumption), since the total energy consumption exceeds 500 toe – 1120.46 toe (0.06 toe / ton biodiesel) – the company is considered an Intensive Energy Consumer (CIE).

Through the plot presented in Figure 5 (a), it is possible to observe the evolution of energy consumption throughout 2021. For the period under analysis, a significant variation in energy consumption over time is observed. Throughout January and February, the average flow rate of biodiesel produced was 2.7 tons/h, a value lower than the average flow rate seen in the rest of the year (3.5 tons/h). On the other hand, in February a stoppage of about 2 weeks due to a fire occurred. During the summer months, the company was once again stopped, for 3 weeks for the vacation period and in December the average flow rate of biodiesel produced was 2.4 ton/h due to a limitation in a pump. For these reasons, it is possible to perceive the existing variations in energy consumption and biodiesel production, Figure 5 (b), since energy consumption is directly related to biodiesel production. Moreover, an analysis was conducted to determine the major contributors to energy consumption. These contributors were divided into two groups, the boiler, which is responsible for heating the thermal oil that feeds the heat exchangers in the factory, and electrical equipment which includes all the electric motors that power the pumps, lighting, office equipment as well as other less relevant equipment. It should be noted that the Chiller is also included in electrical equipment, which further demonstrates that energy consumption related to utilities (production of heat and cold) is much higher than the energy consumption of

other equipment directly associated with the biodiesel production process. The plot depicted in Figure 6 (a) shows the difference between the weight of energy consumption between the boiler and the electric motors, being responsible for 63.4 % and 36.6 % of the consumption of the total energy consumed by the company, respectively. To provide more information regarding the energy consumption throughout 2021, the monthly specific energy consumption was plotted and presented in Figure 6 (b). The data show that although January, February, and December are the months with lower biodiesel production, 2.7 ton/h for the first two months and 2.4 ton/h for the last one, the specific energy consumption is much higher. On the other hand, this parameter in the coldest months (October to April) is higher than in the remaining months of the year due to the lower operating temperatures used in the production process, requiring a greater amount of thermal energy.

Figure 5. (a) Evolution of energy consumption throughout 2021; (b) Variation in biodiesel production throughout the year (2021).

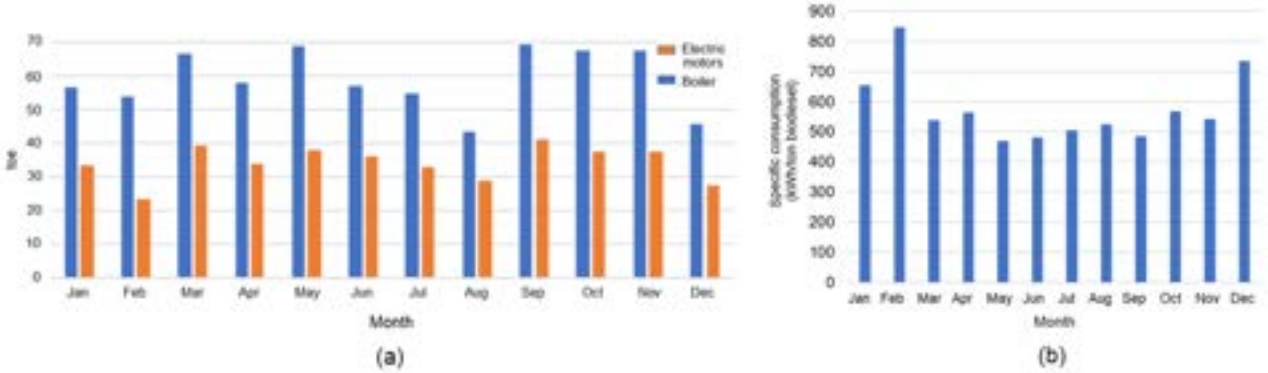

Figure 6. (a) Energy consumption by the boiler and electric motors; (b) Specific energy consumption.

4.2. Mass balance

As previously mentioned, the biodiesel is produced by a chemical reaction between triglycerides, which in this case are composed of virgin oils (VO) and used oils (UO), methanol (CH_3OH), and catalysts, in this case, the phosphoric acid (H_3PO_4) and the sodium methylate (CH_3NaO). In this unit, recovered biodiesel is also introduced into the process. From these inlet components, biodiesel, glycerine, and methanol are produced, as expressed in Figure 7.

Figure 7. Mass balance of the biodiesel production process.

Regarding the scheme presented in Figure 7, the mass balance of the PEBD unit can be written as follows:

$$\dot{m}_{in} = \dot{m}_{H3PO4} + \dot{m}_{UO} + \dot{m}_{VO} + \dot{m}_{CH3OH} + \dot{m}_{CH3NaO} + \dot{m}_{RecBio} \quad (18)$$

$$\dot{m}_{out} = \dot{m}_{bio} + \dot{m}_{gly} + \dot{m}_{CH3OH} \quad (19)$$

$$\dot{m}_{gly} = \dot{m}_{in} - (\dot{m}_{bio} + \dot{m}_{CH3OH}) \quad (20)$$

where $\dot{m}_{in}$ and $\dot{m}_{out}$ are the inlet and outlet mass flow rates, respectively. In this study, all the mass flow rates were measured, except for the case of the glycerine which was obtained by difference.

For the mass balance, in-site mass flow rate measurements were conducted in the PEBD Unit. The mass flow rate of each pump was recorded directly from the control room except for the following pumps: P-3005 and P-3007 in the Flash 31 and P-3010 Evaporator and P-3022 in the Flash 32 evaporator. To determine the mass flow of these 4 pumps it was necessary to take samples at strategic points, as presented in Figure 8. In Flash 31 (Evaporator Fe-31, Figure 8), 2 samples were collected: one before the evaporator (sample 1, Figure 8) and another later (sample 2, Figure 8). The analysis of these samples allowed to determine the methanol percentage in biodiesel upstream and downstream of the evaporator and, consequently, the evaporated methanol flow rate. This process was repeated for the Flash 32 evaporator.

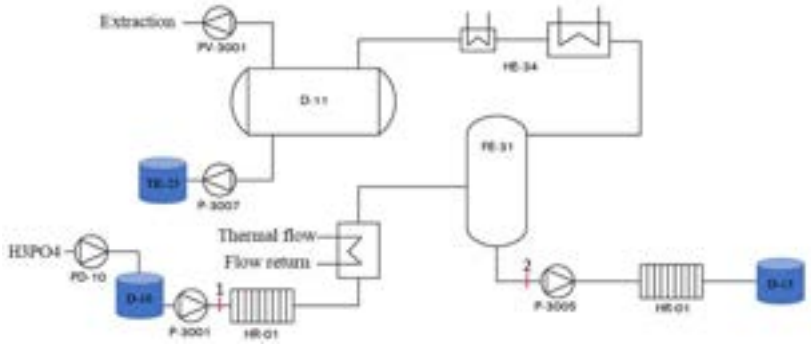

Figure 8. Schematic of sample collection in Flash 1.

According to the data presented in Table 1, it was possible to determine the working time of the PEBD for each month, based on the monthly production of biodiesel and the mass flow rate measured for each product that integrates the biodiesel production process is expressed in Table 2. The results are expressed in Figure 9 and represent the percentage of the products consumed (inlet) and produced (outlet) in 2021.

Table 2. Measured mass flow rates.

Process	Products	Mass flow rate (kg/h)
Output	Biodiesel	3404.32
	CH_3OH	195.68
	Glycerine	631.64
Input	H_3PO_4	3.15
	UO	2244.2
	VO	875
	CH_3OH	588
	CH_3NaO	140.49
	Rec. Biodiesel	380.8

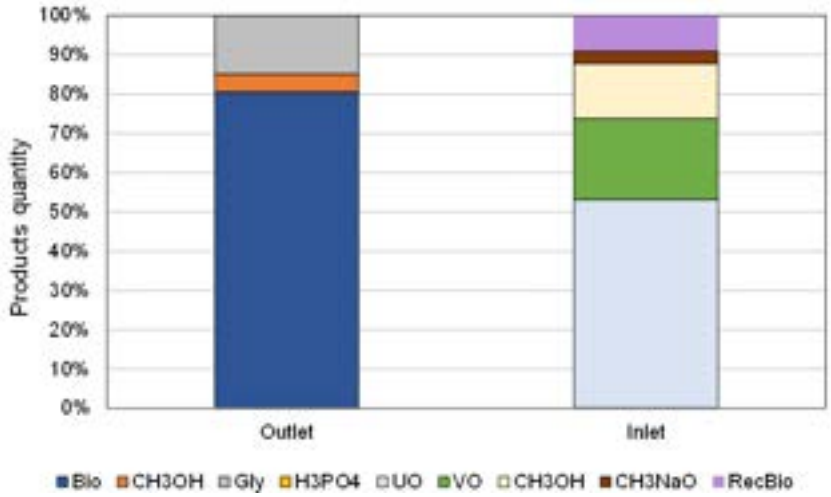

Figure 9. Products consumed (inlet) and produced (outlet) by the PEBD Unit in 2021.

As it can be observed in Figure 9, used cooking oils represent the major consumption (53 %), followed by virgin oils (21 %) and methanol (14 %). The recovered biodiesel introduced into the process is approximately

10 % while the catalysts are residual. Regarding the final products obtained from the PEBD Unit, the analysis shows that biodiesel represented 80 % of the products, followed by 15 % of glycerine and approximately 5 % of methanol.

4.3. Energy balance

The energy balance of the PEBD Unit is presented in Figure 10. As previously stated, the outflow energy from the production of the biodiesel process is equal to the energy inflow plus the thermal energy provided by the boiler. This initial energy is the sum of the energy provided by virgin oils (VO) and used oils (UO), methanol (CH_3OH), and catalysts - phosphoric acid (H_3PO_4) and the sodium methylate (CH_3NaO). Besides these products, the PEBD unit uses electrical energy (Elec.) that feeds the pumps and the chiller and biomass (Biom.) as the heat source that provides thermal energy to the entire process. From this process, biodiesel (Bio.), glycerine (Gly), and methanol (CH_3OH) are produced. Moreover, part of this energy is lost (Loss), which is obtained by the difference between the energy consumed and produced. The energy balance equations used are expressed in Eqs. (21)-(22). It should be noted that the calculations were conducted in function of mass instead of mass flow rate. Therefore, $\dot{E}$ in section 2.2 becomes E.

$$E_{in} = E_{H3PO4} + E_{CH3NaO} + E_{UO} + E_{VO} + E_{CH3OH} + E_{Bio.\ Rec} + E_{Elec.} + E_{Pellets.} \quad (21)$$

$$E_{out} = E_{Bio.} + E_{CH3OH} + E_{Gly.} \quad (22)$$

Regarding the energy of each product, E_{H3PO4}, E_{CH3NaO}, E_{UO}, E_{VO}, E_{CH3OH}, $E_{Gly.}$and $E_{Bio.}$, only the chemical energy is considered using the data obtained from the mass balance and the LHV of each compound. Based on the literature, the LHV used is as follows: $LHV_{H3PO4} = 23.5$ MJ/kg, $LHV_{CH3OH} = 19.9$ MJ/kg, $LHV_{UO} = 37.0$ MJ/kg, $LHV_{VO} = 37.0$ MJ/kg, $LHV_{Gly} = 19{,}0$ MJ/kg, $LHV_{Bio} = 19.0$ MJ/kg. No information was found regarding the sodium methylate LHV, therefore it was not considered in the energy balance. Regarding the thermal energy provided by the pellets, Pellets in Figure 10, it is obtained by multiplying the mass of pellets consumed by the PEBD unit by the biomass LHV which was considered equal to 18 MJ/kg.

To determine the pellet consumption of the PEBD, the heat exchanged between the thermal flow (thermal oil heated by the boiler) and the cold stream, which consists of used cooking oils, virgin oils, and biodiesel, in each three heat exchangers of this unit is calculated. From this analysis, it was found that the PEBD unit is responsible for 14 % of the total pellets consumption.

Regarding the consumption of electrical energy consumed by the pumps and the chiller, measurements were conducted. For the case of the power consumed by the pumps, the current and tension were measured, and the total power resulted from the sum of the power consumed by each pump, resulting in 18 % of the total electrical energy consumed. The chiller is used to produce cold water to condensate the methanol evaporated during the process of purification of biodiesel. To determine the power consumed by the chiller, the vapor-compression refrigeration cycle was analyzed. Temperatures involved in the heat exchanged between the cold source and the evaporator and between the hot source and the condenser were recorded. The refrigerant fluid used in this process is R410a. From these temperatures, the properties of the thermodynamic cycle were defined in terms of power consumption for each stage, resulting in a total of 684,050 kWh/year, which represents 36 % of the total electrical energy consumed.

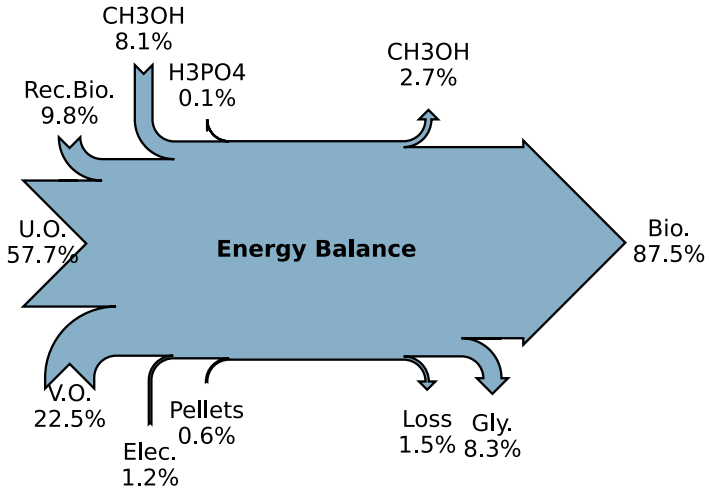

Figure 10. Energy balance of the PEBD Unit.

4.4. Exergy Analysis

The exergy balance is always performed along with the energy balance of the unit. However, energy analysis relates directly to the first law of thermodynamics, where exergy is always destroyed when a system involves an irreversible reaction (21). The irreversibility of the process was calculated using equation (5) by the difference between the exergy that enters the system and the exergy that leaves the system. The determination of the exergy flows was the same principle as the energy flows shown in Eq. (21) and Eq.(22). The electric exergy is the same as the electric energy, and the chemical exergy of the other streams was calculated using Eq. (7). The exergy balance of the PEBD was determined and is depicted in Figure 11.

The irreversibility of the process depends on the system's entropy variation. The literature shows that biodiesel production presents a higher exergy efficiency. This is mainly due to the reversibility of the transesterification reaction and the biodiesel's high chemical exergy in relation to the exergy consumed in the process (22,23). The boiler associated with the unit might be the equipment that most influence the irreversibility of the system. However, the total exergy of the pellets is insignificant compared to the total exergy of the input flows involved in the system (0.6 %) which explains the small difference between heat loss and irreversibility in the system.

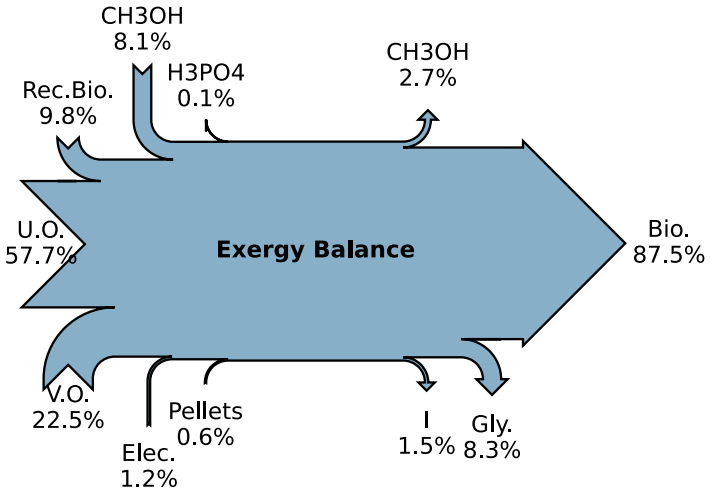

Figure 11. Exergy balance of the PEBD Unit.

4.5. Process enhancement

From the energy balance, it is clear that the PEBD unit is highly optimized in terms of heat consumption, representing around 14% of total pellet consumption this is mainly due to the use of heat exchangers at the beginning of each biodiesel purification stage, allowing the recovery of energy from the hot streams to preheat the cold streams. On the other hand, the use of low vacuum pressures in the evaporators allows operating conditions at lower temperatures, reducing the consumption of electrical energy. However, after a careful analysis of the PEBD unit, it was possible to find some solutions that improve the energetic process performance. Regarding the pellet consumption, it was found that the continuous operation of the heat exchanger HE-33 is redundant and unnecessary since it is expected to keep the operating temperature of Flash 1 near 77 ºC. With proper insulation, the heat exchanger HE-01 could be connected directly to the evaporator FE-31, since the heat lost from the biodiesel flowing through the pipe to the environment between the HR-01 and the HE -33 heat exchangers is of the same order of magnitude as the heat supplied by the HE-33. Thus, HE-33 can operate in a bypass mode during the first few hours of the unit starting time. With thermal equilibrium reached, it was found that deactivating the HE-33 exchanger would result in annual savings of more than 29.5 tonnes of pellets, which represents a decrease of approximately 2.2 % of the annual pellets consumption. Even though this value seems to be irrelevant, it corresponds to cost savings in the order of 7,000 €/year, taking into account the rising in prices observed for this fuel over the last months.

Regarding electricity consumption, an opportunity to improve the methanol recovery/condensation process was identified, by acting on the existing chiller. Measurements reveal a high water flow rate, compared to a low evaporated methanol flow rate, with a maximum ΔT between the inlet and outlet of the chiller of 1.6 ºC, showing that the water flow rate is oversized. Therefore, a need arises to calculate an optimized water flow rate for a minimum ΔT of 5 ºC in the evaporator, as well as an increase of 1 ºC at the cold water outlet, allowing the use of a lower refrigerant flow rate as well as the increase of temperature in the evaporator and, consequently, an increase in its pressure, reducing the compression work. Moreover, this optimized water flow rate allows to estimate the minimum cooling power needed by the process, allowing the selection of a new chiller. With this optimized equipment, a reduction of more than 70 % of the electrical power consumed by the chiller is possible.

Considering these optimized solutions, the energy and exergy efficiencies of the system were estimated and compared with the present scenario. To conduct this analysis, the equations presented in section 2.2 were used to plot the graphs presented in Figure 12. The results show that in the actual scenario, the energy and exergy efficiencies for biodiesel production are 87.6 % and 87.5 %, respectively. While for the process, which includes the production of both biodiesel and glycerine, the energy and exergy efficiencies are 96.0 % and 95.8 %, respectively. There is not much difference between both efficiencies as the thermal loss and the irreversibility of the system are identical. However, the difference is due to the irreversibility caused by the boiler.

Compared with the present scenario, the optimization proposed increases by almost 0.6 % in both energy and exergy efficiencies. It is not a significant increase as the energy saved is relatively low compared with the overall energy of the process. However, by observing Figure 13, it is possible to conclude that this optimization decreases around 117 toe the annual irreversibility. This may not have a major impact on the energy or exergy balances, however, it will be translated into a reduction in biodiesel production cost.

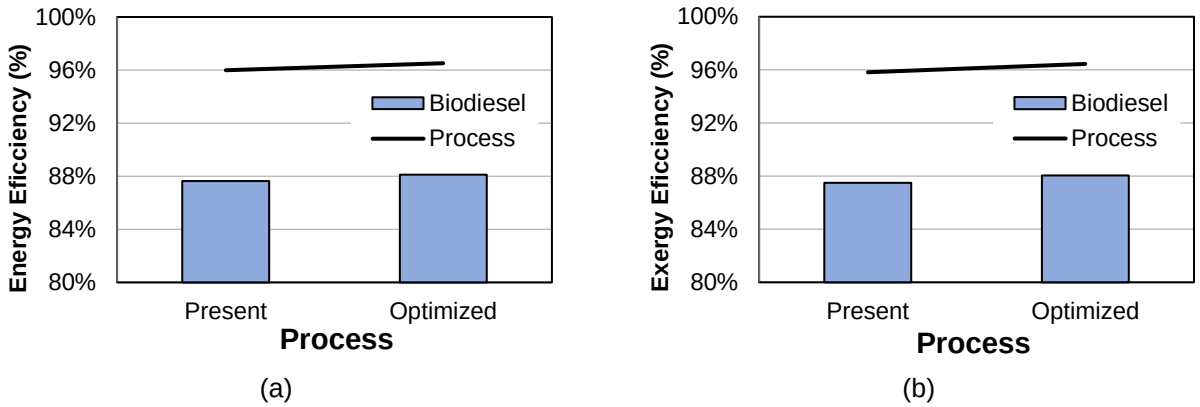

Figure 12. Energy (a) and Exergy (b) efficiency analysis for the present and optimized scenarios.

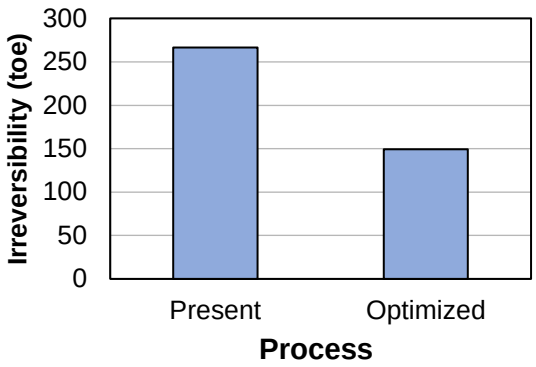

Figure 13. Influence of the optimization in the process irreversibility.

5. Conclusions

This study presents a detailed analysis of a biodiesel power plant. The different products used for biodiesel production are characterized and the different reaction processes are presented. Considering the complexity of analyzing the entire power plant, an energy and exergy analysis is conducted on the specific unit of biodiesel production or PBDE, as previously mentioned. To determine the mass balance, in-site measurements were conducted. From this analysis, a total of 18,504 tons of biodiesel are produced in 2021 as well as 3,433 tons of glycerine, which is sold for other industry sectors. These products represent a total of 87.6 % and 8.4 % of the total energy produced, the remaining percentage is methanol and energy loss. Regarding the sources of energy used for biodiesel production, electricity came from pumps and a chiller, while the thermal energy is provided by pellets burned in a boiler. The study conducted shows that the PEBD is responsible for a total consumption of electrical energy corresponding to 54 %, from which 36 % is consumed by the chiller, while this unit only consumes 14 % of the pellets. In terms of energy efficiency, the biodiesel production process is estimated to be equal to 88.1 %, while the process that includes both the production of biodiesel and glycerine represents an efficiency of 96.5 %. In terms of exergy, the results are slightly different from the energy analysis, being the difference mainly due to the irreversibility caused by the boiler. The entire process was analyzed and solutions were presented in order to enhance the process efficiency. This enhancement results in a slight

increase of both energy and exergy efficiencies of the process, approximately 0.6 %. Although this improvement seems to be reduced, it leads to non-negligible cost savings in the power plant.

Mild Hybrid Multi-Energy Systems: Waste Energy Recovery by Bottom ORC System

Roberto Capata

Sapienza, University of Roma

Abstract:

The goal of this paper is to evaluate, from a thermodynamic point of view first, and then constructive one, the possibility of inserting a waste heat recovery system in a hybrid vehicle in mild-hybrid configuration. The vehicle considered is a standard 1000 cc gasoline turbocharged ICE. The characteristic and proposed configuration of the vehicle allows to mechanically separate the existing turbo-compressor unit and to couple them with the respective electrical devices: electric motor and generator. This new architecture enables an electrical generation that can be used to recharge the installed battery package. Moreover, thanks to the new configuration of the turbine of the group, i.e. without the wastegate valve, the turbomachinery provides a high gas flow rate at high temperature (about 380 °C). These exhaust gases can be used for a bottom ORC group, with additional electricity generation. All these considerations permit to have an extra on-board recharge of the batteries, to consequently increase the electric range of the vehicle (a sort of range extender) and to install a battery group of limited size and power, with consequent advantages of payload and vehicle efficiency. Besides, it allows to achieve the well know and inflated aspects (from a citation point of view) of the emissions reduction.

Keywords:

Mild Hybrid Vehicle, Electric Generation, ORC plant, Compressor Turbine Condenser design

1. Introduction

The aim of the research is to verify the feasibility of an on-the-road prototype of a power train for a hybrid propulsion vehicle. In detail, the project consists in the study and implementation of an innovative complex energy plant for the ICE (900cc) of a city car [1-4]. The solution studied is to mechanically disconnect the compressor/turbine complex, supporting the C compressor with a dedicated electric motor and connecting the T turbine to a generator. Mechanical C/T decoupling allows both machines to be designed so that they operate close to the maximum efficiency point for the maximum part of the expected real operating range. Specifically, the turbine has a lower rotation speed than that of the original group and therefore is characterized by slightly larger dimensions. The advantage is that in current supercharger units the surplus at high revs is discharged through the waste-gate valve without expanding into the turbine. In the configuration proposed here, however, all the energy of the gases is used by the turbine to generate electrical power, that can be used where required. Finally, with a view to optimizing all energy flows, the turbine exhaust is used for a bottoming ORC group, for electricity generation. The surplus of energy thus obtained can be used to power the auxiliaries, reducing both fuel consumption and lengthening the time of use of the electrical part, via battery pack. The actions taken were [5]:

a) Study a suitable configuration of a new turbocharging unit (hereinafter, "TC") for the specific thermal engine chosen here (ICE 900 cc turbo ≈ 66 kW), separating the compressor and the turbine and realizing the two devices with ad hoc components;
b) Simulate the behavior of the new TC group over the entire operating range of the engine, possibly making appropriate changes to the configuration originally chosen;
c) Design and implement a prototype configuration of the new C/T group (integrating the part relating to the motorization/electric generation and test it in advance);
d) Simulate and design the submitted ORC group.

2. Compressor and Turbine design

Once the engine of the vehicle (999 cc) of the city car being searched was established, the existing group on the vehicle was identified, the operational map of which is shown in figure 2.

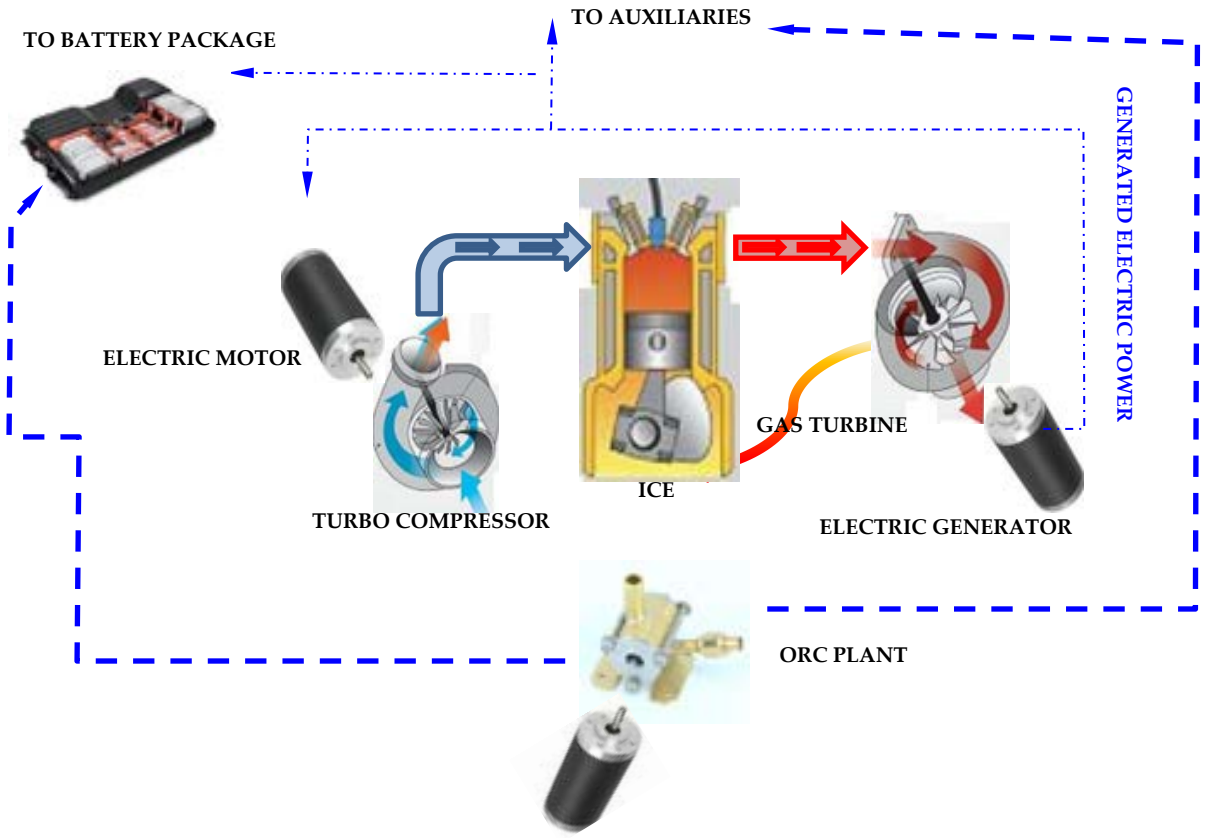

Figure 1. The electro-assisted configuration of the proposed turbocharging unit and the ORC group

Based on the n_s/d_s design theory [5-8], the geometric characteristics of the compressor shown in table 1 are obtained. Obviously, the dimensions and speeds are established here based on the values provided by the manufacturer of the installed compressor. The operating point was also fixed and derived since the maps of the business model [5,6]. The operating specifications are as follows:

$\beta = 1.5$
$\dot{m} = 0.02\text{-}0.06$ kg/s
n = 140000-210000 rpm

the range includes operation at the minimum and maximum speeds assumed by the ICE (2000-5000 rpm)

Table 1. Compressor data designed

m [kg/s]	0.02	**W_{EUL} [J/kg K]**	44652.74	ψ_2	1
β	1.4	**U_2 [m/s]**	211.3	ψ_1	0
c_p [J/kg K]	1004	**r_2 [m]**	0.014421	φ_1	0.3
T_1 [K]	293	**ΔT [K]**	22	φ_2	0.55
ω [rad/s]	14653	**ρ_1 [kg/m^3]**	1.20108	δ_p	0.98
ε	0.42	**Q_1 [m^3/s]**	0.016652	χ	0.65
p_1 [Pa]	101000	**r_{1e} [m]**	0.011005	R_ρ	0.5
T_2 [K]	337	**r_{1i} [m]**	0.007153	**$(1-\chi^2)$**	0.5775

From the analysis of the data it can be noticed the correspondence to the existing model, installed in the vehicle. The operation of the compressor at various speeds of the ICE engine was then evaluated and using the previous map it was possible to fill in the following table and the figure shows the trend of the power required by the compressor as the number of revolutions of the ICE changes.

Table 2. Compressor operation at different ICE speeds

rpm ICE	**$\dot{m}$ [kg/s]**	**rpm**	**β_c**	**T_{in} [K]**	**T_{out} [K]**	**P [W]**	**η**
2000	0.021	145000	1.42	298.4	344	920.71	0.68
3500	0.0408	180000	1.64	297.5	354	2474.39	0.8
5500	0.0619	210000	1.84	297.5	366.8	4444.96	0.82

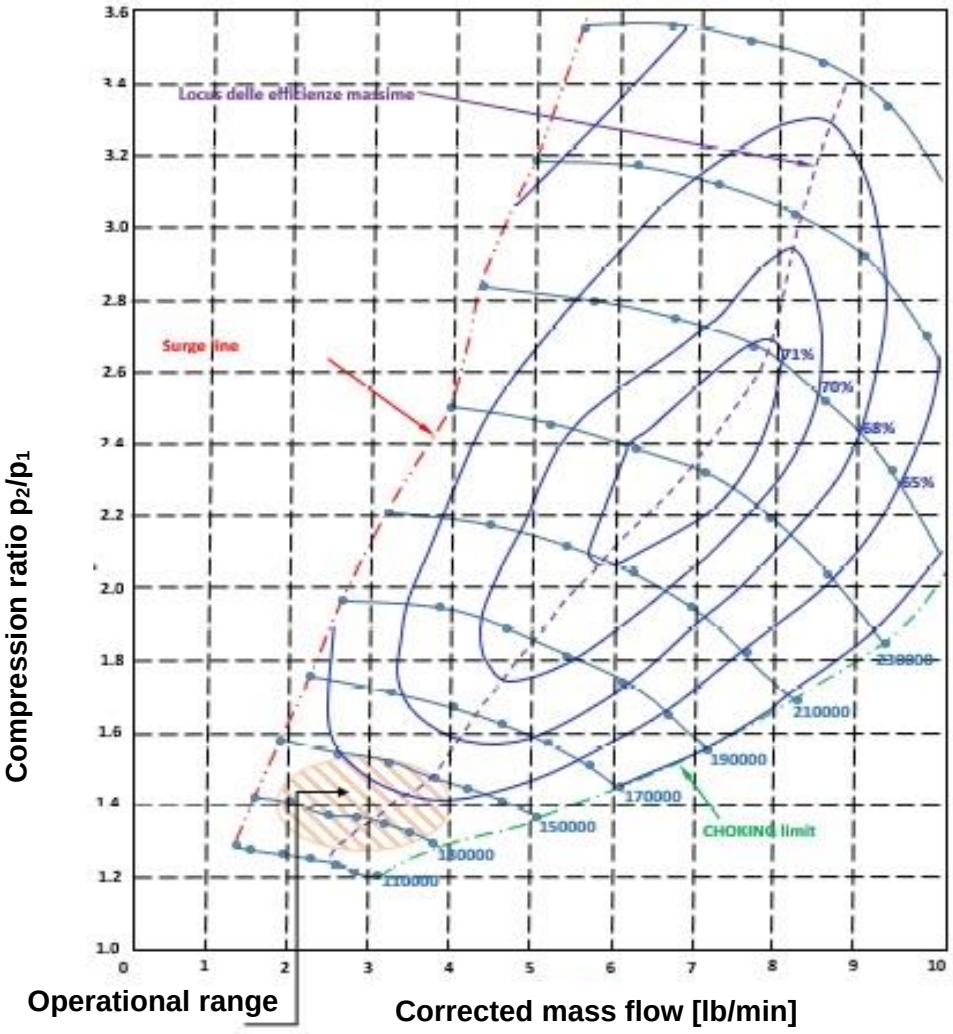

Figure 2. Compressor chart

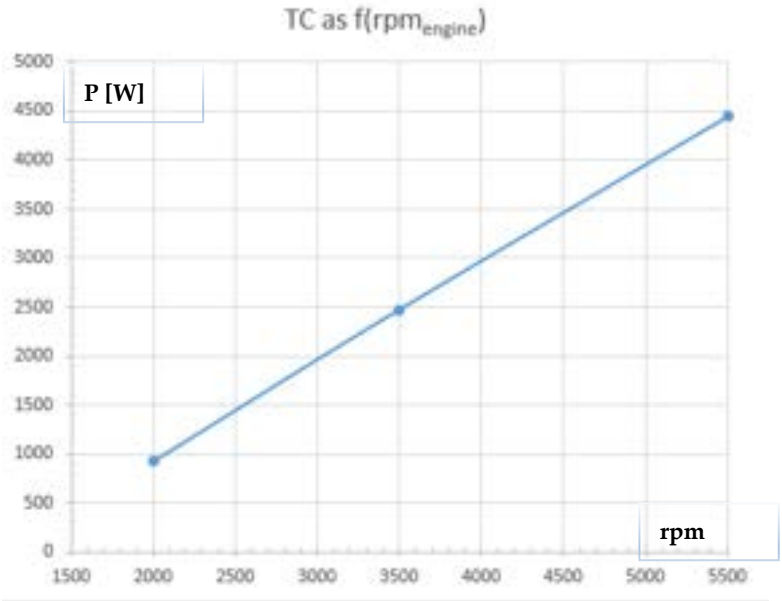

Figure 3. Compressor power required as a function of the ICE speed

Using the same procedure described above, the turbine was designed [9-15]. The main characteristics are shown in Table 3.

Table 3. Turbine data

m [kg/s]	0.021	**L_{EUL} [J/kg K]**	103194	ψ_2	0
β	1.4	**U_2 [m/s]**	321.2	ψ_1	1
c_p [J/kg K]	1397	**r_2 [m]**	0.051153	φ_1	0.3
T_1 [K]	980	**ΔT [K]**	34	φ_2	0.4
ω [rad/s]	6280	**ρ_2 [kg/m^3]**	0.387992	δ_p	0.98
ε	0.23	**Q_2 [m^3/s]**	0.05412	χ	0.65
p_2 [Pa]	101000	**r_{1e} [m]**	0.011159	R_ρ	0.5
T_2 [K]	907	**r_{1i} [m]**	0.007253	**$(1-\chi^2)$**	0.5775

From the analysis of the data, the correspondence to a turbine model available on the market is evident, whose operational map is represented in figure 4. The operation of the turbine at various ICE engine speeds was then evaluated using the map, so the turbine trend generation is reported in figure 5 and, as above, it is possible to fill the following table, in function of ICE speed.

Table 4. Turbine operation at different ICE speeds

rpm ICE	**$\dot{m}$ [kg/s]**	**rpm**	**β_c**	**T_{in} [K]**	**T_{out} [K]**	**P [W]**	**η**
2000	0.024	82170	1.2	954	922	780	0.87
3500	0.04	134483	1.6	1005	930	3510	0.86
5500	0.07	164002	2.00	1045	932	9500	0.81

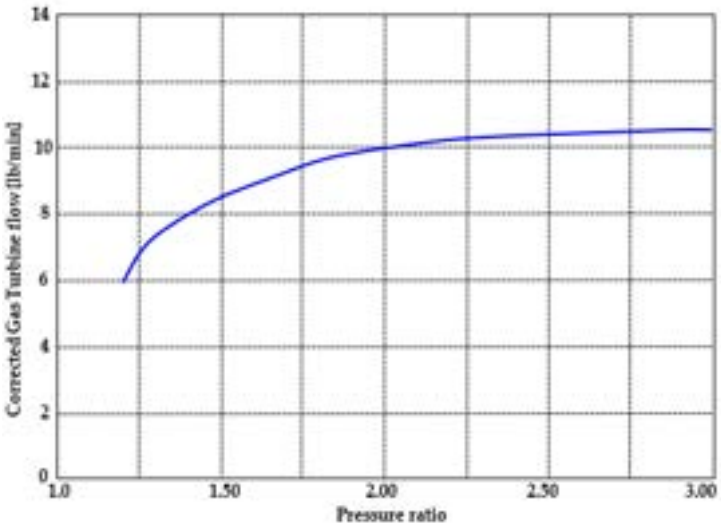

Figure 4. Turbine operational chart

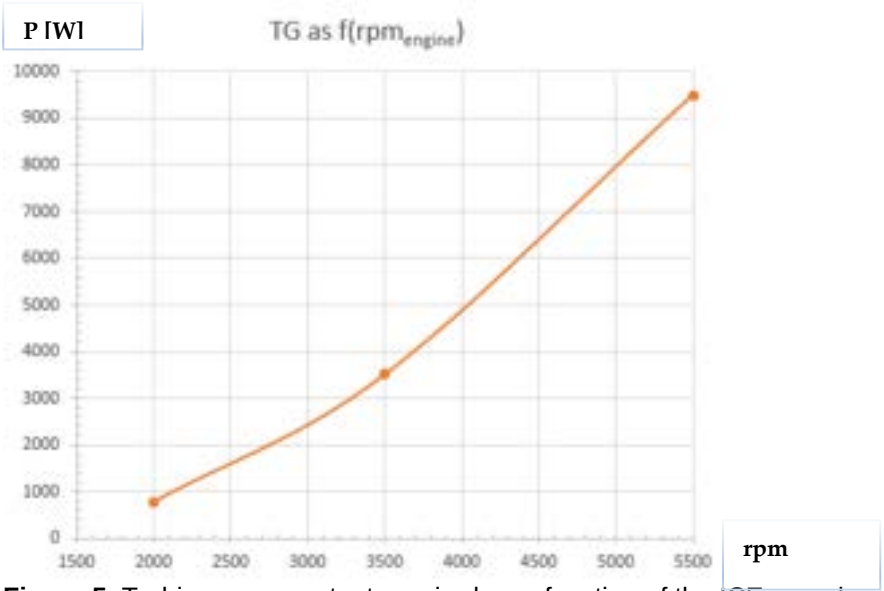

Figure 5. Turbine power output required as a function of the ICE speed

3. Energy Recovery and Vehicle Energy Balance

Thanks to the proposed design changes, the new electrically assisted turbocharger offers extra power at all engine speeds, except for about 2500 rpm and the power curve are shown in figure 6. It can be noted that the reported values include mechanical and electrical efficiency. For any type of mission (ETC, EUDC, WVU and NDC [17-21]), the engine energy balance is calculated by calculating the instantaneous power demand to the wheels, adding transmission losses, adding the compressor power and subtracting it from the turbine power and considering the battery charging efficiency. The effect of KERS has not been included in the simulations at this time. For almost the entire mission, the turbocharger unit can deliver extra net power. This power will be used mainly to recharge the battery pack and power the auxiliaries. When the power is negative (almost always on restart and during braking operations) the compressor will draw the required power from the on-board battery package. Since the vehicle is conceived as a *mild hybrid*, this battery pack is obviously much smaller than in a common HEV [22-29]. In longer missions, the instantaneous surplus generated by the turbocharger, minus the contributions sent to the auxiliaries, can lead to a condition in which the battery pack has a SOC close to 100% and cannot accept further charges. In these circumstances, the extra power could be used or sent to an auxiliary electric motor for additional propulsion.

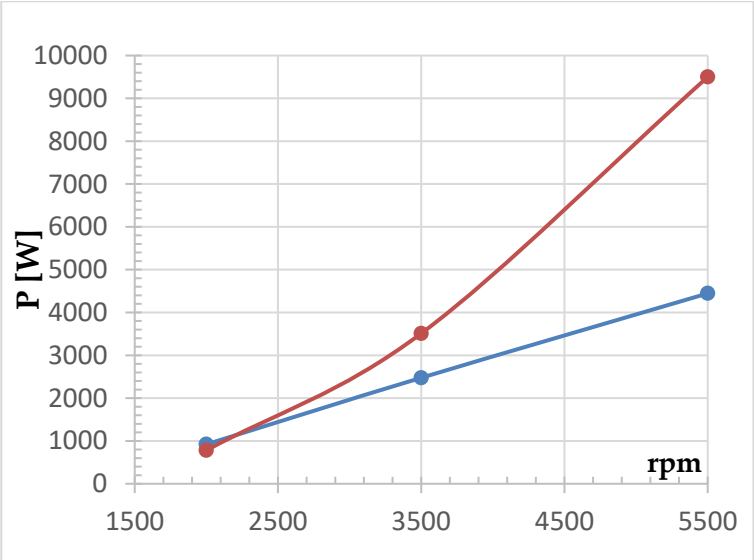

Figure 6. Power of the Turbine (orange curve) and the Compressor (blue) as a function of ICE rpm

The proposed solution, namely to physically decouple the compressor and turbine, using an electric motor for the first and producing electricity from the second via electric generator, showed that the total energy recovered on the simulated missions amounts to 1.01 kWh (compared to the 18 kWh of total energy required by the vehicle), which means that a net saving of about 5.6% can be achieved by the installation of this new turbocharger unit (figure 7).

4. The Bottoming ORC cycle

A further optimization of the considered system is to insert a bottoming ORC cycle. This possibility is thermodynamically feasible because the outlet temperature of the exhaust gases from the turbine, which must be remembered that it works without a wastegate valve, is about 800 K. The fluid used is an organic fluid R245fa. In the worst case, the exhaust gas flow rate is 0.024 kg/s. This temperature is high for a typical ORC application, especially for the required low power; this means that the energy content is too high and probably the use of Rankine Cycle instead an ORC would be more efficient, nevertheless for a compact application an organic fluid is more convenient, because the dimensions of the heat exchangers are smaller. Using commercial software, the thermodynamic simulation of the ORC cycle was performed. Among the various parameters to be set, the value of the maximum power that can be delivered, of about 2 kW, was chosen. Since the power is not high, it is not convenient to design a sophisticated cycle with preheaters or re-heaters commonly used in large-size plant. Thus, the cycle is very simple and only few components are required (Fig. 8) [30-35]:

1. Air Heat Recovery: it is a heat exchanger where the organic fluid warms up and changes its phase from liquid to vapor. This transformation is considered isobaric and, in the phase, changing is also isothermal.

2. Expander: it operates between the pressure imposed upstream and downstream by the heat recovery and the condenser.
3. Condenser: used to condensate the organic fluid with water. This transformation is considered isobaric and isothermal during the phase changing.
4. Pump: it increases the pressure of the organic fluid, now liquid, up to the pressure inside the Air Heat Recovery.
5. Flow Mixer: necessary to add the possible make up flow rate.

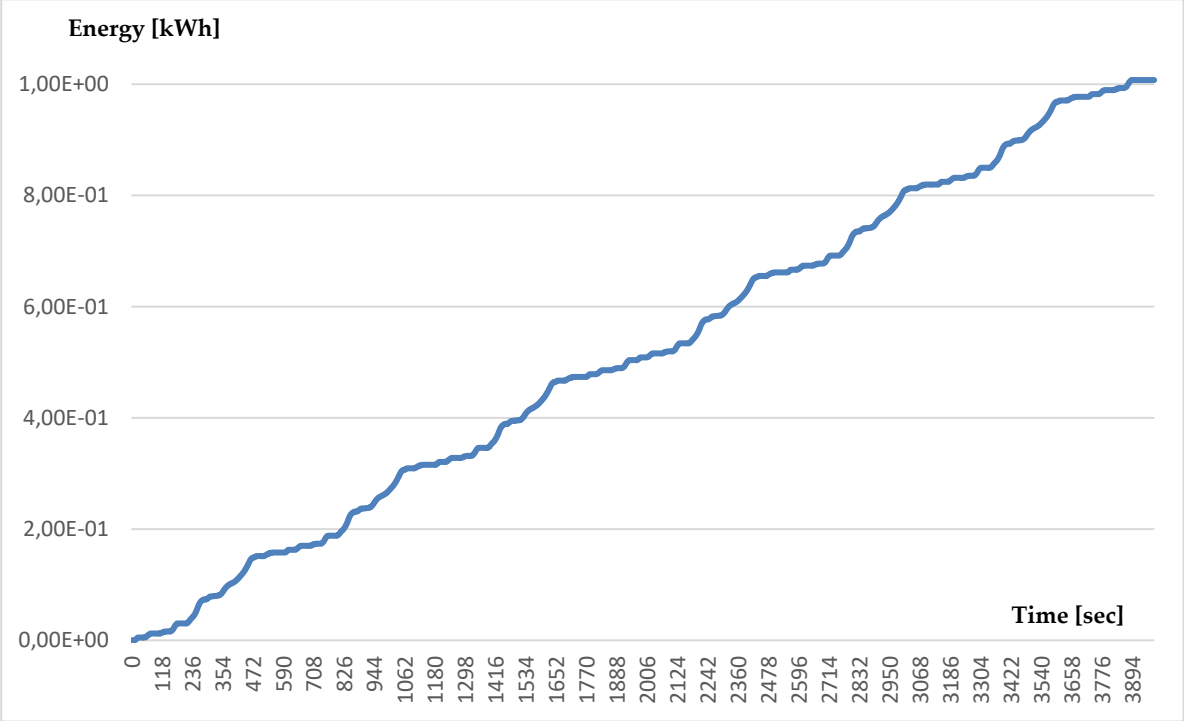

Figure 7. Net energy supplied by the GT group during the mission

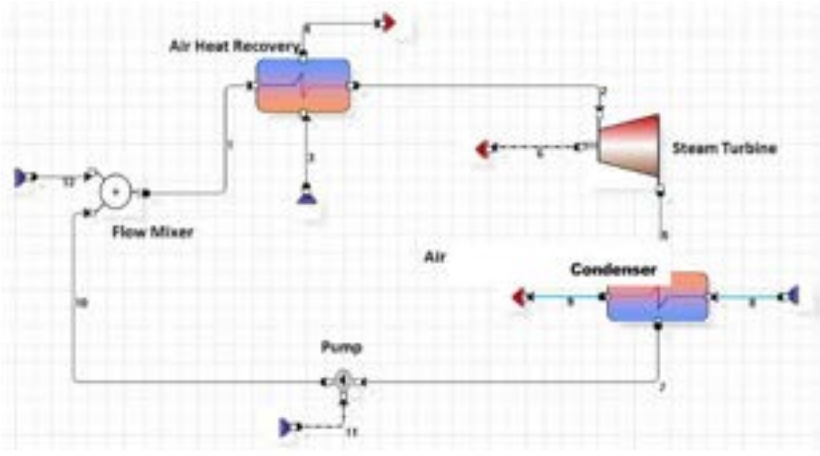

Figure 8. ORC cycle layout

From the statement of the problem, the input constrains are:

- The output power from the turbine (flow 6): 2 kW
- The available mass flow rate of the exhaust gas (flows 3): 0,024 m^3/s
- Temperature of the exhaust gas (flows 3): 723 K (conservative set)

The temperature of the inlet water is set to 293 K, hence, considering the finite dimensions of the condenser and its losses, the organic fluid should condense at 301 K, because it cannot reach lower temperature. Thanks to the thermodynamics properties, setting the condensation temperature means that the condensation pressure is fixed. From the thermodynamics tables for R245fa, this fluid condenses at 301 K with a pressure of 170 kPa. The expander efficiency has been underrated at 0.7 to be sure that the outlet power was at least 2 kW and the efficiency of the pump is fixed to 0,9. The results obtained by the process simulation indicates a mass flow rate for the organic fluid of 0.13 kg/s.
In summary, thermodynamic feasibility of whole system is confirmed. The current state of research focuses on the advisability of using a helical evaporator [36] for the ORC plant. For the study of the expander we will follow the procedure described in previous papers [31-37], trying to define the more efficient device. Only the condenser is under evaluation. First, the possibility of using the existing radiator of the car has been considered, but due to the limited overall available dimensions a compact capacitor [38-42] is being studied.

Table 5. R245fa operating specifications

Mass flow rate [kg/s]	0.13
Evaporator inlet temperature [K]	301
Evaporator outlet temperature [K]	383
Condenser inlet temperature [K]	370
Condenser outlet temperature [K]	301
Condenser inlet pressure [Pa]	170000
Water inlet temperature [K]	293
Water outlet temperature [K]	301
Pump required power [W]	100
Power output [W]	2000

4.1. Condenser design procedure

The chosen configuration (Figure 9) is the “circular tube fin”. It has several advantages such as reduced weight, better temperature control and easier transport. The type of tube is often chosen to reduce losses [28,29]. The inner diameter of the tube is 8 mm, the fin length is 3 mm, the tube thickness is 1 mm and the distance between two consecutive fins is 2 mm. The staggered arrangement is triangular, to avoid interference problems, and the distance between each arrangement center is 17 mm (the distance will be called p_t or p_l if it is from tube to tube or from tube to the outer shell). After the number of tubes is set, the width, thickness, and length are defined. At this point, we must distinguish what happens in the mono-phase or the two-phase condensation. The analysis will be conducted for both the working fluid (inside) and the water (outside).

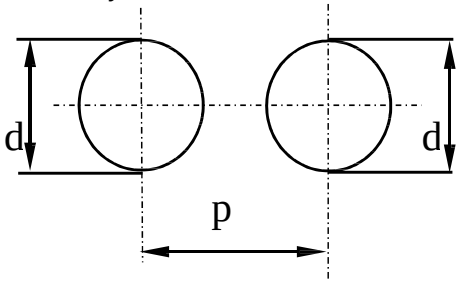

Figure 9. Reference scheme.

4.1.1 Monophasic Condensation

Working fluid side

The fluid characteristics (viscosity coefficient, thermal conductivity, etc.), were derived from the Coolprop library. First, the enthalpy difference is calculated to compute the thermal exchange. Then, the LMTD is derived with the HEM method. It is now necessary to compute the overall heat coefficient U to find the required exchange area. To compute the coefficient U we have to introduce the basic dimensionless numbers: Reynolds, Nusselt, Prandtl, and Froude. Once all quantities have been defined, the following procedure will be used.

1. The Prandtl number is calculated, and secondly, the calculation of the fluid velocity inside the pipes is evaluated, permitting the evaluation of the Reynolds number, which leads to the Nusselt numbers.

2. After computing the Nusselt numbers, it is then possible to estimate the "h_i" that is the heat transfer coefficient.
3. Finally, it is necessary to introduce the areas. When the numbers of tubes are known, where N_s is the number of pipes where the mass flow condensate, N_r is the numbers of transits of the same bundle of tubes, and the total number N_t, the geometrical properties can be calculated. The inner area of the pipes is:

$$A_i = \pi d_i \, L_1 \, N_t \quad (1)$$

and the minimum free flow area is:

$$A_{0,i} = \frac{1}{4}\pi \, d_i \, N_s \quad (2)$$

Cooling fluid side

As previously mentioned, the characteristics of the fluids are derived from the Cool- prop library. The main areas (external pipes side) are the A_p, the primary area, the fin area A_f and the heat transfer surface area A_0. The primary area is the difference between the pipe surface area and the area blocked by the fins. The A_0 is the total heat transfer area, computed by the sum of the primary area and the fin area. Another important parameter to determine is the minimum areas among the pipelines, where the water flows. If a triangular configuration is chosen [29], it is possible to consider that surface, as a flat surface.

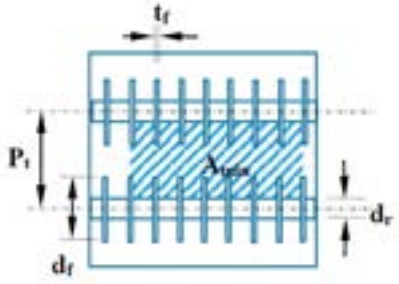

Figure 10. Minimum area description of the condenser.

4.2. Biphasic Condensation

As the condensation process proceeds along the pipes, the working fluid velocity decreases. At first, the condensation will occur on the wall of the pipes, then layer by layer, the liquid phase will increase. When the fluid is condensing, its thermodynamic characteristics change. The same procedure for the mono-phase has been adopted, introducing some necessary changes [40-44]. The evolution of the working fluid, from quality "0" to quality "1", has been divided into four-parts.

1. Part one, when the quality x is within 0 ÷ 0.75.
2. Part two, when x = 0.75 ÷ 0.5.
3. Part three, when x = 0.5 ÷ 0.25.
4. Part four, when x = 0.25 ÷ 0.

Similarly, for the cooling fluid side, there will be four corresponding stages. The four stages of the cooling water have been computed, if every property is changing linearly. From the working fluid side, the Martinelli parameter is introduced to compute the Nusselt number. The formulae used for the R245fa is:

$$Nu = 0.023 Re^{0.8} \, Pr^{0.3} \, g(Xtt) \quad (3)$$

4.2 Design results

The system geometry has been defined respecting the required constraints. A square configuration of the condenser has been chosen. The previous Figure 10 represents the simulated condenser. Streams numbers 1 and 2 are the inlet and outlet of the working fluid, and streams 4 and 5 are the inlet and outlet of the cooling fluid. Stream 3 is the refill of the fluid; in this case, it is not considered, but it is important to mention the fact that this opportunity exists. Table 6 reports the operating specifications of the main streams. After numerous iterations, the optimal solution has been found. The considered configuration is a compromise between a reasonable pressure drop and the smallest area. All data and a representation of the condenser are, respectively, reported in Table 7 and Figure 11

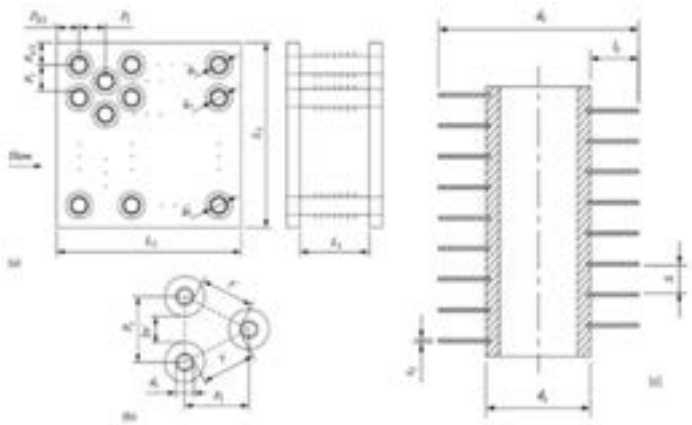

Figure 11. The condenser's chosen configuration. (a) actual disposition in the condenser assembling, (b) triangular configuration characteristics, (c) finned pipe representation.

t_f **(m)**	0.0003
N_r	16
N_S	14
N_{tot}	16 × 14 = 224

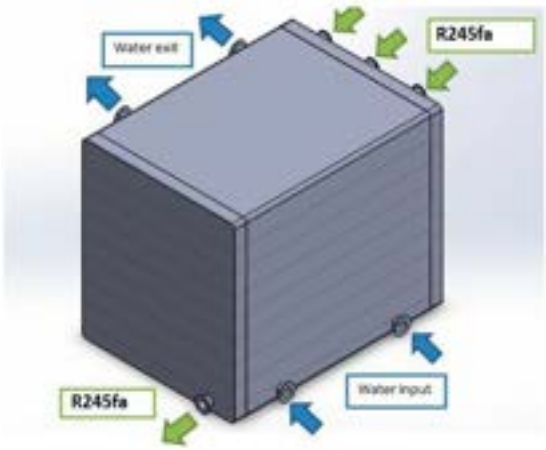

Figure 12. Condenser 3D assembled view.

Finally, the procedure adopted for the design is satisfactory. In fact, given that one of the constraints is the limited space inside the vehicle (the design philosophy is, remember, not to modify the vehicle and to use, when this is possible, all the existing devices and components), the exchanger obtained is small and can be easily inserted inside the vehicle, as will be described in the following paragraph.

5. The On-Board configuration of ORC cycle

An empirical method has been used to demonstrate that the proposed ORC system can be mounted on a vehicle. In the considered commercial vehicle, respecting the available spaces and volumes, the tank has been replaced and modified. For the positioning in the vehicle, since the HRSG has not been measured (at present), it has been assumed to be the same size as the condenser. It is known that the HRSG device is usually smaller than the condenser. Figures 13 represent the possible plant configuration in a commercial vehicle. It is important to remember that it is necessary to realize an auxiliary circuit forthe water cooling.

Figure 13. Proposed on-board ORC assembled plant configuration view.

Future Developments and Conclusions

The next steps in the realization of the vehicle and therefore for the completion of the project, the electrical part is now testing. The compressor side tests have almost been completed and have given satisfactory results and in line with what was assumed and chosen. On the turbine side, the test bench has been assembled, which involves the use of a rechargeable battery of about 17 kWh, and once the electrical connections have been completed, will be tested.

At the same time, the expander and evaporator for the ORC group will be designed, always trying to respect the overall constraints imposed by the chosen vehicle. As far as the expander is concerned, we will opt for a

compact solution and consequently the choice could fall on a dynamic expander or most likely on a rotary volumetric, screw type. For the evaporator, the opportunity to create a helical heat exchanger coaxial to the turbine exhaust pipe is being studied, to reduce the size as much as possible.
In conclusion, a very important and “innovative” aspect was the possibility of creating, as part of the electrification process of the power train for the mild hybrid, a “direct coupling” between the electric motor and compressor, and to optimize all waste energy fluxes of the vehicle. All these are thanks to the design of a new electric motor, operating at high rotational speeds, which are characteristics of turbomachinery. The redesigned turbine (now separated from the compressor) has confirmed to be less problematic than the compressor. The turbine can now use all the enthalpy drop of the ICE exhaust gases and operate at lower speeds. As a result, the connected electrical equipment is less complicated, compared to that designed and built for the compressor. The tests - cold site - validate the design choices and the further turbine ones - in case of positive results - confirm and "freeze" the electrical configuration. Then, thanks to the characteristic configuration of the turbine (no wastegate valve), the total exhaust gases can be used for generate additional energy by ORC plant. The bottoming ORC systems has to be completed, from a design point of view. Actually, the condenser realization is "on going". Once realized, a "substitute" circuit will be realized to simulate the operational conditions. The simultaneously design of expander and evaporator will conclude the design process. Last step will be to implement all devices and test the vehicle on the road.

Nomenclature

C	Compressor
EM	Electric Motor
EG	Electric Generator
ICE	Internal Combustion Engine
m	Mass flow rate [kg/s]
p	Pressure [bar]
P	Power [W], Pump, Pressure gauge
Q	Volumetric flow rate [m^3/s]
r	Radius [m], Resistance [Ω]
rpm	Revolutions per minute
R_ρ	Reaction degree
T	Temperature [K], Turbine
V	Velocity
Greek Symbol	
β	Compression ratio
χ	Hub to shroud ratio
δ	Blockage factor
ϵ	Diameter ratio
η	Efficiency
ϵ	Flow coefficient
ω	Rotational speed Density
p	[kg/m^3]
ψ	Load coefficient

Abstract:

In electric vehicles, the Heating, Ventilation and Air-Conditioning (HVAC) function is often performed by a heat pump. Heating and cooling the cabin air drains energy directly from the vehicle's battery. In addition, these vehicles may operate in environments with high level of air pollution. In the cabin, passengers are confined to a small space where particles and harmful gases can accumulate. In addition, the ventilation system must also handle the air which does not enter the cabin through blower operation. This "infiltration" is a function of the vehicle speed and allows pollution to enter the cabin without being filtered or thermally treated.
The objective of the study is to optimize the competing goals of the HVAC system: achieving the best air quality while maintaining good thermal comfort, at minimum energy costs.
A system simulation tool is calibrated to represent the heating and cooling of an electric car. With this model, the influence of key factors is evaluated. Depending on ambient conditions and other parameters (number of occupants, vehicle speed, etc.), the blower flow rate and recirculation ratio can be adjusted to reach the objectives. The management of the proportion of fresh and recirculated air allows to regulate the humidity and carbon dioxide levels. Optimum controls are proposed as good trade-offs to reduce the power consumption, while maintaining a safe and comfortable environment for occupants. Compared to the full fresh air mode, the driving range gains are estimated in cold (−15°C) and hot (30°C) scenarios at 9 and 26 km respectively.

Keywords:

Ventilation; Filtration; Heat pump; HVAC; Driving range.

1. Introduction

Heating and cooling of the vehicle cabin is an important feature, and its design can vary a lot based on the car model. It depends on cabin size, vehicle-mounted actuators, materials, and occupants (in terms of both perception and changes in thermal environment). In full electric vehicles, the motor efficiency leads to low heat losses. Contrary to thermal vehicles, this waste heat is not enough to heat the cabin. Previous research [1] shows that the HVAC system of electric vehicles can reduce the driving range by 35% to 50%, depending on weather conditions. There are other options to reduce the HVAC system's energy usage, for example by using reversible heat pumps. A key advantage of the heat pump is its ability to provide more heat output than its electrical consumption. This is made possible by its ability to absorb energy from the environment, even in cold or hot conditions. This solution is already implemented in Tesla vehicles, Renault ZOE, or also as an option in the Volkswagen ID series.

The heat pump is integrated to the HVAC module, with other main components as the blower and the recirculation flap. Figure 1 illustrates typical airflow within a passenger car. The air inlet is often found near the base of the windshield, where the blower forces the outside air into the cabin. The outlet is generally a decompression flap located in the car body near the rear trunk. As an alternative or complement to the fresh air intake, the vehicle also has a recirculation mode. Furthermore, there is the infiltration phenomena, which occurs due to the air entering the cabin through small openings in the (not airtight) car body and this is caused by the air resistance of the vehicle. This infiltrated air is not thermally treated by the HVAC system.

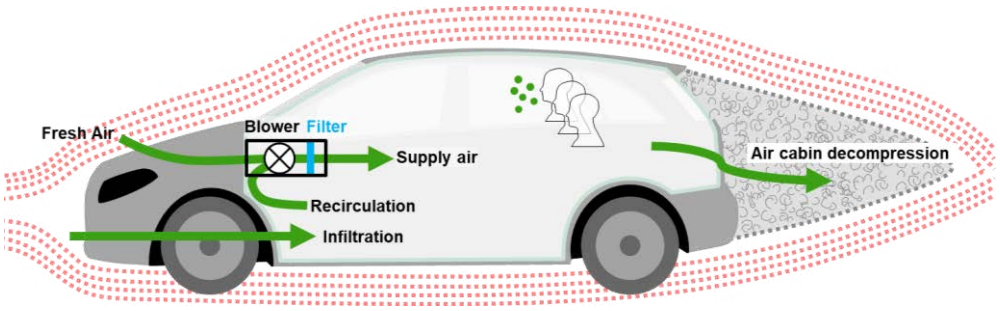

Figure 1. Overview of airflows inside a car cabin.

The global objective of the HVAC system is to provide a comfortable environment for the driver and the passengers. Thermal comfort can be characterized as a feeling of harmony with one's surroundings. Comfort in a closed environment is well documented, with many articles focused on the building sector. A passenger car cabin is significantly different because it has a small volume (generally less than 5 m^3) and can hold several passengers. In addition, driving a car requires a certain degree of attention. It is preferable to feel comfortable in order to prevent weariness, and thus a decline in driving ability. Fojtlín *et al* [2] links driver fatigue to different temperature settings. Heat stress has been found to negatively affect driver skill.

According to a standard [3], the human comfort depends on six parameters: human metabolism, clothing insulation, relative humidity, temperature, radiation, and air flow velocity. Thermal comfort, however, is a complicated idea that is challenging to guarantee and is not restricted to the aforementioned factors. This is because it's a mix of subjective, psychological and socio-cultural factors [4].

Assuming a comfortable temperature, the level of relative humidity for people should be between 30% and 70% (preferably in the range 40-60%) [5,6]. A low humidity level can irritate the eyes and throat and dry the mucous membranes and nasal passages. A high relative humidity can reduce the evaporative cooling of the body through sweating, causing a suffocating sensation. It also promotes the growth of fungi and leads to other moisture related problems. Experimental research [7] measures the comfort and fatigue of passengers in a cabin under different environmental settings and shows that an excess of water (humidity above 60%) increases the rate of fatigue related complaints, particularly on the eye dryness sensation and visual fatigue.

Moreover, air renewal, an essential component of comfort, has not yet been considered. The interior air must be changed frequently, to enable the removal of odours, contaminants, water vapour, and CO_2 (Carbon Dioxide) emitted by the materials and occupants. Monitoring the CO_2 concentration is one way to assess how well a ventilated space is perceived by humans. Carbon dioxide serves as a reliable indicator for biological effluents (i.e., odours) that are known to be unfavourable for comfort. Then, besides the comfort, the HVAC system plays an important role in keeping the driver at their full capacity. It is therefore important that temperature, humidity and CO_2 levels are regulated together in the vehicle's cabin.

The literature review reveals different solutions to either reduce the energy consumption, enhance the comfort, or improve the air quality in a vehicle cabin: air renewal [8], efficient filters [9], air purifier [10], catalytic conversion [11]. All the filtration and air treatment solutions mainly address the air quality issue, not the energy management nor the thermal comfort since CO_2 and humidity are not filtered. Some solutions are attractive for their field of application, but their use in a car cabin is often limited by a drawback on another aspect. For example, the use of recirculation mode to reduce the energy consumption should be used with caution because of the risk of high carbon dioxide levels. There are several good concepts, but with a single objective (limited scope). The literature review does not reveal any complete solution for air quality, energy savings and thermal comfort.

2. System modelling with holistic approach

To evaluate the HVAC system of an electric vehicle, a simulation tool is developed. It is a multi-physics model based on numerous individual elements: blower, filter, cabin, etc. All individual elements are connected to represent the complete system: the holistic approach focuses on a macro scale level. The model contains all necessary elements of the heating, ventilation and air-conditioning (HVAC) of a vehicle cabin, exposed to various external interactions. This model will be used to evaluate different strategies for the HVAC system.

2.1. 1D simulation tool

For the present work, a 1D simulation level is considered. It appears to be the most suitable tool to achieve a good trade-off between computational time and accuracy of results at a system level. Neither the time required to build such a model nor the chosen system approach is compatible with a 3D simulation tool. In addition, a bloc modelling with transfer function requires many calibration data without offering sufficient robustness in the results. With a 1D model, the geometry of components is simplified and only one spatial dimension is considered (commonly in the flow direction). It allows completing transient or stationary scenarios with a fast computational time.

GT-Suite, a software developed by Gamma Technologies is selected for this task. It is a well-known software for system modelling at a 0D/1D level in the automotive domain. At each time step, the solver integrates the conservation equations (mass, energy and momentum) in space and time.

The complete HVAC system is depicted in the model as shown in Figure 2. It can be divided in two main parts: the heat pump (left side of the figure) and the cabin air circuit (right).

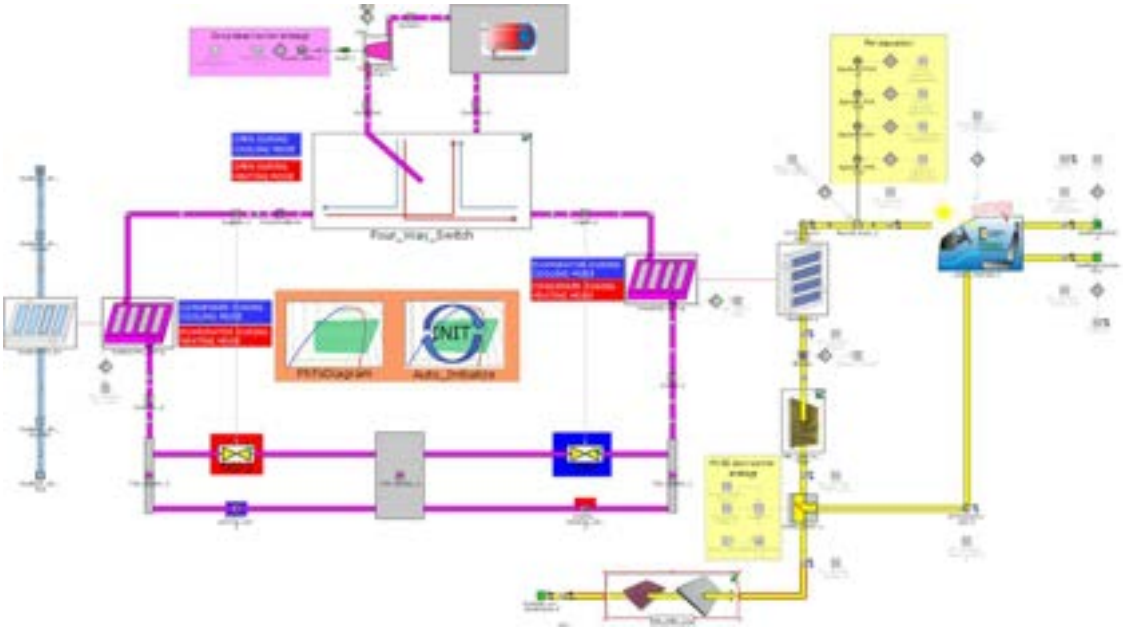

Figure 2. Overview of the complete simulation model in GT-Suite.

2.1.1. Heat pump model

This model is based on a Renault ZOE architecture, which remains a common structural design for electric vehicles. The elements of the heat pump circuit are a compressor, an accumulator, two heat exchangers, a four-way switch, two expansion valves and some piping elements. The refrigerant working fluid is R134a.

The cabin temperature is regulated by adjusting the compressor speed. This compressor is modelled from a GT-Suite template with a map-based approach relying on measured performance data. The refrigerant fluid is guided by the four-way switch from the compressor to the condenser.

In heating mode, the condenser is on the cabin side and the evaporator is on the outside air side. It is the opposite in cooling mode. The two heat exchangers are interacting with either the outside air circuit or the cabin air circuit. The outside air circuit is connected to ambient air conditions (pressure, temperature, humidity), with flow rate depending on vehicle speed (additional wind speed is assumed to be 0). For both heat exchangers, predictive correlations are used to compute Reynolds and Nusselt numbers during a simulation. The fluid phase changes are resolved in the exchangers with computation of the resulting variations in heat transfer coefficients.

The refrigerant fluid exits the condenser to enter the thermal expansion valve. It manages the flow rate of refrigerant released in the evaporator, thus controlling the superheat. Finally, the heat pump circuit is completed by a 1L accumulator upstream the compressor.

2.1.2. Air circuit model with mono-zone cabin

Like the heat pump circuit, the cabin air circuit is built with several components. The inlet of air from the outside is upstream the recirculation flap. This flap manages the amount of air coming either from the outside environment or back from the cabin. The next element after the recirculation flap is the blower and it drives the circulation of the airflow. Before entering the cabin module, the air is either heated or cooled in the heat exchanger connected to the heat pump circuit. From the cabin, the outlet is either the recirculation path or the outside environment.

Finally, an inlet is connected to the cabin element to represent the inlet of air directly from the outside into the cabin vehicle. This is called infiltration. This air, neither filtered nor set at proper temperature, can have great influence on the thermal balance (and air quality) in the cabin. The modelling and calibration of the infiltration flow rate is detailed in a previous study [12].

The cabin is a mono-zone volume based on the generic GT-Suite module to compute the thermal balance inside a medium size vehicle cabin. The mono-zone model implies that there is complete homogeneity inside the cabin. This approach against multiple volumes or CFD is motivated by fast computational time and less number of inputs required.

2.1.3. Humidity calculations and windshield condensation

Modifications are made in the model to consider further humidity calculations. It is a comfort parameter for occupants and a safety factor considering the condensation on front windshield and side windows. The objective is to have an accurate prediction of the humidity level and condensation risk in the cabin.

With that purpose, the standard GT-Suite windshield model is improved to include a variable heat transfer coefficient. A moving vehicle implies an air movement on the external surface of the front windshield, thus suggesting heat transfer by convection mode. The convective heat transfer coefficient can be calculated using the Nusselt number equation, as in Eq. (1), where L_c is the characteristic length of the windshield.

$$Nu = \frac{h.L_c}{\lambda}, \tag{1}$$

To simplify the model, no wind is considered. Hence, air velocity on windshield is equal to the vehicle speed. This improved convection heat transfer model allows a more accurate prediction of the windshield surface temperature, which plays an important part in the condensation risk assessment.

Assuming that all the water in the air above saturation condenses from gas into liquid, the condensation mass (mass of water per mass of dry air) can be computed with the mixing ratio as in Eq. (2).

$$\text{if } X_w > X_{ws} \text{ then } Cm\left(g_{water}/kg_{dry\ air}\right) = X_w - X_{ws}, \text{ with: } X_w\left(g_{water}/kg_{dry\ air}\right) = \frac{M(H_2O)}{M(air)}\frac{x_w}{1-x_w}$$

$$\text{and } X_{ws}\left(g_{water}/kg_{dry\ air}\right) = \frac{M(H_2O)}{M(air)}\frac{P_{ws}}{P_{tot}-P_{ws}} \tag{2}$$

Besides the calculation of the condensation mass, a complementary factor is created in order to have a second option to evaluate the creation of condensate. More precisely, it is made to estimate the risk of fog formation on the glass surfaces inside the vehicle's cabin. This factor, so called $Fog\ risk$, is based on the calculation of relative humidity on the glass surfaces, as in Eq. (3).

$$Fog\ risk = \frac{P_w}{P_{ws}}, \tag{3}$$

The partial pressure of water vapour (P_w) is obtained with Dalton's law ($P_w = P_{tot}.x_w$) where the mole fraction of water is taken from the mono-zone cabin air. The partial pressure of water vapour at saturation (P_{ws}) is calculated from the saturation tables, in which the temperature is taken at the wall of the involved surface (e.g., windshield temperature at cabin side). According to the definition of the factor:

- There should be condensation if $Fog\ risk$ is above 100%
- There should not be condensation if $Fog\ risk$ is below 100%

The fog risk factor gives additional information to the computation of condensation mass. On one hand if the condensation mass is zero, the fog risk factor gives an assessment to know the margin before condensation: the situation is more perilous with a 99% fog risk rather than a 1% risk. On the other hand, if the condensation mass is strictly positive, the fog risk factor gives knowledge about the closeness to regain a clean windshield: condensation with a 101% fog risk is easier to remove than condensation with a 150% fog risk.

The main limitation in the calculation of the condensation mass and the fog risk factor is the mono-zone approach. Indeed, the whole air volume inside the cabin is seen as one entity. There is no possibility to separate or orient the air flow driven by the blower. For instance, Figure 3 displays a photo of the windshield during an experiment made in the scope of this project. There is condensation on a major part of the windshield, besides a small area highlighted in the picture (zone A). This is explained by the air blown in this direction from the vent grid located at the bottom of the windshield. Locally, the humidity conditions do not trigger condensation while compared to the rest of the windshield. Such a phenomenon cannot be evaluated with the simulation model as is. So, the condensation mass and the fog risk factor only give a global evaluation.

Figure 3. Evidence of condensation on the windshield during an experiment.

2.1.4. Thermal model

There is a thermal interaction between the air flowing through the cabin, the internal elements and the outside environment factors (sun, wind). The modelling of the cabin involves many processes, showcased in Figure 4.

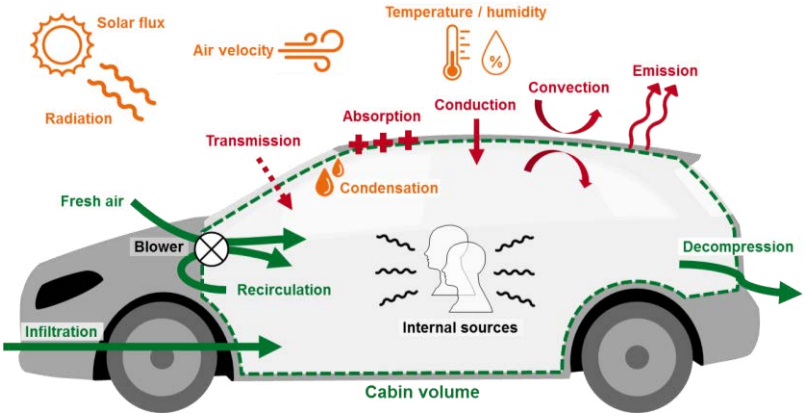

Figure 4. Model of the thermal behaviour of a car cabin.

The mono-zone modelling implies that the air temperature is homogeneous inside the whole cabin. The cabin characteristics are imported in the simulation code. A standard three-layer material is selected for doors, floor and roof: polyamide, polyurethane and stainless steel. Material properties like mass and geometry (thickness and surface area) are adjusted to match the characteristics of a Renault ZOE.

A solar view factor describes the portion of solar flux reaching each part of the cabin. The sun is considered to be at full height (90°C) for all simulations. Hence, the solar flux mostly affects the roof and the windshield while the side and rear parts of the car experience a lower impact. An absorptivity coefficient (0.4) and an emissivity coefficient (0.96) are introduced to represent the solar effect on the outside of roof and doors. Another set of coefficients is used for the glass windows (0.15 for absorptivity and 0.9 for emissivity), with the addition of a transmission coefficient (0.7).

The modelling of the cabin floor thermal interaction is obtained with convection at both sides: internal and external. Heat rate through the three-layer floor material is calculated with conduction. Similar modelling is also possible for the roof and side doors of the cabin, with the addition of the solar flux on the external side. This modelling is also the same for all glass surfaces (windows and windshield) but with a single layer instead of a three-layer material. The thermal effect on the internal lumped material of the cabin is governed by the solar flux coming through the glass surfaces. Finally, two heat sources are included in the cabin:

- 100W that represents the heat coming from the electrical motor and the dashboard auxiliaries
- 75W per person, which is the heat input from occupants [13,14]

2.1.5. Passenger model

In the model, the number of occupants is multiplied by the amount of heat, CO_2 and humidity emitted by an average adult. A CO_2 injector placed in the cabin volume simulates the exhalation flow rate from the occupants: CO_2 mass flow rate of 18.75 L/h. This value is an average for one human adult in normal seated activity level (e.g. office work, paper reading, driving…) [15]. The variability of CO_2 exhalation flow rate can be widely discussed as it is influenced by numerous factors, like age, metabolic rate, stress level, activity level, etc.

Breathing and sweating of the occupants is also a source of humidity. This is highly dependent on the ambient conditions (temperature and humidity) and human factors (clothing, activity level, metabolism, age, weight, etc.). Average values and models are found in the literature [16–18]. The main factors of influence that are relevant are the temperature and humidity. In the model, different cases are implemented depending on outside conditions: 30 g/h in cold condition (below 10°C), 50 to 65 g/h in standard condition (around 20°C and 50% of relative humidity) and 100 g/h in hot and humid condition (above 30°C and 65% of humidity). These values are fixed for the duration of a simulation, i.e., there is no dependence with cabin temperature. Lastly, the model considers that this H_2O source is emitted in pure vapour condition (and not liquid). It has a direct impact on the cabin humidity level, with consequences on the performance of the heat exchanger (e.g., condensation) connected to the heat pump circuit.

2.1.6. Ventilation strategies: opti-CO_2 and opti-H_2O

In the cabin air circuit, the ratio of fresh air against recirculated air is controlled by the recirculation flap. Control of the recirculation ratio is required to reduce the energy consumption, particularly in rough environments with extreme temperatures. It can be set at a predefined variable or constant value for a simulation scenario. For safety and health concerns, a full recirculation mode is not possible. Two additional modes are created in the

model: “opti-CO_2” and “opti-H_2O”. In both cases, the opening of the recirculation flap is controlled by a PID regulator. The idea is to find a trade-off between moderate energy consumption and safe air inside the cabin.

In the opti-CO_2 mode, the recirculation flap is regulated between its two extreme positions to achieve a target CO_2 concentration in the vehicle. As no regulation exists for vehicle in-cabin CO_2 level, a standard limit value between 1100 and 2000 ppm can be selected to keep passengers in a comfortable and safe space. According to an experimental study [19] this level is not associated to health risks, but is the baseline to first signs of cognitive dysfunctions (e.g. lack of concentration). The ASHRAE guideline [20] states that the comfort limit for air renewal in a closed space is strongly correlated to a CO_2 level below 1100 ppm. This limit can be discussed for a vehicle application, where the level and duration of exposure can be quite variable.

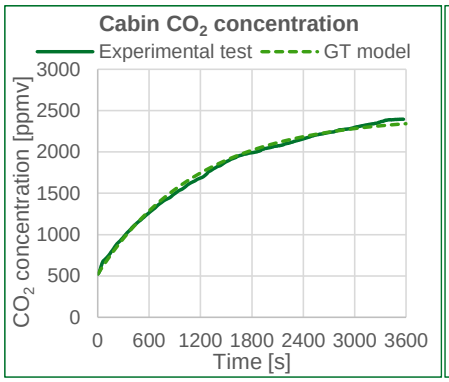
Similar to the opti-CO_2 mode, a control of the recirculation flap is implemented to limit the condensation issue. This opti-H_2O mode is based on the variable that monitors the risk of fogging on the front windshield. The target of the PID regulator is a fog risk of 95% (5% margin before condensation).

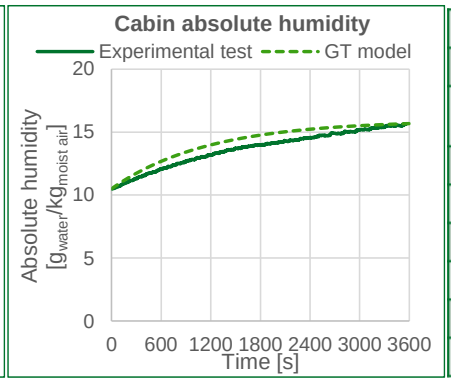
2.2. Calibration and validation with experimental data

If available, the input model data is filled to match the characteristics of a Renault ZOE (eco2 phase 1). It is a full electric car (88 ch), with five doors and a cabin volume of 2.5 m^3. In the scope of this project, different test campaigns (more than 20) are used to calibrate and validate the simulation model. Otherwise, the generic data provided by GT-Suite for similar sized-vehicle and components is used. This is as per the recommendation in the software manual and only considered if the input data is limited. Such data is mostly based on predictive correlations and literature models. Then, the calibration stage allows to adjust the parameters.

A small sample of the validation tests are described in this article, and a separate paper focuses on the infiltration topic [12]. The idea is to compare the experimental results with the simulation results. The test conditions are then reproduced in the simulation tool. Given the large number of experimental evidence, only a few examples are shown in this paper.

Figure 5 depicts the evolution of the CO_2 and humidity concentrations in the cabin over time. The test is done with a parked vehicle (0 km/h) for a duration of one hour. The blower flow rate and recirculation ratio are fixed respectively at 180 kg/h and 94%. This ventilation condition leads to a rise of the CO_2 and humidity concentrations in the cabin. Once again, the simulation tool gives similar results to the tests.





Vehicle speed	0 km/h
Cycle duration	3600s
Blower flow rate	position 4 out of 8 = 154 m^3/h (180 kg/h)
Recirculation ratio	94%
Amb. temperature	15°C
Ambient humidity	82%
Ambient CO2	445 ppmv
Occupants	1 (only the driver)
Water emission	50 g/h per person

Figure 5. Sample of the validation of the simulation tool with experimental results regarding cabin CO_2 concentration and absolute humidity.

These results are a part of larger experimental test campaigns, covering a diverse range of environmental conditions. It shows that the simulation tool can predict accurately the cabin state regarding temperature, CO_2 concentration and humidity level.

3. Results and discussion

3.1. Potential increase in driving range with the opti-CO_2 strategy

The traditional ventilation setting in a passenger car is the fresh air mode (0% recirculation). This configuration leads to a good amount of air renewal, but it is not optimised for the energy consumption of the HVAC system. In an electric vehicle, the heat pump energy required to heat or cool the cabin is drained directly from the battery, thus decreasing the driving range. Controlling the recirculation ratio is necessary to decrease the impact of the HVAC system, particularly in rough environments with extreme temperatures. For health and safety related concerns (CO_2 intoxication), a full recirculation mode is not possible. The idea of the opti-CO_2 mode is to find a trade-off between a moderate energy consumption and safe air inside the cabin.

Table 1 depicts the maximum recirculation ratio allowed to keep the cabin CO_2 concentration below the target. These values depend on the number of occupants (and their CO_2 emission), the blower flow rate, and the infiltration flow rate. If the CO_2 target is increased from 1100 to 2000 ppm, the recirculation ratio can be set to a higher value.

Table 1. Regulation of CO_2 concentration with a blower flow rate of 200 m3/h and assuming no infiltration.

	Stabilized volumetric recirculation ratio in opti-CO_2 mode	
Number of occupants	Target = 1100 ppm	Target = 2000 ppm
1	79%	90%
2	61%	83%
3	42%	75%
4	21%	65%
5	2%	57%

The power consumption for heating and cooling is calculated using the simulation tool. Three ambient scenarios are compared: summer, winter, and spring. The outside temperatures are 30°C, −15°C and 19°C, respectively with a solar flux of 750, 250 and 500 W/m^2. The heat pump targets a cabin temperature of 19°C in the case of winter and spring, and 25°C in the summer. The other simulation settings, along with the results regarding power consumption and driving range gain estimations are given in Figure 6. The range is roughly estimated using Eq. (4):

$$Range_{loss} = Range_{max} - \frac{Range_{max}}{1 + \frac{Spec_{range} * Power}{Speed}} \quad (4)$$

The maximum driving range is 300 km, with a specified range of 6.6 km/kWh and an average speed of 47 km/h as described in WLTC (Worldwide harmonized Light-duty vehicles Test Cycles). The “range gain” chart (Figure 6) is calculated by subtracting the $Range_{loss}$ of the given configuration to the common 0% recirculation case.

Eventually for the three scenarios, the best trade-off between energy consumption and safe air environment is achieved with the opti-CO_2 mode. Compared to the traditional “full fresh air” mode, the power gains of the heat pump in winter, spring and summer scenarios are respectively 14%, 19% and 38% (1100 ppm target). These gains are important because they can directly influence the driving range. In the 0% recirculation case, the range loss is estimated at 88, 26 and 85 km in the winter, spring and summer scenarios, respectively.

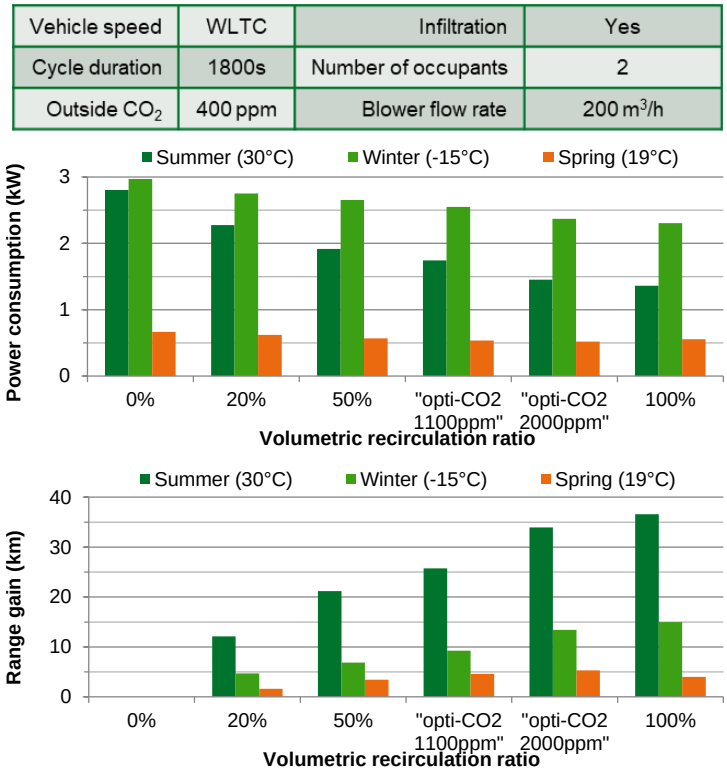


Figure 6. Power consumption (of compressor heat pump) needed for thermal comfort and impact on the driving range of an electrical vehicle.

With the opti-CO_2 mode at 1100 ppm, the driving range is increased by 9, 5 and 26 km compared to the full fresh air case. Increasing the opti-CO_2 target from 1100 to 2000 ppm gives an additional range gain in the three scenarios: 8, 4 and 1 kms. These benefits must be weighed against the potential health risks caused by slightly higher CO_2 exposure. The health aspect is not well documented, so it is difficult to give a precise health assessment in the range between 1100 to 2000 ppm. Besides, a different strategy could be applied to the HVAC system. In the simulation tool, the CO_2 target is continuously fixed over time. A new control strategy

could set the target at a higher value in steady state mode, but provide periods of fully fresh air. Nevertheless, the results presented in this section give an idea of the influence of the CO_2 target on increasing the driving range. The objective of the next subsection is to assess another risk inside the cabin: humidity accumulation.

3.2. Humidity level and evidence of fogging risk

The humidity level is evaluated with the simulation tool in simple scenarios. The objective is to establish the conditions under which condensation can occur on the glass surfaces inside the cabin. Different ambient temperatures are tested, from −10°C to +10°C, with a relative humidity of 85%. A moderate solar flux of 250 W/m^2 is also considered. The vehicle speed is set to 60 km/h for a duration of 10 minutes. A fixed speed is preferred rather than a realistic driving cycle to limit the variations due to infiltration. There are two occupants in the cabin. Each person emits water vapour at a 50 g/h rate. The blower flow rate is set to 200 m^3/h, which corresponds to a medium blower position in a Renault ZOE.

Different recirculation modes are compared, including the standard 0% and 100% fresh air modes. Depending on the vehicle speed, such ventilation settings can trigger infiltration. The infiltration flow rate is null in the fresh air mode, and at 20 m^3/h in recirculation mode. An additional recirculation mode is implemented in the simulation: opti-CO_2. The target of CO_2 concentration in the cabin is fixed at 2000 ppm. With two occupants, the recirculation mode is activated during 425s. This is the time required to increase the CO_2 concentration to 2000 ppm. Then, the fresh air ratio is fixed to 5%. The main simulation results of humidity and fogging with two occupants are given in Figure 7.

Vehicle speed	60 km/h	Infiltration	Yes	Ambient humidity	85%
Cycle duration	600s	Number of occupants	2	Solar flux	250 W/m^2
Blower flow rate	200 m^3/h	Water emission	50 g/h per person	Opti-CO_2 target	2000 ppm

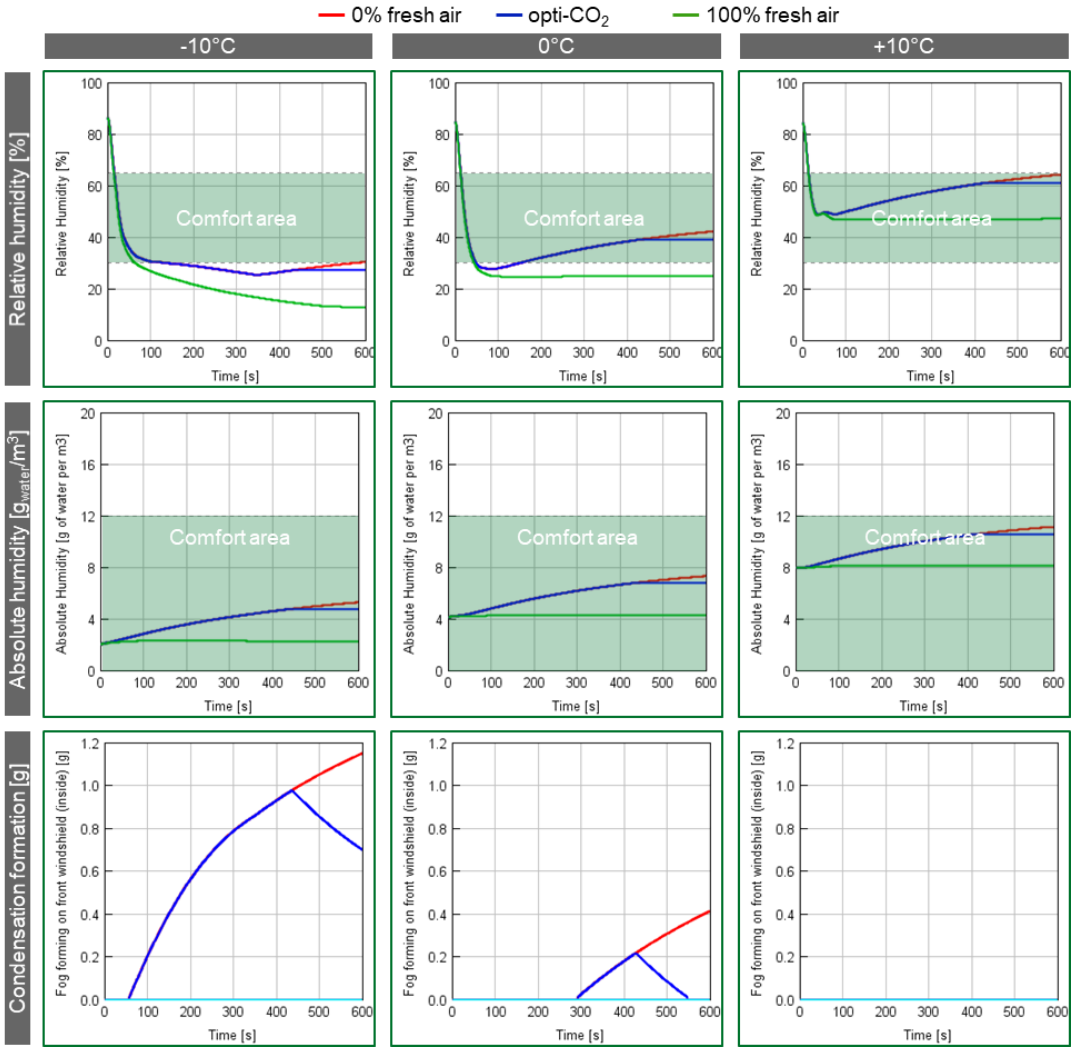

Figure 7. Cabin humidity level and fog formation in the front windshield for three ambient temperatures, and three recirculation modes.

The relative humidity in the cabin depends mainly on the outside temperature. In all cases, the relative humidity is dropping very quickly at the beginning of the cycle. In approximately one minute, the level drops from 85% to a value between 25% and 50%. At −10°C, the humidity ranges between 13% and 30% at the end of the simulation, which is just below the minimum requirement for comfort. At each step of increasing the temperature by 10°C, the relative humidity increases as well. At 0°C and 10°C, the comfort area is globally more achievable. The absolute humidity is kept below the comfort limit in all cases. Regardless of the temperature, humidity is increased by 17% when switching from the fresh air mode to the recirculation mode. It reaches 3.1 g_{water}/m^3 at the end of the simulation.

The amount of condensation on the windshield is also shown on Figure 7. It depends on the amount of water inside the cabin, and the wall temperature of the windshield on the cabin side. In fresh air mode, there is no condensation, regardless of the temperature. In recirculation mode, although there is less humidity at lower temperature, there is more condensation. It appears approximately one minute after the start at −10°C, and after five minutes at 0°C. During these iterations, the relative humidity decreases rapidly, but the absolute humidity increases. Once the absolute humidity reaches a sufficient level along the windshield temperature, there is condensation. At −10°C, it is up to 1.2 g at the end of the cycle, and 0.4 g at 0°C. However, at +10°C, there is no condensation.

The analysis of the amount of condensation in the opti-CO_2 configuration is very interesting. Until 425s, the condensation curve follows the 0% fresh air curve. This is because the vehicle is in recirculation mode to increase the CO_2 level. At 425s, the condensation amount is 1.0 g at −10°C, and 0.2 g at 0°C. At this time, the CO_2 concentration hits the target (2000 ppm). Then, the fresh air ratio is regulated at 5% to stabilise the CO_2 level. From 425s to 600s, the condensation amount decreases in opti-CO_2 mode. At −10°C, it is down to 0.7 g at the end of the cycle. At 0°C, there is no more condensation after 550s.

Inversely, in recirculation mode, there is still fog forming at the end of the cycle, the condensation amount is still increasing. Then, there is a large difference of condensation behaviour between the two configurations (opti-CO_2 mode vs. recirculation mode). However, the change in fresh air ratio is not much (5% vs. 0%). It means that a slight change of the recirculation flap position can lead to a large change in fogging.

A sensitivity analysis is made with the simulation tool. The responsiveness of the humidity level and the condensation amount against several parameters is summarised in Table 2.

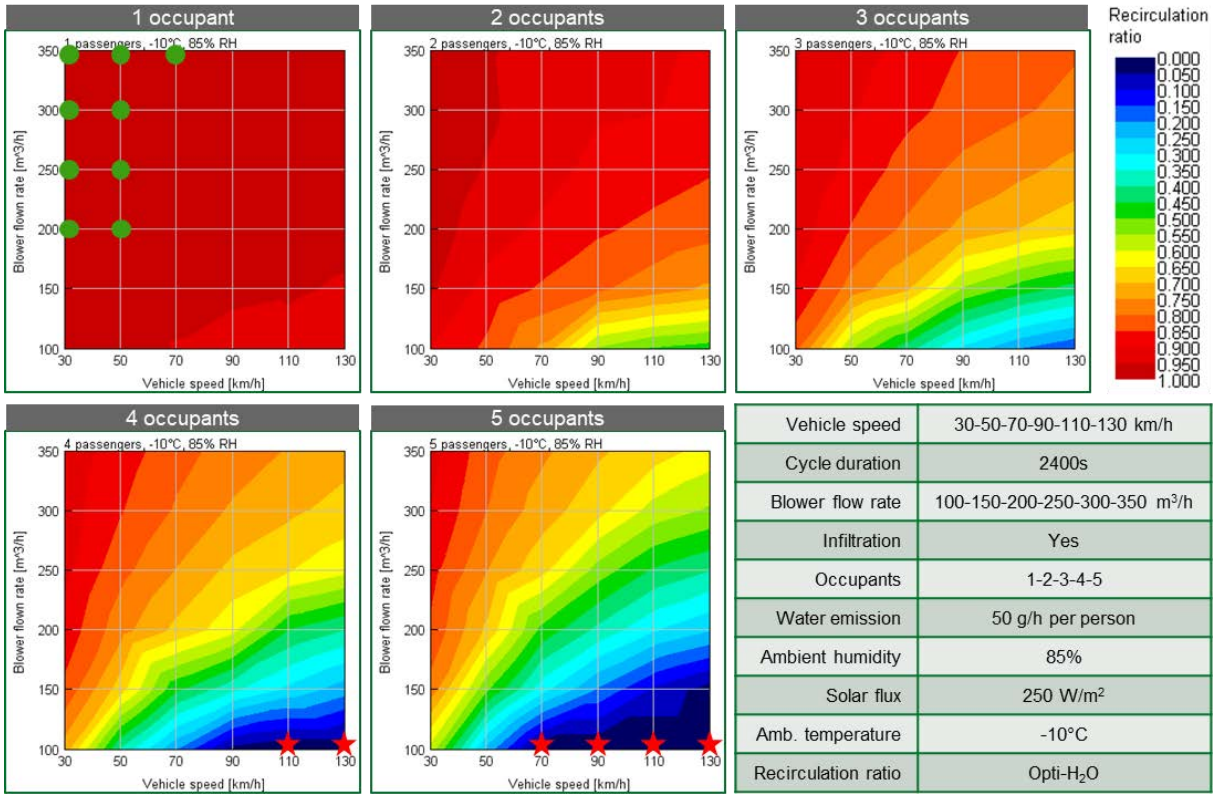
Table 2. Influence of four parameters on the cabin humidity and amount of condensation.

If …… increases (↗),	then humidity level …….	and condensation ……
temperature	increases (↗)	decreases (↘)
fresh air ratio	decreases (↘)	decreases (↘)
blower flow rate	decreases (↘)	decreases (↘)
number of occupants	increases (↗)	increases (↗)

Globally, there is a higher relative and absolute humidity in the cabin as the temperature increases. However, the level of condensation on the front windshield is higher for lowest temperatures. At +10°C, there is no condensation. Besides, for all outside temperatures, the recirculation mode leads to a higher level of humidity and a higher level of condensation. The fresh air mode prevents the appearance of condensation on the front windshield, even at −10°C. Then, the blower flow rate has a limited influence on the humidity level and condensation. A minimum flow rate is required to limit condensation, but the gains at high blower flow rates are small. Finally, as the number of occupants increases, the source of humidity in the cabin increases as well. This leads to a much higher level of humidity in the cabin, and a higher risk of fog formation on the windshield.

3.3. Investigation of the opti-H_2O strategy

The opti-H_2O is applied to a set of simulations with the ambient temperature −10°C. The objective is to obtain the ideal recirculation ratio in each situation. Different parameters are varied to obtain a wide range of results. The blower flow rate is set between 100 and 350 m^3/h. The vehicle speed is fixed over time for each simulation, between 30 and 130 km/h. This allows the full spectrum of infiltration to be covered. Finally, the number of occupants is a major parameter for the humidity aspect. It is set between one and five. The other simulation parameters are fixed as described in Figure 8. In total, 180 simulations are performed: 6 vehicle speeds, 6 blower flow rates and 5 number of occupants. The cycle duration (2400s) is long enough to reach stabilisation in all cases. The recirculation ratio at the end of the simulation is presented in the five contour plots of Figure 8. Each map represents a single number of occupants, i.e., 36 simulations. The recirculation ratio at 2400s is given between 0 (full fresh air mode) and 1 (full recirculation mode). It should be noted that the fog risk might cross the 95% target during the transient stage of the cycle, thus condensation could appear.



Vehicle speed	30-50-70-90-110-130 km/h
Cycle duration	2400s
Blower flow rate	100-150-200-250-300-350 m^3/h
Infiltration	Yes
Occupants	1-2-3-4-5
Water emission	50 g/h per person
Ambient humidity	85%
Solar flux	250 W/m^2
Amb. temperature	-10°C
Recirculation ratio	Opti-H_2O

Figure 8. Recirculation ratio in stabilised stage of opti-H_2O mode at −10°C, depending on vehicle speed (x axis), blower flow rate (y axis) and number of occupants (map).

In some cases (red stars), the 95% target cannot be reached even with 100% fresh air. The fog risk stays above 95% as there is too much humidity in the cabin. These cases are for a low blower flow rate combined with a high number of occupants and a high vehicle speed. These cases must be avoided to prevent continuous fog formation. In other cases (green dots), the 95% target cannot be reached event with 100% recirculation. These cases are not really an issue because the fog risk stays below 95%. It is possible to reach the minimum energy consumption without any risk of condensation. In the simulation, it occurs only with one occupant, at high blower flow rate and low vehicle speed.

The analysis of the results can be divided in three parts. Firstly, as the number of occupants increases, the humidity level in the cabin increases as well. A higher amount of fresh air is required to avoid condensation. With five occupants, at a medium speed (50 km/h) and medium blower flow rate (200 m^3/h), the recirculation ratio should be kept below 70%. With a single occupant in the cabin, whatever the ventilation settings, the recirculation ratio can be kept above 90% with a low risk of fog formation.

Secondly, as the blower flow rate increases, the recirculation ratio can be increased. Indeed, the idea is to keep a certain amount of fresh air that enters the vehicle. For a fixed amount of fresh air, the recirculation ratio can be increased if the total flow rate increases as well.

Finally, for a fixed blower flow rate, a higher vehicle speed tends to decrease the recirculation ratio. There are two impacts of a higher vehicle speed. On one hand, the infiltration flow rate increases. This brings more fresh air into the cabin, which helps for the condensation issue and also leads to a higher recirculation ratio. On the other hand, the windshield convection coefficient increases with speed. There is more heat exchange on the outside surface of the windshield, which leads to a colder temperature in the interior surface. At the end of the simulation, the interior windshield temperature is 6.6°C at 30 km/h, and −3.7°C at 130 km/h. A lower windshield temperature triggers the formation of condensation. This would lead to a lower recirculation ratio to avoid condensation. Due to the shape of the map, the impact of the convection coefficient is larger than the impact of infiltration: higher vehicle speed leads to lower recirculation ratio.

3.4. Air quality considerations

The air quality includes management of the CO_2 and H_2O species, but also the different pollutants in and out of the vehicle environment: volatile organic compounds (VOCs), fine and ultrafine particles (PM and UFP) or pollutant gases such as ammonia (NH_3). Alongside the regulation of temperature, CO_2 and humidity, the goal of the HVAC system is to provide a clean environment for the passengers. This function is performed by a filtration system, comprising of one or several filters. Then, the energy management strategy can influence the design of the filtration system. Depending on the pollution source (within the cabin or outside the car), the best position of the filter can be in the fresh air path or in the supply air path. In a small and closed volume, an

interior pollutant can rapidly degrade the health of the occupants. Similarly, an external pollutant may expose passengers to a health risk. In both cases, the ventilation strategy alone cannot provide a safe solution. As shown in Figure 9, both the recirculation and fresh air modes have some drawbacks. The use of filter appears as a more sustainable solution.

	100% Recirculation	Opti-mode	100% Fresh air
CO_2 concentration in the cabin	☹	Smart controlled recirculation ratio to find best trade-off depending on driving condition	☺
Protection against external pollutants	☺		☹
Protection against internal pollutants	☹		☺
Filter lifetime savings	☺		☹
Infiltration flow rate	☹		☺
Energy savings for thermal comfort	☺		☹
Condensation risk at low temperature	☹		☺
Humidity comfort	It depends on ambient conditions (temperature and relative humidity)		

Figure 9. Pros and cons of the different recirculation strategies.

Most vehicles have a single filter placed on the supply air path. This approach, which allows to get rid of a proper portion of the pollutants, can be improved by introducing additional and more efficient High Efficiency Particulate Air (HEPA) filters. This high-end media has >99% efficiency against fine particles. Thereby, it can decrease the level of particulate matter exposure for the passengers. With this technology, the lifetime of the filter must be evaluated to have a durable system. An aged filter has a high differential pressure that can decrease the blower performance. So, the ventilation system could include an air quality control strategy, alongside energy and humidity optimization strategies. A smart cabin air Filtration system (Smart CAF) has been evaluated in a study [21].

4. Conclusion

There is a difficult challenge with the ventilation system. In order to decrease the energy consumption to heat or cool the cabin, it is best to increase the recirculation ratio. However, it is not possible to have a prolonged full recirculation mode in the vehicle without having a high condensation risk and high concentration of CO_2. Both the opti-CO_2 and opti-H_2O modes intend to maximize the recirculation ratio up to a safe level. Consequently, it reduces the power consumption of the HVAC system. The gains in driving range compared to the common fresh air mode result to only a few kilometres. This is particularly appealing for electric vehicles in cold or hot regions. In the opti-CO_2 mode, the idea is also to provide good thermal comfort and keep the CO_2 concentration in the cabin at a safe level. In the opti-H_2O mode, the goal is to prevent the formation of condensation on the windshield. In a complete system, the opti-H_2O mode should probably be prioritised over the opti-CO_2 mode because it is a safety aspect for driving the vehicle.

These modes are only tested with the simulation tool and it has some limitations. The main one is that it is a mono-zone model. In most vehicles, it is possible to orient the blower flow rate in different directions, including toward the windshield. This can be a strategy to manage the level of humidity near the windshield.

Abstract:

Industrial processes share a relevant portion of global energy consumption. Heat can be provided by solar thermal technologies aimed at the sustainable industry. A large variety of high energy-demanding industrial processes need hot air in the medium temperature range, provided by natural gas combustion or by electricity. Hot air is used as a medium in a large variety of processes such as drying, curing, and thermal treatments of several products and materials. Non-concentrating flat plate type solar collectors can directly heat air up to 100 °C while higher temperatures can be achieved using linear concentrating technology. In this study an innovative system using linear Fresnel collectors directly provides hot air for the industry up to 350 °C, avoiding the need for liquid heat transfer fluids. Accordingly, the installation is simplified, and lower installation and maintenance requirements are expected compared to other solar technologies. The present studies provide an energetic and economic analysis of the concentrating solar air heater, considering a medium-scale benchmark as a reference case in Southern Europe locations. The results indicate that the solar technology here presented can be economically competitive with other solar thermal solutions, having a huge potential for fossil fuel source replacement in hot air based industrial processes.

Keywords:

Solar heat for industrial processes, linear Fresnel; solar air heater, thermo-economic analysis; solar drying

1. Introduction

Industry consumes more than one-third of global energy [1] and is responsible for a quarter of global emissions. The greater industrial energy demand is heat, followed by electricity, provided almost totally from fossil fuel sources. Industrial heat consumption is estimated at around 85 EJ at the global level and is almost completely provided from fossil fuel. The total heat demand for low and medium temperature applications (< 400°C) accounts for 44 EJ, required by a large variety of industrial processes in any industrial sector.

Aiming at decarbonization, solar thermal technologies are good candidates for replacing fossil fuel technologies in industrial heat production. Besides costs, space availability, and solar resource, the application of Solar Thermal (ST) technologies to industrial heat is limited by their operating temperature range. Flat Plate Collectors (FPC) and Evacuated Tube Collectors (ETC) are suitable for low-temperature heat requirements (< 150 °C). Linear concentrating solar collectors are capable to provide heat at higher temperatures and efficiency than non-concentrating solar collectors e.g. [2] and they are receiving increasing attention for application to industrial processes [3]. Both Parabolic Trough Collectors (PTC) and Linear Fresnel Collectors (LFC) can provide heat in the medium temperature range (150 - 400 °C).

Hot air is used as a medium (working fluid) in a large variety of processes such as drying, curing, and thermal treatments of several products and materials [4]. Hot process air can be obtained by heating ambient air “indirectly” through a heat exchanger which is fed by a proper heat transfer fluid HTF (thermal oil, steam, hot water). HTF is heated by a conventional heat supply. Another common option is to heat air “directly” through a burner so that heated air and exhaust gases are mixed and utilized in the thermal process.

Linear concentrating collectors such as Parabolic Trough Collectors PTC and Linear Fresnel Collector LFC are commonly equipped with a heat transfer fluid HTF. Such are pressurized water, thermal oil, or steam, to

carry heat from the receiver tube that absorbs the concentrated solar irradiance and conveys it to the industrial process where it is needed. A heat exchanger is required to deliver heat to the processes when the heating medium differs from the HTF.

Their application for hot air production has been rarely documented, e.g. [6] and [7]. They use an indirect scheme where an HTF/air heat exchanger HX is needed to heat the process air.

An innovative scheme was proposed by [8] aiming at direct heating air inside the evacuated tube-type receiver of a linear concentrating collector. The theoretical analysis carried out revealed the feasibility of direct heating air in PTCs or LFCs under the appropriate range of solar field configuration. The pumping power needed for blowing air through the standard evacuated receiver tube rapidly grows with the solar field scale. To overcome this limitation, they propose to couple the solar field with an automotive turbocharger in a specific Brayton cycle configuration. The turbocharger allows operating with higher air density without consuming external auxiliary energy for pumping and blowing. A further numerical study [9] confirmed the technical feasibility of the turbo-assisted concentrating solar air heater, in that case, using a linear Fresnel Collector. A prototype has been built and tested allowing the full characterization of the small-scale linear Fresnel solar field available, using only air as the heat transfer fluid [10]. It operated assisted by a commercial turbocharger for air pumping [11].

The present study provides an energetic and economic analysis of the turbo-assisted concentrating solar air heater (T-SAH) applied to a generic process air heating case study, considering a -medium-scale benchmark as a reference.

2. Turbo-assisted concentrating solar air heater

According to the methodology detailed in [12], a benchmark solar field configuration is set. It is based on a commercial linear Fresnel collector [13], Fig.1. The solar field consists of 32 modules with 26.4 m^2 of primary mirrors area, forming a total active area of 845 m^2. The gross area of each module is 36 m^2 which gives a gross area occupied by the installation of 1270 m^2, including minimum spacing.

The LFC is equipped with a standard evacuated receiver tube. An automotive turbocharger joins a compressor c and a turbine e in a compact device with a common shaft, Fig.1. The compressor increases the air pressure up to 2 to 3.5 bar, according to operating conditions, before solar heating. Air velocities and stagnation pressure drops are minimized due to the increased density. After heating up to 450 - 550 °C, air expands through the turbine, which recovers the compressing power. This way no external auxiliary power is needed for air blowing. An auxiliary compressor is used for control and during starting transients only, with negligible yearly energy consumption.

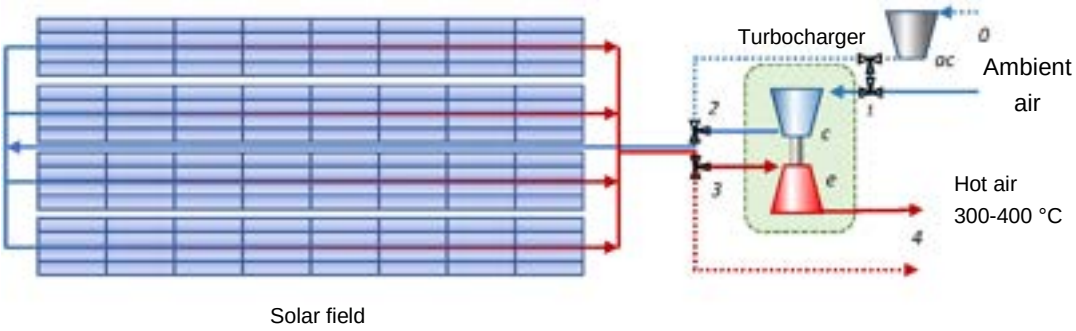

Figure. 1. Benchmark turbo-assisted concentrating solar air heater plant T-SAH.

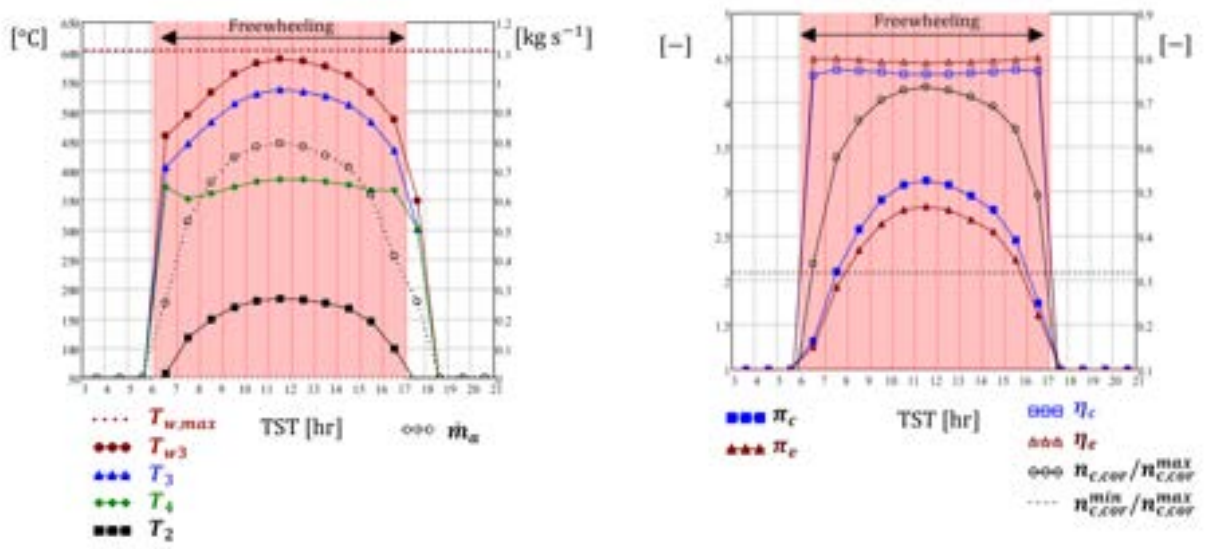
Using a Typical Meteorological Year TMY, the delivered hot air stream and the thermal power delivered to the user are simulated for each hour of the year for a given location, resulting in a detailed yearly based assessment. The benchmark plant simulated is located in Madrid city, Spain.

Figure 2 shows the behavior of the system across a typical summer clear day through the main operating parameters involved. Fig.2 (a) reports the temperature profile during the day in the main points of the air circuit according to Fig. 1. It can be noticed as the delivered air temperature is relatively flat around T_4 =350 °C, thanks to the behavior of the turbocharger. The mass flow rate $\dot{m}_a$ varies according to the solar thermal power available. Pressurization imposed by the turbocharger reaches a pressure ratio of $\pi_c = \frac{p_2}{p_{amb}} = 3.5$ at midday,

which allows the minimization of pressure drops across the solar field and enables the turbine to drive the compressor without external aid (freewheeling). Accordingly, the required inlet turbine temperature goes up to 550 °C, while the receiver wall temperature T_w does not overcome its thermal limit ($T_{w,max} = 600$ °C). In spring and winter days both mass flow rate as well as operating temperature are lower, while the outlet air temperature is steadily above 300 °C.



(a) (b)

Figure 2 Turbocharged Solar Air Heater T-SAH performances vs. true solar time TST during a clear summer day. Solar field orientation N-S. TST: true Solar Time; T, p: temperature and pressure according to Fig.1; $\boldsymbol{T_{w3}}$: receiver wall temperature at tube outlet, $\boldsymbol{T_{w,max}}$: maximum allowable receiver wall temperature; $\boldsymbol{n_{c,cor}}$: turbocompressor (corrected) rotational speed; $\boldsymbol{\eta_c}$: compressor efficiency; $\boldsymbol{\eta_e}$: turbine efficiency; $\boldsymbol{\pi_c}$: compressor pressure ratio; $\boldsymbol{\pi_e}$: turbine pressure ratio; $\boldsymbol{\dot{m}_a}$: mass flow rate; $\boldsymbol{\eta_{th}}$: thermal efficiency.

Extending the simulation to the whole Typical Meteorological Year (TMY) annual results can be obtained. Oriented in the North-South direction and located in Madrid, Spain (40° 24' 59'' N, 3° 42' 9'' W) the solar field provides an annual energy yield $Q_a = 500$ MW h year^{-1} of thermal energy as hot air between 300 °C and 400 °C, working 2880 h year^{-1}, Tab.1.

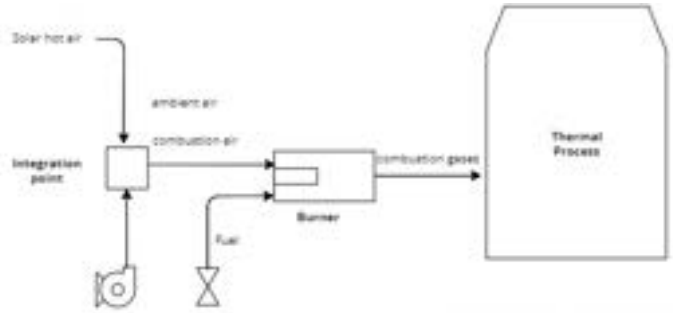
Table 1. Yearly energetic performances

$\boldsymbol{A_{tot}}$	m^2	845
$\boldsymbol{h_{ON}}$	h	2880
$\boldsymbol{Q_a}$	MW h y^{-1}	500
$\boldsymbol{Q_a/A_{tot}}$	kW h y^{-1}m^{-2}	592.1
$\boldsymbol{Q_{a,u}}$	MW h y^{-1}	491
$\boldsymbol{Q_d}$	MW h y^{-1}	1600
$\boldsymbol{SF_y}$	-	0.3

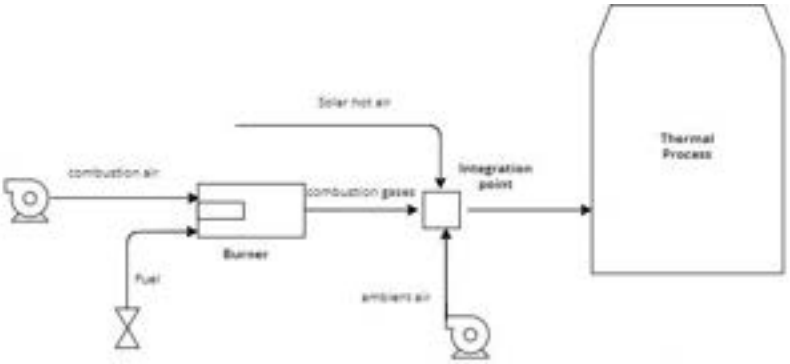
Although the previous results have general validity, in this analysis T-SAH delivers hot air to a specific thermal process, i.e. a medium-temperature drying process. The pre-existing conventional air heating device is assumed to be a natural gas burner, which is a common option in the industry. The burner sends to the process a mixture of combustion gases and air (referred to as hot air for simplicity) at the desired temperature, here assumed to be constant at 300 °C.

At least two options are viable for the integration of solar hot air into the existing air heating system: series and parallel integration with the natural gas burner, Fig.3. The integration concept chosen here is a parallel scheme

where T-SAH and the burner provide hot air for the process as in Fig.3(b). Whenever solar air flow is provided by the solar field it is totally sent to the process, having a priority over the burner airflow. The latter is adjusted by controlling the mass flow rate and temperature in order to meet the process requirements in terms of thermal power and air temperature. This way the solar air flow enables a reduction of burner thermal power, resulting in natural gas savings.



(a)

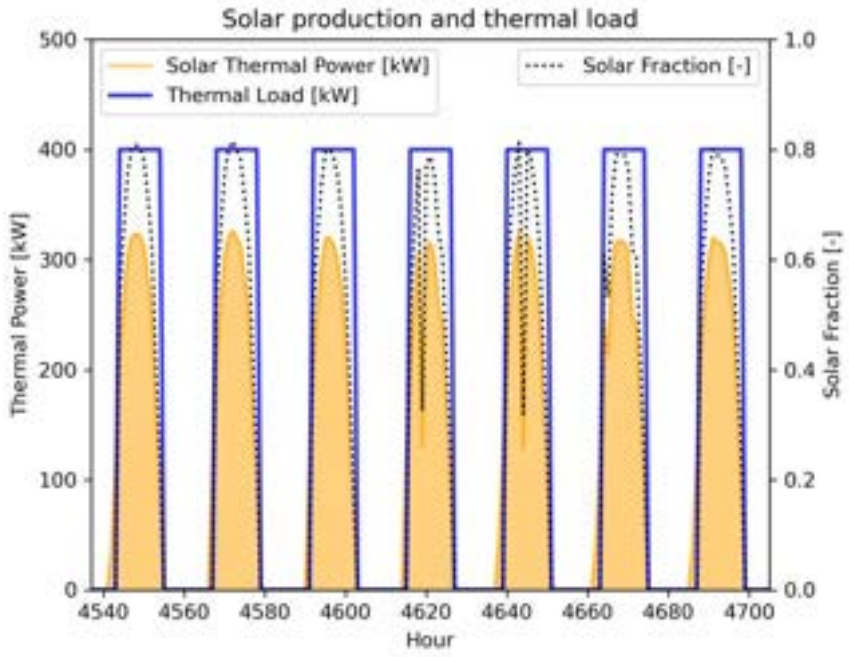


(b)

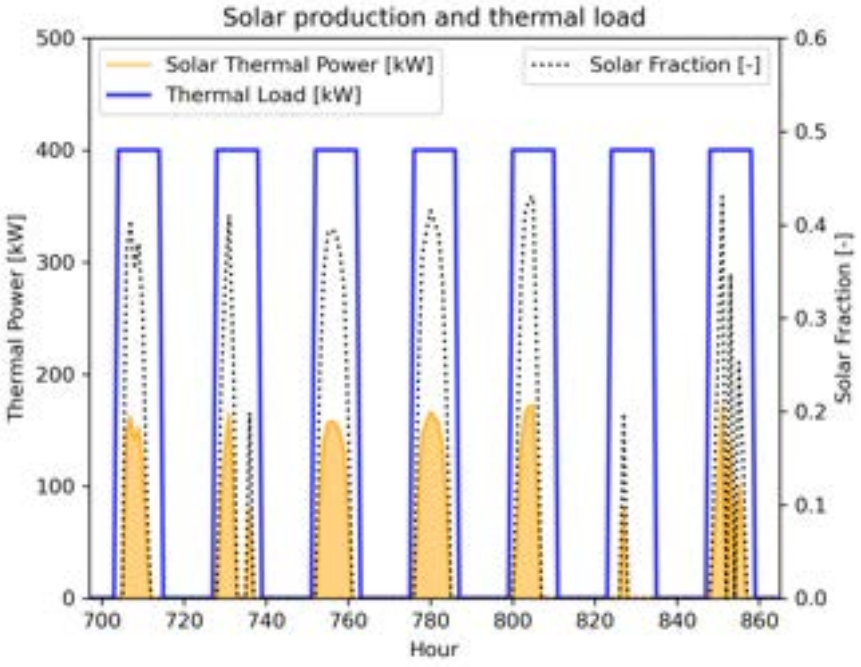
Figure. 3 Integration concept of T-SAH into air bases thermal process. i.e. drying: series integration (a); parallel integration (b).

The thermal load profile of the process depends on the specific factory, its requirements, and production schedule. Although any load profile is possible, some common patterns are recognized. A typical case is having a constant thermal load for continuous production. Another option is having a daily variation of thermal load according to the working hours of the factory. This can include or not the weekend among the working days. Here the thermal load $\dot{Q}_d$ is assumed to be 100% of the peak load $\dot{Q}_{d,pk} = 400\ \mathrm{kW}$, each day of the week including weekend days, from 7:00 a.m. to 6:00 p.m. During the rest of the hours thermal load is null.

The thermal load profile is shown in Fig.4 together with the solar production profile $\dot{Q}_a$ vs. the hours of the year for one week in summer Fig.4(a) and one week in winter Fig.4(b). The solar production interval and thermal load-interval are quite similar so that, even without thermal storage, the process can absorb almost all the solar thermal energy provided. The used thermal energy is in each hour $\dot{Q}_{a,u} = \min(\dot{Q}_d, \dot{Q}_a)$. On annual basis $\frac{Q_{a,u}}{Q_a} = 0.96$. The solar fraction SF is the ratio between the $\dot{Q}_{a,u}$ and $\dot{Q}_d$ in each time interval and indicates the amount of thermal load provided by solar. Fig. 4 reports on the second axis the SF for the selected weeks. It is clear that on summer days SF reaches up to 0.8, while it is much lower on typical winter days, $SF < 0.5$. On an annual basis, the solar fraction is $SF_y = 0.3$.



(a)



(b)

Figure 4. Solar production and thermal load weekly profiles: (a) typical summer week; (b) typical winter week.

3. Economy analysis

The economic analysis is carried out on the benchmark plant of Fig.1. Estimations of the installation costs CAPEX and operating cost OPEX are obtained on the grounds of the current stage of development of the technologies and products involved. Levelized cost of heat (LCOH) and discounted payback period (DPB) are used as the main economic parameters for the analysis.

Here it is assumed that solar-generated heat replaces the corresponding amount of convectional heat, generated by a natural gas burner.

The evaluation of conventional energy cost evaluation is non-trivial. Natural gas cost for industrial consumers varies by country, besides varying with the consumption volume of the factory and time. The price volatility has increased in Europe in recent months as a consequence of the geopolitical situation and supply uncertainties related to the major gas suppliers.

Eurostat [14] provides the natural gas price for "non-household" consumers across recent years in Europe. The "non-household" consumer definition includes industrial consumers and other large consumers with annual consumption above 1000 GJ (277 MWh), excluding powerplants and chemical process consumers. Non-household consumers are divided into six bands as reported in Tab.2.

As a general trend of the averaged value, since 2008 the price trend was increasing until 2013 reaching a peak at 42 €/MWh in the first half of 2013, then decreased down to 28 €/MWh in the first part of 2021. In 2021-2022 the prices have grown remarkably up to 65 €/MWh. Tab. 2 reports the recorded values for Spain and EU27 countries during the first semester of 2021 and 2022 when a large price variation occurred. These values are considered as a span for the price variation in the following economic study.

Table. 2. Non-household natural gas price including taxes by consumption bands, 2021-2022, €/MWh

		2021-S1		2022-S1	
Consumption band	Annual consumption	EU27	Spain	EU27	Spain
Band-I1	< 277 MWh	57.2	45.2	90.8	108.1
Band-I2	277 – 2 770 MWh	48.3	39.6	81.6	89
Band-I3	2 770 - 27 700 MWh	36.7	28.7	76.4	88.2
Band-I4	27 700 - 277 000 MWh	29.7	27.1	76.2	93.3
Band-I5	277 000 -1 108 000 MWh	27.7	28.1	87.7	92.1
Band-I6	> 1 108 000 MWh	26.6	26.1	97.7	89.2

3.1. LCOH

The LCOH is the cost of the generation of thermal energy (Heat), hence the minimum price at which it must be sold to recover the cost of installation (CAPEX) and the costs of operation and maintenance (OPEX, here named $C_{O\&M}$) during the lifetime of the plant. It is defined in an analogous way as the Levelized Cost of Energy $LCOE$ used for electricity production financial analysis. Here it is assumed that $LCOH$ is the cost of solar-generated heat, substituting the corresponding amount of convectional heat, generated by a conventional heating system.

According to IEA task 54, the $LCOH$ can be estimated as follows, considering constant annual discount rates r_{dis}:

$$LCOH = \frac{I_0 - S_0 + \sum_{n_y=1}^{N_y} \frac{C_{O\&M_{n_y}}(1-TR) - DEO_{n_y} TR}{(1+r_{dis})^{n_y}} - \frac{RV}{(1+r_{dis})^{N_y}}}{\sum_{n_y=1}^{N_y} \frac{E_{n_y}}{(1+r_{dis})^{n_y}}} \quad (1)$$

with I_0: initial investment and in due case discounted end-of-life replacements; S_0: subsidies on the installation; $C_{O\&M_{n_y}}$ yearly operation and maintenance cost, TR: corporate tax in %; DEO: asset depreciation; RV: residual value; E_{n_y}: Annual energy yield; N_y: Lifetime; r_{dis} discount rate % year-1.

The above expression results in the following simplified version when assuming $TR = 0$; $RV = 0$, and is used in this study.

$$LCOH = \frac{I_0 - S_0 + \sum_{n_y=1}^{N_y} \frac{C_{O\&M_{n_y}}}{(1+r_{dis})^{n_y}}}{\sum_{n_y=1}^{N_y} \frac{E_{n_y}}{(1+r_{dis})^{n_y}}} \quad (2)$$

Relevant parameters used are reported in Tab. 3. Initial investment $I_0 = C_{SF} + C_0$ has two main components.

The solar field $C_{SF} = A_{tot} C_{SFu}$ cost plays the major role compared to other costs C_0, including hydraulic and auxiliary equipment, control, and instrumentation. Solar field cost represents close to 90% of the initial investment. Although this is a common feature in solar installation, here is more evident since the auxiliary equipment is simplified thanks to the novel layout of direct air heating. The heat transfer fluid HTF and air/HTF heat exchanger are avoided with their related installation and maintenance costs.

Table 3. Financial parameters

Discount rate	r_{dis}	5%
Operation and Maintenance	$C_{O\&M}$	1% of initial investment I_0
Lifetime	N_y	25 years
Solar field cost per m²	C_{SFu}	380-580 €/m2
Other costs (hydraulic and auxiliary equipment, control and instrumentation…)	C_0	50 000 €

The LCOH is obtained as a function of unitary solar field cost C_{SFu}, for the benchmark case having an annual energy yield of $Q_{a,u} = 491$ MWh. It ranges between 61 €/MWh ($C_{SFu} = 380 \frac{€}{m^2}$) and 89 €/MWh ($C_{SFu} = 580 \frac{€}{m^2}$), with an average of 75 €/MWh ($C_{SFu} = 480 \frac{€}{m^2}$). The comparison with natural gas costs suggests as the adoption of T-SAH can be economically viable when natural gas cost stays above its average value.

Fig. 5 shows the obtained LCOH in comparison with the natural gas cost for different consumption bands as in Tab. 2. The LCOH is higher than the minimum natural gas price so economic convenience is not guaranteed. When the natural gas prices are higher (as in 2022) the solar heat can be competitive or even cheaper. Besides, the smaller consumers suffer higher prices which can facilitate the adoption of solar energy solutions, but they must be able to consume all the solar heat provided by a flexible heat demand or via storage, not considered in this analysis. Considering the subsidies on the initial investment LCOH decreases: 48 €/MWh with $C_{SFu} = 480 \frac{€}{m^2}$ and the percentage of subsidies on the initial investment of $s_0 = \frac{S_0}{I_0} = 40\%$.

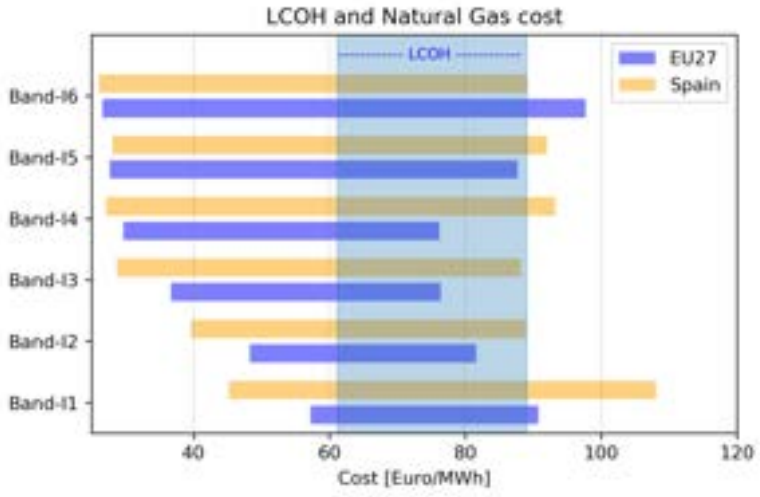


Figure 5. LCOH and natural gas cost span (2021-2022) in EU27 and Spain.

3.2. DPB

Discounted payback time DPB accounts for the time value of the money, hence it discounts the actual cash inflow for each year at the defined discount rate. Discounted Payback time DPB also depends on the cost of the conventional energy that is being replaced. A simplified equation is used for its evaluation are Eqs. (3) - (4). Yearly cash flow CF comes from natural gas costs avoided C_{NG} and operation and maintenance costs

$C_{O\&M}$. The conversion efficiency of natural gas burner is assumed unitary.

$$CF = \mathrm{Q_{a,u}} C_{\mathrm{NG}} - C_{O\&M} \tag{3}$$

$$DPB = \frac{\ln\left(\frac{CF}{CF - r_{dis}\,(I_0 - S_0)}\right)}{\ln(1 + r_{dis})} \tag{4}$$

Due to the variability of the conventional energy source price, it is convenient to show the DPB as a function of that price, as in Fig. 6. Three curves are shown representing the DPB assuming a solar field cost $C_{SFu} = 580\,\frac{€}{\mathrm{m^2}}$, $C_{SFu} = 480\,\frac{€}{\mathrm{m^2}}$, $C_{SFu} = 380\,\frac{€}{\mathrm{m^2}}$ and considering the subsidies $s_0 = \frac{S_0}{I_0} = 40\%$ of the capital costs. The DPB holds relatively high values, above 10 years in the actual range of natural gas prices. A decrease in LFC cost is required to lower the DPB either with subsidies or not. Considering an average natural gas price of 65 €/MWh, $DPB = 12$ years is obtained when the LFC cost drops to $C_{SFu} = 250\,\frac{€}{\mathrm{m^2}}$, without subsidies on the initial investment.

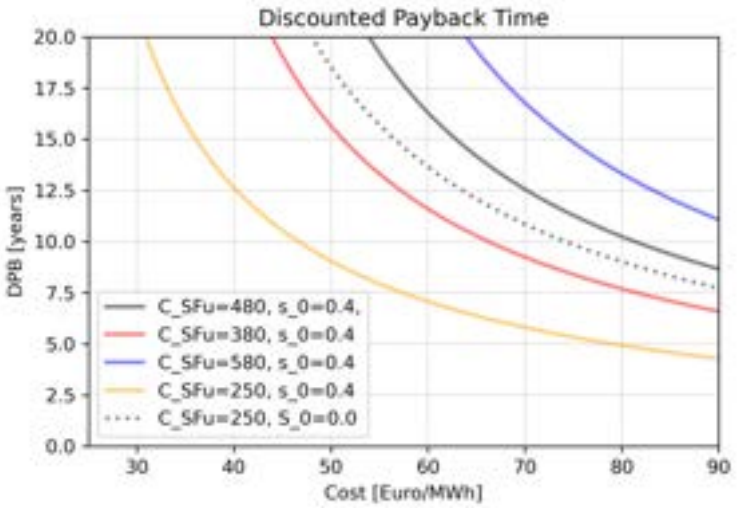

Figure 6. Discounted Payback Time *DPB* against the natural gas cost, for different unitary solar field costs and subsides percentage on the initial investment $s_0 = S_0/I_0$.

Conclusions

A novel layout for solar heat production for industrial processes has been studied from the economic perspective according to the energy yield utilization. The innovative concept uses concentrating linear Fresnel collectors to implement a solar air heater able to heat directly ambient air up to 300-400 °C for its usage in air-based thermal processes in the industry. An energetic analysis is carried out through numerical modeling of the solar heating system. A benchmark plant is configured and simulated across a typical meteorological year in Madrid city, Spain. The concentrating solar air heater is coupled with a thermal process, taking into account a parallel integration scheme and a given thermal load time profile. The simulation provides the annual performance of the solar facility in terms of energy provided and natural gas consumption avoided. An 845 m^2 solar field delivers to the process up to 500 MWh per year of thermal energy, corresponding to 30% of the consumption of the considered thermal process. The solar field allows for saving 52,000 Sm^3 of natural gas and 104 tons of CO_2 per year. The results indicate that the solar technology here presented can be competitive with other solar thermal solutions, having a huge potential for fossil fuel source replacement in hot air based industrial processes.

An economic analysis is carried out to evaluate the investment and operation costs of the solar system. The Levelized cost of Heat and Discounted Payback time indicates that the solution proposed can be competitive

with natural gas in the recent European price range, despite a reduction of solar field cost and sustained subsidies policy are required to improve economic feasibility.

Abstract:

Several literature works have highlighted that the expansion of electrification across all sectors is a crucial factor in promoting the transition of energy systems towards carbon neutrality by mid-century. However, polygeneration systems through the appropriate integration of different renewable energy sources are expected to play an important role in such transition by effectively reducing the total primary energy demand, as explored in the present work for an energy community (EC) case study. Therefore, this paper presents the optimal synthesis, design, and operation of an EC system working under three different scenarios and evaluates the trade-offs between the total annual costs and greenhouse gas (GHG) emissions (evaluated as CO_2 equivalent emissions). The EC is a District Heating and Cooling Network (DHCN) composed of nine third sector buildings in the northeast of Italy. The DHCN superstructure includes several possible energy supply components for each EC member, a central unit, and heat and/or cooling connections between buildings. Moreover, peer-to-peer electricity sharing is allowed among EC members, through a local electricity grid, before buying/selling electricity from/to the main grid. The superstructure was optimised through a mixed integer linear programming (MILP) model considering a multi-objective optimisation for the total annual cost (for owning, operating, and maintaining the entire system) and the total annual CO_2eq emissions as the objective functions. The three scenarios through which the EC system is optimized and evaluated consider the type of consumed gas (natural gas or biomethane) and the electricity consumption configuration (on-grid or off-grid). Results have shown that the cost (per ton of CO_2eq) to reduce emissions is too high if the European Union's carbon market is considered. This was especially critic for the natural gas scenario, where the cost per ton of CO_2eq (between two optimal solutions) was about four times higher than its cost on carbon market.

Polygeneration systems; Renewable energy sources; Energy community; Carbon neutrality; Multi-objective optimisation.

1. Introduction

The 2021/2022 global energy crisis was essentially the consequence from two main worldwide problems regarding primary energy: supply and prices. According to a report by IEA [1], such problems were ignited by several factors, including the economic recovery that started to take place as the Covid-19 pandemic progressively weakened in 2021 and the beginning of Russia/Ukraine war in February 2022. The result was a brutal energy prices increase [2] in comparison with pre-pandemic levels, followed by a substantial coal consumption growth [3]. The European Union (EU), deeply affected by a plunge in Russian's gas supply, released a report [4] with a set of actions to avoid gas shortages in 2023 such as energy efficiency improvements of industries, and public and private buildings, deployment of renewables, and electrification of heat.

The aforementioned context has highlighted the ever importance of primary energy savings. Among the main solutions the scientific community has developed, energy communities have arisen as an advantageous way for energy savings in different types of buildings. In a recent work [5], our research group

studied the design and operation of an energy community (EC), comprising nine tertiary sector buildings, for a city in the northeast of Italy. Besides a reduction in total costs and CO_2eq emissions, the implementation of peer-to-peer electricity sharing within the EC demonstrated the possibility of saving primary energy (natural gas, in this case) since the cogenerated and shared electricity among the EC members allows a substantial reduction in the total amount of electricity imported from the main electric grid. It is possible to find in literature not only other works dealing with EC optimisation for tertiary sector buildings [6], but also studies focused essentially on the same kind of work but aiming residential, commercial, and industrial buildings [7-10].

In addition to primary energy savings, the report from EU [4] highlights also the importance of deploying renewables. This is a key concern for EU since it has fixed deadlines, through different pieces of legislation, to reach carbon neutrality by 2050. For instance, the EU 2030 target plan [11] aims a more ambitious and cost-effective direction to reach the carbon neutrality by 2050, without forgetting the encouragement for creating new green jobs and for stimulating international partners to also increase their carbon neutrality ambitious. As a part of the EU 2030 target plan, the so called “Fit for 55” package [12] proposes an ambitious target for decreasing the net greenhouse gas (GHG) emissions by at least 55% (of the 1990 net GHG emissions level) by 2030. According to the EU council [13], the package aims to create a balanced and coherent framework for attaining the EU's climate goals, while ensuring a just and equitable transition, promoting innovation and competitiveness of EU industry, and maintaining a level playing field with third country economic operators. Still according to them, to accomplish these goals, member states must implement concrete measures to decarbonize their economies, and the “Fit for 55” package provides legislative proposals and amendments to assist in achieving this objective.

Figure 1. Categories included in the “Fit for 55” package [12].

The “Fit for 55” package describes also, in detail, how the EU will translate its climate goals into legislation. Specific categories (Fig. 1) will give directives that include energy taxation, energy-efficient transition, reform to the EU emissions trading system, energy performance of buildings, and boost of renewable energy sources. For instance, the directive regarding energy-efficient transition [14] claims that energy saving is the most cost-effective solution for reaching the climate goals in the energy sector. Indeed, with such a solution it is possible to reduce lots of GHG emissions besides providing more affordable energy. In the same line, the directive for boosting renewable energy sources [15] says that moving towards such energy sources the GHG emissions will be substantially reduced while the human health and air quality will be improved. Different studies regarding improvement of energy communities have already analysed the agreement of their results with the “Fit for 55” package [16] or, at least mentioned their awareness and importance of such piece of legislation [17,18].

From the depicted literature review, one can verify the attention that the scientific community has given to enhancing energy communities’ performance. Moreover, it is also possible to verify the attention that the EU has given on the reduction of net GHG emissions by 2050. Such EC improvements aim not only to achieve lower costs and emissions but also lower levels of primary energy consumption (in line with the European Union report [4]). In agreement with these issues, this work aims to conduct an analysis of different scenarios in order to evaluate the performance of an EC (located in Pordenone, northeast of Italy) comprising nine buildings from the third sector and working with natural gas or biomethane, as one of the input energy vectors. For each one of these fuels, the EC behaviour will be assessed when it is connected or not to the electricity grid. The evaluation will be made through a multi-objective optimisation (total annual costs and CO_2eq emissions) using a mixed integer linear programming (MILP) model that evaluates the optimal solution regarding the synthesis, design, and operation of the specified superstructure for the EC. The

energy system structure for each building is optimised individually, in accordance with its energy demand. The district heating network (DHN) and the district cooling network (DCN) are also optimised, i.e., depending on the energy demand of each building and the distance between them, the pipelines network is also optimised in accordance with the energy system structure of each building. Besides heating and cooling, peer-to-peer electricity sharing is also allowed in the community, which gives the EC a lower dependency on the electric grid or even the possibility to be off-grid.

2. DHCN superstructure

The superstructure shown in Figure 2 is comprised of three main subdivisions. The first one is the Polygeneration Unit k, which is a set of equipment assigned to a specific user building (referred to as "User Building k"). The second subdivision is the central unit, an independent structure that provides heating and electricity to the energy community. The third subdivision is "User i", which represents the remaining buildings within the energy community. These three subdivisions are linked through the DHCN for thermal energy exchange and the distribution substation (DS), which serves as an electricity hub. The model optimizes the pipeline connections between buildings and central unit. Rather than being connected directly to the electricity grid, all buildings and the central unit are connected to the DS, which manages the flow of electricity for all three subdivisions. This means that based on an electricity balance, the DS can:

- distribute electricity to a building, if their Polygeneration Unit cannot meet their demand,
- receive electricity from a building, if it has an electricity surplus,
- purchase electricity from the grid, if the surplus from all buildings is insufficient, and
- sell electricity to the grid, if there is a surplus and all buildings demands have been met.

For a more detailed description about all internal energy flows among components, the reader may refer to our previous work [5].

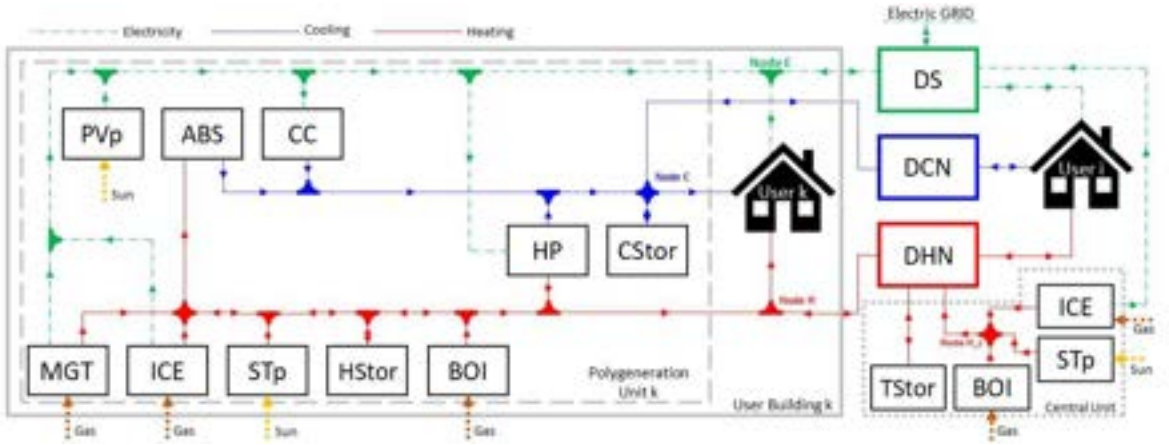

Figure 2. Superstructure of the energy community [5].

3. Model description

The optimal synthesis, design, and operation of the EC showed in Fig. 1 were defined using Mixed Integer Linear Programming (MILP) optimisation method, which involves decision variables, constraints, and objective functions. Decision variables can be binary or continuous and determine the selection, on/off status, and sizing of equipment. Constraints determine the model's limitations in terms of equipment size, performance, and energy balance, while objective functions aim to minimize predefined targets. A flow diagram of the inputs, outputs, and the core characteristics of the model can be found in Fig. 3.

The sizes of some devices, such as MGT, ICE, ABS, and HP, are predetermined, while others (BOI and CC) are left free to optimize their installation and sizes. ABS devices are only allowed to be fed by cogeneration systems and STp. The partial load performance of cogeneration systems is represented by linear relations obtained through a linear regression of their characteristic load curves. PVp and STp production data consider local hourly insolation obtained through a dedicated software [20], and the size of these solar technologies is limited to a maximum of 200 m^2 per building. The HP modelling is more complex than other devices, as the heating and cooling production cannot happen at the same time and considers both the heating and cooling demands of each EC building.

The DHCN pipelines layout and capacity are also optimised by considering the geographical location of the buildings and the distances between each other. Thermal losses are expressed by an equation that depends on the pipeline length and a coefficient of proportionality. A constraint does not allow the model to connect two users with two pipelines sending heating or cooling energy at the same time. The maximum heat flow

rate is constrained by the pipelines size, and the energy flow into each pipeline is bounded between a lower and upper limit. The optimisation of the DHCN is important to minimize thermal losses through pipelines and ensure efficient energy distribution.

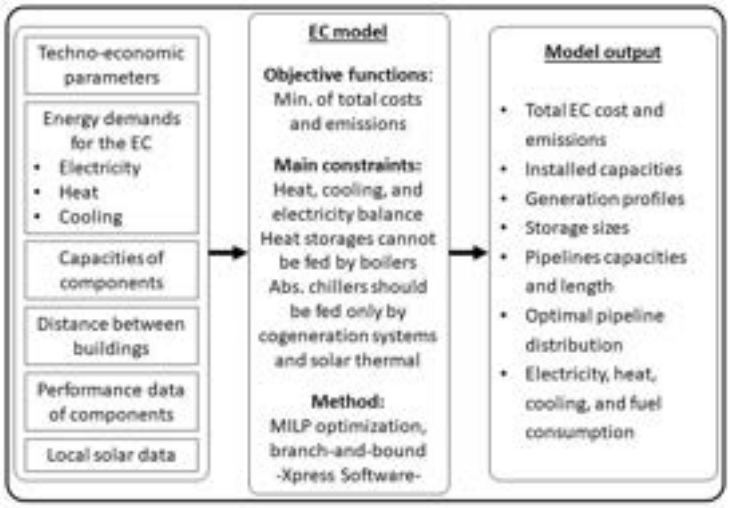

Figure 3. Flow diagram from main inputs to main outputs.

Thermal storages systems are implemented to overcome the intermittence and scarcity of sunlight during winter and, combined with cogeneration devices, to reduce the usage of backup boilers. In this way, fuel consumption and environmental impacts can be mitigated. The proposed thermal storage models provide a means of calculating the energy stored and the energy balance within them, considering thermal loss and energy input from the DHCN pipelines. These models describe the storage of thermal energy for the entire year, without time decomposition, and the connection between hours, days, weeks, and months for a whole year representation.

Energy balances are used to model the heating, cooling, and electricity constraints of the system, which are applied for the individual buildings, the central unit, and the distribution substation. The EC buildings require all three types of energy balances, which are applied at specific nodes for each type of energy. The central unit requires only the heating balance, as its electricity production is sent directly to the DS, which is responsible for managing the peer-to-peer electricity sharing among buildings.

The peer-to-peer electricity sharing methodology is implemented with the aim to reduce the amount of electricity exchanged with the electric grid, which can reduce overall costs and environmental impacts. The methodology involves the local production of electricity by each EC member and, in the case of surplus, send the overbalance to the DS to distribute it for other EC members or selling it to the electric grid. The proposed methodology has the potential to benefit EC members by reducing their reliance on the electric grid and promoting a more sustainable use of energy.

For this work, a multi-objective optimisation problem was defined to minimize the total annual cost and CO_2eq emissions. The total annual cost includes investment, maintenance, and operation costs, while the total annual CO_2eq emissions are related to the net electric energy received from the grid and the fuel consumption by boilers and cogeneration energy systems. The two objectives are conflicting, as adopting environmental efficient energy systems is costly and the solution that allows for minimum annual cost does not necessarily result in minimum total annual CO_2eq emissions. The ε-constrained method [21] is used to obtain the Pareto front solutions. The method involves identifying a set of intermediate emission levels and introducing each level as an additional constraint in further economic optimisation (it could be carried out in the other way around, i.e., performing an emissions optimisation while setting intermediate values for cost). The method allows decision-makers to explore the trade-offs between different solutions and identify the optimal trade-off between economic and environmental objectives.

For a more detailed description of the model, the reader may refer to our previous work [5].

4. Case study

The case study is an EC designed for the city of Pordenone, northeast of Italy, which provides heat, cooling, and electricity to nine different buildings: town hall, hospital, library, primary school, secondary school, retirement home, theatre, town hall archive, and a private swimming pool (Fig. 4). This study is based on a mathematical model that divides the year into 24 typical days (two typical days/month – working and non-working) of 24 hours each and calculates the optimal design and operation for the entire EC system based on the energy demand data of each building. The heterogeneous mix of buildings with different energy demands ensured that the results obtained were not biased towards a specific user profile. Furthermore, this mix of users is expected to be representative of many other small and medium-size towns in Europe.

As an example, Figure 5 illustrates the energy demand patterns of the hospital during winter and summer, based on two representative working days. During winter, the hospital exhibits a higher demand for electric energy during daylight hours, attributed to a higher occupancy factor. Additionally, there is a higher heating demand during morning and evening periods, and minimal cooling demand. Conversely, during summer, the hospital experiences a higher cooling demand, with the peak occurring around 2 p.m. The electric energy demand is similar to that of the winter season. Notably, comparing to the winter curve, the heat demand during summer is reduced by a factor between 2 and 3, as the hospital still have a high demand for sanitary water. It is noteworthy that the energy patterns of each building vary based on several factors, including occupancy factor, thermal insulation, and night lighting.

Selecting appropriate and proportionate equipment for the energy structure of the EC system is key to ensure its effective integration. The equipment should be capable of fulfilling the energy requirements of the buildings while maintaining compatibility with the system. The optimisation process involves considering two types of components, namely fixed and variable size, both of which are commercially available. The optimal size and configuration of the energy system can be achieved by determining the number of installed fixed size equipment and the size of variable size components including boilers, compression chillers, and thermal storages.

Figure 4. DHCN pipelines superstructure [5].

The interest rate is assumed to be 5%, while lifespan is determined to be 30 years for DHCN, 20 years for PV, ST panels, and TS, 15 years for ICE, MGT, ABS, and HP, and 10 years for BOI and CC. Operation costs are also considered, which include fuel and electricity costs. The price of natural gas, biomethane, purchased electricity, and sold electricity are introduced in the next section and specified for different scenarios. CO_2eq emissions related to electricity, natural gas, and biomethane consumption are taken from literature. Electricity carbon intensity was assumed to be 0.356 kgCO_2eq/kWh, natural gas carbon intensity 0.202 kgCO_2eq/kWh [5], while biomethane was assumed to produce zero net emissions [22] as the considered CO_2eq emissions for this work are only the ones related to the energy resources.

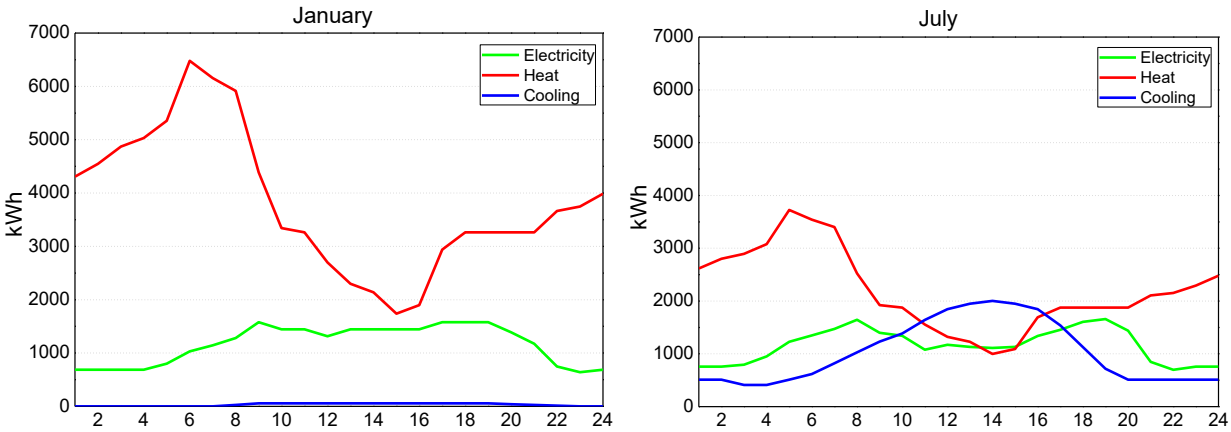

Figure 5. Hospital demands for working days of January and July.

5. Results and discussion

In order to have a reference case, a conventional solution (CS) scenario is designed, which reflects the current reality in most cases. In this scenario, electricity is obtained from the electric grid, while a local boiler (BOI) and a local compression chiller (CC) are used to meet heating and cooling demands, respectively. Heat and cooling storage systems were also taken into account to support the BOI and CC. In this case, there is no connection between the buildings, which means that there are neither DHCN pipelines linking them nor peer-to-peer electricity sharing. For a detailed CS schematic diagram, the reader may refer to reference [5]. In this scenario and for all the nine buildings combined, the total annual cost was 4370.7 k€/y

while the total annual emissions were 11,281.2 ton/y. These results are considered as the references to calculate the potential decrease in total costs and emissions.

For this work, a multi-objective optimisation of the EC was conducted considering the following scenarios:

- Scenario 1: Grid-connected - natural gas consumption
- Scenario 2: Grid-connected - biomethane consumption
- Scenario 3: Grid-isolated

In line with the “Fit for 55” package from the EU [12], these scenarios have, as the main objectives, the reduction of the total annual CO_2eq emissions from the CS scenario, while reducing also the total annual costs. The Grid-connected scenario means that the EC is allowed to buy electricity from the national grid at 170 €/MWh and to sell it, also to the national grid, at 100 €/MWh [5]. The difference between these two scenarios is that they are analysed also for two types of gas consumption: natural gas or biomethane. For this work, no proportion between them was considered for any of the scenarios. The purchase price for gas was dependent on the type of consumption: for CHP equipment or for boilers. For the scenario with natural gas consumption, the purchase price was 45 €/MWh (CHP) and 60 €/MWh (boilers) [5]. For the scenario with biomethane utilization, the purchase price was 52 €/MWh (CHP) and 70 €/MWh (boilers) [19].

5.1. Scenario 1: Grid-connected – natural gas consumption

Figure 6 shows the Pareto curve for scenario 1 and the comparison with the CS scenario. Tables 1, 2, and 3 present, respectively, the configurations for each building for points A, B, and C in the Pareto curve. Point A represents the optimal economic optimisation solution, point C represents the optimal emissions optimisation solution, while point B represents the optimisation solution which has the same emissions level as point C, but with 68.5% of the cost.

In the comparison between scenario 1 and CS scenario, one can observe that the lowest reduction in CO_2eq emissions was obtained for point A (optimal economic solution), which resulted in 34% less CO_2eq production. For the comparison between CS scenario and the optimal emissions solution (point C), the CO_2eq emission reduction was 51%. However, very similar level of reduction can be reached through the trade-off solution represented by point B, i.e., with a decrease of 31.5% on the total annual costs (which represents 1307.3 k€/y), the EC will still emit around half of the emissions resulted from the CS scenario. Such a fact can be explained by the amount of equipment installed by the solution in point C (Table 3). As the simulation, in this case, is not worried about costs, it will find a solution that has minimum emissions no matter how many components would have to be installed. One of the main characteristics of the model is that the economic sub-model is relatively more complex than the one for emissions. Therefore, when reducing emissions is the only target, the simulation will not do further calculations once it has found the optimal solution. Another plausible point of view for the results presented in Fig. 6 is a comparison between point A and B. The obtained results show that an increment in economic cost of 24.5% is capable of reducing the total CO_2eq emissions by 26%. Assuming point B as the best trade-off solution, the results regarding scenario 1 have demonstrated that the EC has the potential of cutting emissions by 51% (representing almost 5800 ton of CO_2eq/y) while reducing costs by 35% (representing savings around 1530 k€/y), when compared to CS scenario.

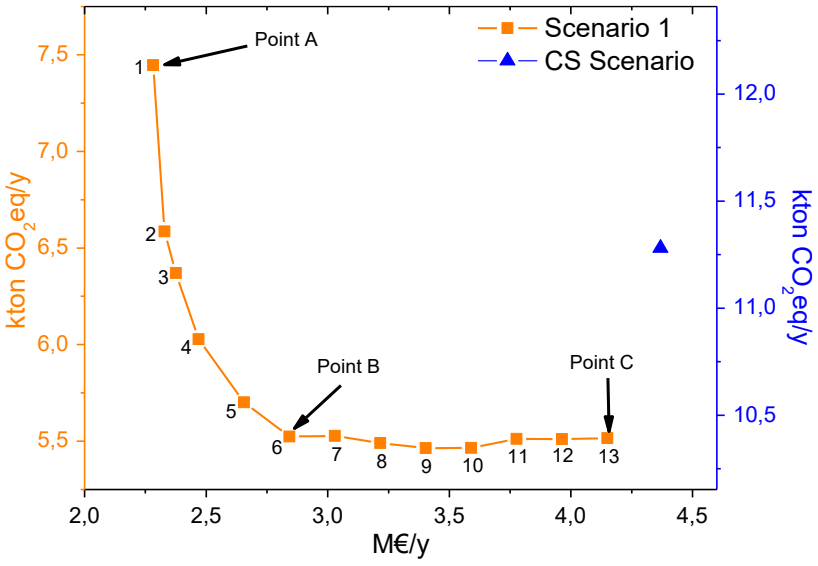

Figure 6. Pareto curve for scenario 1 and CS scenario data.

By analysing Tables 1 and 2 from the point of view of the communication between the EC and the national electric grid, it is possible to reveal some insights. The total electricity purchased by the EC was 1.18 MWh and 8168 MWh, while the total electricity sold by the EC was 3049.8 MWh and 819.1 MWh, for the optimal solutions from point A and B, respectively. Point A, which is the optimal economic solution, bought way less electricity and sold considerably more electricity compared to point B, i.e., the system of point A tried to compensate expenses related to investment, operation, and maintenance costs by selling more electricity. Moreover, the solution in point B installed 15% less engines (ICE), two thirds of heating storage (HST), one third of cooling storage (CST), and installed 43 times more solar thermal panels (ST), when compared to point A. Also, solution from point B installed around 50% more heat pumps (HP) and compression chillers (CC), which explains the higher level of electricity bought and the lower installed capacity of absorption chillers (ABS) (which is coherent with the lower installed capacities for ICE). In summary, point B saved emissions with respect to point A by consuming considerably less natural gas.

5.2. Scenario 2: Grid-connected – biomethane consumption

In agreement with the EU 2030 target plan [11] for a more ambitious and cost-effective direction to reach the carbon neutrality by 2050, this section has been thought as a possible scenario to help EU achieving its environmental goals.

By picturing scenarios where the proportion of biomethane in the natural gas grid is increasingly higher, it is reasonable to infer that emissions in scenario 1 would be increasingly lower (biomethane has been considered a net-zero CO_2eq emitter [22]). From this point of view and considering the limit case of a natural

gas grid in which its methane content is completely replaced by biomethane, this work analysed the EC compared not only with the CS scenario, but also with scenario 1.

Figure 7 shows the Pareto curve for scenario 2, while Table 4 shows each building configurations for points D, in the Pareto curve, which represents the optimal economic solution. The first reasonable comparison is between points A and D (Figs. 6 and 7), which represent the optimal economic solutions for scenarios 1 and 2. The total annual costs for these solutions were, respectively, 2282.1 k€/y and 2587.8 k€/y, while the correspondent CO_2eq emissions were 7446.4 ton of CO_2eq/y and -457.1 ton of CO_2eq/y. Therefore, one can observe that an increase of 13.4% in the total annual costs (around 305.7 k€/y) allowed a reduction of 106% in the total annual CO_2eq emissions, which means that the emissions were cut off and then compensated by almost 460 ton of CO_2eq/y. This happened due to the CO_2eq emissions compensation when electricity is sold to the national electric grid. Although the total electricity sold in solution of point A was more than 2 times higher than that of point D, the fact that the biomethane emits way less CO_2eq than natural gas (net-zero for this work) has contributed for the dominance of the electricity compensation. By comparing Tables 1 and 4, it is possible to observe that, besides buying less electricity from the national grid, the solution of point D installed 10% less engines (ICE). To compensate the missing heat production, boilers (BOI) installed capacity for point D was more than five times higher with respect to point A. Also, solar thermal panels (ST) installed capacity for point D was more than three times higher than that of point A, which reflects the search of the model for more economical solutions.

Another reasonable comparison would be between points B and D (Figs. 6 and 7). As explained in section 5.1, point B represents the selected trade-off solution for scenario 1. The total annual cost for that solution was 2842.4 k€/y, while the total annual emissions 5523.5 ton of CO_2eq/y. In this case, there were reductions for both the costs (-9%) and emissions (-108%). Regarding emissions, the same thing happened as for the comparison between points A and D, i.e., emissions were cut off and compensated by the dominance of the electricity sold. As can be observed from Tables 2 and 4, the reduction on costs (around 255 k€/y) were due to a substantial reduction of installed CC and ST. They were reduced, respectively, by 13 and 15 times from solution in point B to the one in point D. As a way to compensate this reduction, it was installed three times more BOI, two times more ABS, and four times more cooling storage (CST).

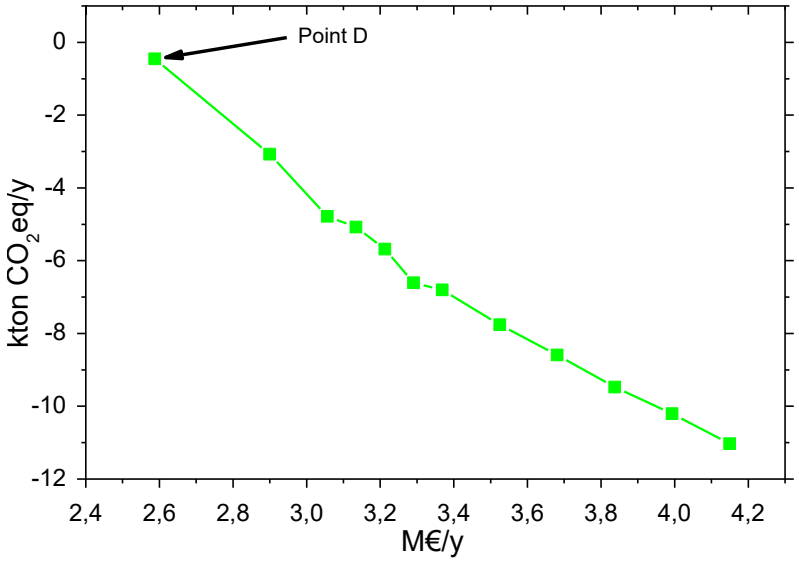

Figure 7. Pareto curve for scenario 2.

Table 4. Scenario 2: optimal emissions solution (point D).

Building	ICE [kW]	MGT [kW]	BOI [kW]	ABS [kW]	HP [kW]	CC [kW]	PV [m²]	ST [m²]	HST [kWh]	CST [kWh]
1	140	0	105	0	0	1	0	11	1579	826
2	840	0	0	420	0	0	0	0	4000	805
3	0	0	0	0	0	0	0	53	180	335
4	50	0	0	0	0	0	0	0	523	0
5	0	0	57	0	70	6	0	14	58	1200
6	0	0	62	0	0	0	0	13	58	1028
7	1200	0	0	525	630	15	0	0	4000	3007
8	0	0	10	0	70	0	0	0	0	0
9	280	0	0	0	0	0	0	0	1802	0

5.3. Scenario 3: grid-isolated

In the same direction of reducing CO_2eq emissions and primary energy consumption, another plausible scenario would be a completely isolated EC from the national electric grid. In this scenario, it was evaluated also the operation with natural gas or biomethane. The results demonstrated that a grid-isolated EC is not attractive from the economic and environmental viewpoints, either for natural gas or biomethane, which is in agreement, for instance, with references [23,24].

For the natural gas case, the optimal economic solution for an off-grid EC was 9.3% higher when compared to the optimal economic solution for grid-connected EC (point A, Fig. 6), which represents 212 k€/y. When the optimal CO_2eq emissions solution is analysed, the increase is even higher. The correspondent off-grid solution emits 21.2% more CO_2eq if compared to the equivalent solution for grid-connected (scenario 1). Besides, for this exact same comparison, the off-grid solution costs 2.2 times more.

In the case of biomethane, as expected, the emissions resulted zero. This is because the biomethane was considered net-zero CO_2eq emitter and there is no electricity bought from the main grid. When compared to the equivalent grid-connected solution (point D, Fig. 7), the grid-isolated one held a slight increase of 0.4% (which represents 12.6 k€/y) in the total annual costs. However, the grid-connected solution allows a CO_2eq compensation of almost 460 ton of CO_2eq/y. Moreover, considering the grid-connected (scenario 2), it could be possible to increase the CO_2eq compensation by around nine times by increasing the total annual costs by only 18%.

5.4. Brief comparison to carbon market and payback evaluation

As introduced in section 1, one of the foreseen directives from the “Fit for 55” package of the EU regards an update to the EU emissions trading system (ETS). According to the European Commission [25], international carbon markets have the potential to serve as a crucial factor in the cost-effective reduction of worldwide GHG emissions. This is demonstrated by the rising of emissions trading systems globally. In addition to the EU ETS, various national and sub-national emissions trading systems are currently in operation or being developed in several countries including Canada, China, Japan, New Zealand, South Korea, Switzerland, and the United States.

With lower environmental impacts and higher energy efficiencies, ECs have a substantial cost advantage if inserted in a carbon trading ecosystem [26]. Moreover, a personal carbon trading (PCT) scheme has been discussed in literature [27,28], as a promising and innovative policy tool to mitigate carbon emissions at the household and individual level, and to encourage the adoption of low-carbon lifestyles. In this sense, the present work analysed the cost of CO_2eq emissions reduction based on the data from Fig. 6. The reference cost was the one resulted from the optimal economic solution for scenario 1 (point A).

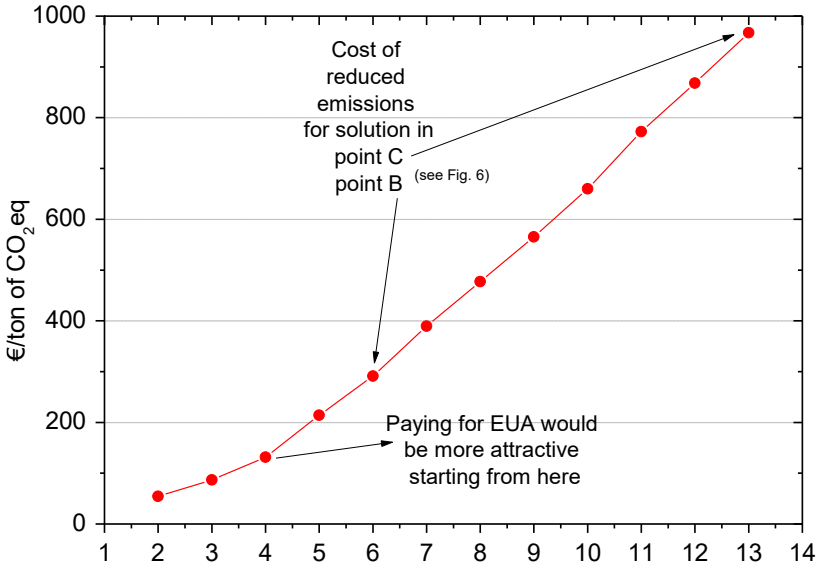

Figure 8. Cost of reduced CO_2eq emissions for each solution in the Pareto curve of scenario 1. Solutions 2 to 13 (see Fig. 6) are confronted to solution 1 (or point A) in order to compare results with the carbon market.

Figure 8 shows the cost of reducing CO_2eq emissions from solution number 1 (point A, Fig. 6) to each one of the other 12 solutions in the Pareto curve of scenario 1. Such cost raises from 54 (solution 2) to almost 970 €/ton of CO_2eq (solution 13). Considering an average European Emission Allowance (EUA) of 85 €/ton of CO_2eq [29] for the past year, the data suggests that, starting from the point indicated in Fig. 8, it would be economically more attractive to pay for the correspondent amount of EUA, rather than choose a solution for

the EC with a lower CO_2eq emissions level. In order to have an idea, if solution in point B would be chosen over that of point A (Fig. 6), the cost increase would be around 560 k€/y. On the other hand, if point A is chosen and the correspondent EUA is paid, the cost increase would be around 163 k€/y. Note that all the solutions of the Pareto fronts depicted in Figs. 6 and 7 present both lower economic cost and lower greenhouse gas emissions than the conventional solution (CS) and, therefore all of them represent an improvement.

Table 5 presents the payback (PB), cost reduction (CR), and CO_2eq emissions reduction (CO_2R) for the four main solutions analysed in sections 5.1 and 5.2. All solutions were confronted with the CS scenario data. Although point C (optimal emissions solution) owns one of the highest CO_2R, its cost decrease was the lowest one, while its payback was the highest one. By comparing points A and B from the CO_2R point of view, the latter would be the best one. However, by joining the perspectives of PB, CR, and carbon market, point A solution would be more attractive since it would have lower PB and lower overall costs (including the payment of EUA). In the perspective of a gas grid fed 100% by biomethane, point D would be attractive if the goal would be to cut off and compensate CO_2eq emissions.

Table 5. Evaluated solutions, payback (PB), cost reduction (CR), and CO_2eq emissions reduction (CO_2R) with respect to the CS scenario.

Solutions (points)	PB (y)	CR (%)	CO_2R (%)
A	1.5	– 48	– 34
B	1.8	– 35	– 51
C	4.7	– 5	– 51
D	1.8	– 41	– 104

6. Conclusions

In order to cover new climate change concerned policies, such as the “Fit for 55” package from EU, and reach a low-carbon future, solutions should be presented throughout different sectors. This is the case, for example, of the efficiency of energy systems and buildings. For that reason, this paper assessed the performance of different scenarios for an EC, through a multi-objective optimisation approach. The EC comprises nine third sector buildings located in Pordenone, northeast of Italy, and was modelled through a mixed integer linear programming (MILP) model. The evaluated scenarios were: 1) Grid-connected - natural gas consumption, 2) Grid-connected - biomethane consumption, and 3) Grid-isolated.

The results have shown that, as expected, all three scenarios present better trade-off solutions when compared to the CS scenario (reference case), i.e., lower total annual costs and CO_2eq emissions. However, each one of the three scenarios presented its particularities.

For scenario 1, which represents the current scenario of natural gas consumption, the selected trade-off solution according to the Pareto curve (Fig. 6) was the one of point B. This solution holds a total annual cost 31.5% (or 1307 k€/y) lower when compared to the optimal CO_2eq emission solution (point C, Fig. 6), but with approximately the same emissions level. When compared to the optimal economic solution (point A, Fig. 6), the total annual cost of the solution in point B is 24.5% (or 560 k€/y) higher, while its total annual CO_2eq emissions is 26% (or 1923 ton of CO_2eq/y) lower. Nevertheless, if the carbon market is considered, and with the current price for each ton of CO_2eq (March 2023), the solution in point B would no longer be economically attractive. Instead, the solution from point A along with the correspondent EUA payment would result an economic saving of around 70% with respect to the solution in point B. Besides, point A solution owns the lower payback among the analysed solutions.

Scenario 2 represents the limit case of a natural gas grid in which its methane content is completely replaced by biomethane (which was assumed a net-zero emitter for this work). When comparing the optimal economic solutions between scenarios 1 and 2, one can see that an increase of 13.4% in the total annual costs (or 306 k€/y) could allow a reduction of 106% in the total annual CO_2eq emissions, i.e., emissions would be cut off and, besides, a CO_2eq compensation of 460 ton per year would be obtained. Therefore, considering the possibility of moving from the optimal economic solution in scenario 1 (point A) to the optimal economic solution in scenario 2 (point D, Fig. 7), the cost per ton of reduced CO_2eq emissions would be economically more attractive when compared to the carbon market.

The third analysed scenario is the one where the EC (in both scenarios 1 and 2) would be completely isolated from the national electric grid. Results demonstrated that the off-grid EC version is not attractive from economic or emissions viewpoints. In scenario 1, the total annual cost and CO_2eq emissions of the EC would be, respectively, 9.3% and 21.2% higher. In scenario 2 the cost increase would be only 0.4%, however, the EC would not be able to compensate CO_2eq emissions by selling electricity to the grid.

Therefore, based on the obtained results, the implementation of an EC as the one analysed in this work would help not only to cope with new climate change policies (such as “Fit for 55”), but would be also economically more attractive than the current scenario.

Energy performance of loading and hauling operations in opencast mines

Lalit Kumar Sahoo*, Seema Ashishan Topno

CSIR-Central Institute of Mining & Fuel Research, Nagpur Research Centre, Nagpur, India, lalitsahoo@yahoo.co.in

Abstract:

Loading and hauling machines accounts for significant share of the total energy usage in large opencast mines. Major share of power is consumed in electric shovels used for loading operations and accounts for 32% of the total electricity usage in mine. Diesel is also used for operating hauling machines (dump trucks) in opencast mine and accounts for 56% of the total diesel consumption. In this paper, a methodology is proposed for calculating overall energy consumption in major energy intensive mining processes such as loading and hauling operations of the coal mine. Statistical approach has been used to estimate minimum SEC of a specific mine based on the annualized data. A linear regression method has been used to develop a mine specific model for estimating SEC by the correlation between SEC and composite production. A case study of an Indian opencast mine is presented to illustrate the results. Minimum SPC of electric shovels is calculated as 0.15 kWh/cum whereas the best operating SDC values of dump trucks operating in same mine is 0.47 l/cu.m. The overall SEC of loading and hauling operations calculated for the same opencast mine is 17.76 MJ/Cu.m and SEC of total operation in mine is 27.2 MJ/Cu.m. The best practices opencast mine without dragline from the literature is 26.3 MJ/cu.m.

Energy performance, Statistical approach, Loading, Hauling, Opencast mine, Specific energy consumption

.

1. Introduction

Dump trucks are used worldwide for handling of ore and waste in most of the opencast mines. It is considered as one of the versatile heavy earth moving equipment. The diesel consumption in dump trucks accounts for about 56 % of the total diesel consumption in opencast mine [1]. Dump trucks are used for material handling in opencast mines using shovel- truck combination. The transportation network of mine includes a fleet of dump trucks moving between crushers/dumping stations and shovels. The diesel consumption in dump trucks depends on the speed, material handling rate and distance between loading and unloading point. Benchmarking and optimization models are generally used for calculating minimum energy consumption. An energy benchmarking model is developed by Sardeshpande et al. for calculating minimum energy consumption in glass furnace [2]. Most of the exercises on optimization in transportation are based on linear programming approach for reducing cost. Energy efficiency of dump trucks operating in opencast mine has been rarely analyzed. The optimization of loading and transport system in opencast mine has been done to optimize number of trucks required serving at loading point, number of trips per hour and theoretical output of dump trucks [3]. Optimization of journey schedule of high capacity dump truck has been done by Vasil'ev et al. to reduce the travel time of dump truck [4]. Fuel consumption depends on the inherent resistances such as gradient resistance, drag force and rolling resistance. Fuel consumption rate is taken as objective function and solved by Langrage's multiplier method with constraint of total time. Solving the optimization problem shows that fuel consumption is minimum by keeping speed profile constant for level, ascending and descending gradient [5]. The results of study made Tolouei et al confirmed that fuel consumption increases as mass increases and is different for different combination of fuel and transmission type [6]. A benchmarking model was developed by Sahoo et.al. for optimization of specific fuel consumption for dump trucks [7]. Specific diesel consumption (SDC) can be used as energy performance indicators to assess and compare the energy performance of hauling operations in operating mine.

Electric shovels dominate the electrical energy consumption in opencast coal mine and consume 32% of the total electrical energy usage [8]. Energy efficiency indices have been used by researchers to assess energy efficiency in mining process. Specific power consumption (SPC) has been used previously to describe the

performance of digging equipment and operators. Energy benchmarking using statistical approach has been done for commercial building [9]. Past studies showed that operator's proficiency plays a significant role in the productivity of shovels [10-13]. Energy efficiency of loading and hauling operations depends on the equipment, operating conditions, mine planning and operator's performance [10]. Specific energy consumption (SEC) is used as energy benchmarking index and is measured as the energy consumed to the production output (MJ/t, kWh/t etc.). Oskouei et al. revealed that the operator's skill affect the energy efficiency of the mining machinery [11]. The study done by Karpuz et al. revealed that there is an increase in digging power consumption with the increase in the cutting depth and operator's performance [12]. The results of simulation experiments conducted by Awuah-Offei, K. et.al revealed that an operator operating near optimal levels with a 44 cu.m bucket capacity can save over $114,000/- in electricity costs for digging cycle alone as compared to an average operator [13].

From the literature review it is concluded that limited literature addresses benchmarking of specific energy consumption for loading and hauling operations in opencast mine using statistical approach. In this paper a methodology is developed for benchmarking of specific energy consumption for loading and hauling operation and validated with energy performance for best operating mine.

1.1. Mining process

Drilling and blasting is the first process of surface mining for fragmentation of overburden and coal seams. An efficient blasting result in lower cost of extraction as the particle size and density of material affects the energy consumption of an opencast mine. Excavators/Hydraulic backhoe, shovels are used for loading material in to dump trucks. Dump trucks are then used to transport coal and overburdens to the specified dumping stations. The fuel consumed in heavy earth moving machines operating in mines varies with mine topography, distance, material handled and the capacity utilization. Pie charts showing the fuel consumption and power consumption of Dipka opencast mine of South Eastern Coalfields Ltd (SECL) is shown in Fig.1a and Fig 1b. From the Fig. 1a, dump trucks consume about 56% of total diesel consumed in opencast mine.

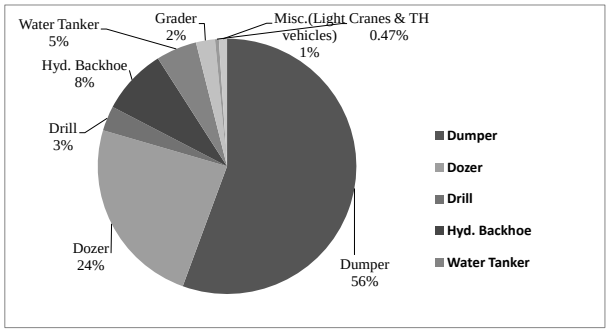

Fig 1a Diesel consumption profile in opencast mine of SECL

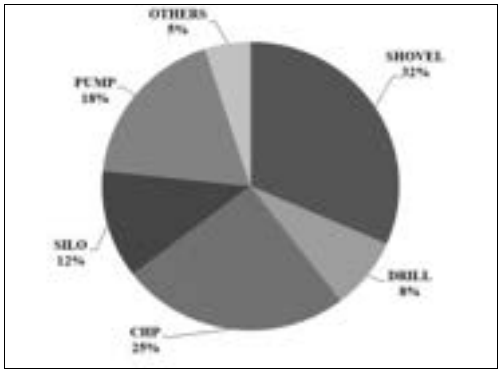

Fig 1b Power consumption in opencast mine of SECL

1.2. Objective

Diesel is used as fuel for operating heavy earth moving machines (HEMMs) such as dump trucks, dozers and drills etc. in an opencast mine. The diesel consumption in haul trucks used for hauling operation consume 32% of total energy consumed in an opencast coal mine and varies with mine topography, bulk density of coal and overburdens and operating practices of haul trucks. Similarly loading operation consume significant energy consumption. Electric shovel consumes 32% of total electrical energy consumption in opencast mine. Hence, these two operations such as loading and hauling consume significant energy in opencast mine. The objectives of the paper are given as follows.

1) Evaluate the energy performance of loading and hauling operations
2) Propose a method for energy benchmarking of shovels and sump trucks
3) Study the variation of SDC of hauling operations with composite production
4) Study the variation SPC of loading operation with composite production
5) Compare the benchmark SEC with best practices mines.

2. Methodology for Energy Benchmarking

2.1. Statistical Benchmarking

Statistical approach has been applied by many researchers for benchmarking energy consumption of commercial buildings, agriculture and industrial sectors. Benchmarking energy consumption in commercial building has been done by Chung et al. using a statistical approach [14]. Chauhan et al., and Omid et al. have also used statistical methods for benchmarking energy for agriculture [15,16]. Benchmarking energy efficiency for Dutch industries has been done by Phylipsen et al.[17]. These approaches are defined as statistical energy benchmarking. The loading and hauling machines in opencast coal mines can implement the idea of energy benchmarking. A study was conducted in a large opencast coal mine in India by author to apply statistical benchmarking methodology [18]. In present paper, the statistical approach has been applied for benchmarking energy consumption for two major operation:

- Loading operations using electric shovel
- Hauling operations using dump trucks

The statistical benchmarking can quickly estimate the minimum energy required per cubic meter of composite coal production in an opencast mine. The statistical benchmarking approach uses specific diesel consumption (SDC) as energy performance indicator for dump trucks, specific power consumption (SPC) for electric shovels and specific energy consumptionn(SEC) for overall energy consumption in loading and hauling operations in opencast mine. The SEC of the best performing year is considered as the energy benchmark target from the annualized data for the specific mine equipment. The monthly data is not appropriate due to seasonal variations of energy performance of mining equipment during rainy and off rainy season. In case of benchmarking mine quipment of different coal mines, multiple mine equipment of different capacities are compared to evaluate the minimum SEC. The specific energy consumption (SEC) of the mine is calculated from the aggregate energy consumption of both loading and hauling operations for electric shovels and dump trucks.

2.1. 1. Energy benchmarking for loading operations

Energy benchmarking of loading operations is the minimum SPC of electric shovels operating in the mine from best operating value. A benchmark SPC of the electric shovels is calculated by comparing progressive SPC based on the aggregated annualized data of power consumption and material handled. A mine specific model of benchmarking has been developed using linear regression analysis by correlating the SPC and composite production. The model helps in predicting the SPC of the mine equipment.

Electric shovels are used for loading materials in to the dump trucks in large opencast mines and consume significant quantity of electrical energy. Smaller opencast mines use diesel operated excavators for loading operations. Depending on the production requirement the machines are deployed by production supervisors. The SPC of electric operated shovel is obtained from the ratio of annualized energy consumed in shovel to the annual material handled and is given as:

$$SPC_j = \frac{\sum_{i=1}^{12} E_{c,ij}}{\sum_{i=1}^{12} Q_{t,ij}} \quad (1)$$

2.1. 2. Energy benchmarking for hauling operations

Specific diesel consumption (SDC) is an energy performance index to assess energy efficiency of heavy earth moving machines (HEMMs) operating in an opencast mine. Dump trucks consume major share of diesel consumption in mine. Therefore, SDC should be monitored regularly for targeting and minimizing diesel consumption in mine. The methodology for practical benchmarking approach for calculating SDC has been discussed in this section. The specific diesel consumption of single dump truck is defined as the ratio of diesel consumed during field trial period (t) to the material handled. The material handled is determined as the product of shovel bucket capacity, actual numbers of buckets filled, number of trips of truck and fill factor.

$$SDC_1 = \frac{m_f(t)}{C_b n_b(t) x_d(t) C_f} \quad (2)$$

Dump trucks are used for transportation of coal and OB from shovels to CHP or OB dumping stations in opencast mine and consume significant quantity of diesel for its operation. Dump trucks are generally accommodated in the workshop of the mine from where it goes to mine site for operation as per the planning and requirement of production supervisors. Diesel is filled once a day at diesel filling station located near the workshop. Diesel is issued to dump trucks of different capacity ($i = 1,2,3$) for example 240t, 120t, 100t trucks.

If 'Q' is material handled by different capacity dump trucks, the benchmark SDC (SDC_{BM}) of multiple dump trucks is obtained using following formula for rainy as well as off rainy season. Minimum SDC is considered as benchmark for same capacity dump trucks operating in same roots. For different roots, average value is taken.

$$SDC_{BM} = \frac{Min\sum_{i=1}^{n} SDC_i Q_i}{Q} \quad (3)$$

Where,

$$Q = \sum_{i=1}^{n} Q_i \quad (4)$$

Average SDC of dump trucks for of dump trucks for rainy/off rainy season is estimated as:

$$SDC_{Avg} = \frac{Avg\sum_{i=1}^{n} SDC_i Q_i}{Q} \quad (5)$$

Eq (3) to Eq (5) are used for calculating benchmark SDC.

3. Case study of large coal mines

A case study of Dipka opencast coal mine of M/s South Eastern Coalfields Ltd (SECL), Bilaspur has been presented for assessing the practical benchmark SDC [18]. Dipka opencast mine of M/s. SECL lies in the latitude 22^0 18'59" – $22^0$19'43" and longitude 82^0 30'47" - $82^0$33'34" and bears the toposheet No. 64J/11 in the *Survey of India* and is located in Korba district of Chattisgarh, India. The installed production capacity of the mine is 25 MTPA with average stripping ratio of the mine is 1 m^3/Te of coal. Diesel is used for operating different HEMMs including dump trucks. Dump trucks consume about 56% of the total diesel consumption. The minimum SDC of the mine from past 4 years data is 0.81 l/cu.m. whereas the benchmark of the mine by comparing with five operating mines of different production capacity is 0.66 l/cu.m. Dump trucks used in hauling operation consume major share of diesel consumption and therefore the benchmarking has been done to evaluate minimum SDC based on statistical approach using methodology given above in para 2.1.2.

Dump trucks of different capacity (240t, 120t, 100t) and model of BEML/Caterpillar/Terex are operating in mine for transporting overburden (OB) and coal from different levels of mine to coal storage/ OB dumping stations. BEML dump trucks uses Cummin's engine whereas Caterpillar has its engine of the own make. Engine performance is very important for fuel economy in mine. Selection of dumper with a fuel-efficient engine helps in reducing SDC of the dump trucks. The engine specifications of dump trucks are given in Table 1.

Table 1 Engine specification of dump trucks

PARAMETERS	CAT 793D (240t)	CAT777 (100t)	BH 100 (100t)	MK 30 /MT 3000 (120t)
Make	Caterpillar	Caterpillar	BEML/Cummins	Detroit diesel
No of cylinders	16	12	12	16
Bore & stroke	170mm x 215mm	145mm x162mm	140mm x165mm	130mm x 150 mm
Displacement	78 lits	32.1 lits	37.7 lits	32 lits
Gross power	1801 kW,2415 hp	765 kW,1025 hp	783 kW, 1050 hp	898 kW

Max torque	9553 N-m	5286 N-m	4629 N-m	-
Engine speed	1800 rpm	1750 rpm	2100 rpm	1900 rpm
Gear ratio	28.1:1	17.49:1	22.21:1	28.8:1
Payload	240 tons	100 tons	91.5 tons	108.8t
Volumetric capacity	96 m^3	41 m^3	41.5 m^3	49.4 m^3
Heaped capacity	129 m^3	60.1m^3	61 m^3	69.4 m^3

P & H electric shovels operating in Dipka opencast coal mine of M/s South Eastern Coalfields Ltd (SECL), Bilaspur, India has been presented in this paper for energy performance assessment using statistical approach. The annual electrical energy consumption of the mine is 49.3 GWh/y in 2014-15. The connected load of the electrical machinery in mine is 38.49 MW. The electric shovels (four numbers of 10 cu.m. and two numbers of 42 cu.m.) consume 32% of the total electrical energy. The power rating for hoist motors, crowd motor, swing motor and propel motors of electric shovel is 1887 kW, 547 kW, 746 kW and 716 kW respectively. The connected of electric shovel is 7235 kW (2 hoist motors, 1 crowd motor, 2 swing motors and 2 propel motors). The physical parameters of P & H electric shovel are given in Table 2. Five dump trucks were allocated to the shovel at the pit for hauling operation. The loading cycle of shovel include five different operations; digging, swinging, unloading, swing back and positioning/waiting time.

Table 2 Physical parameters of P & H electric shovel

Parameters/Model	Value	Unit
Model	4100C	
Nominal dipper capacity	45.9	cu.m.
Nominal Payload	81.6	t
Rated suspended load	154.2	t
Bucket fill factor	0.80	(assumed)

4. Results and Discussions

The variation of SDC with material handled for sample dump trucks during field measurement is shown in Fig.2a. From the analysis of results, SDC of dump trucks decreases with increase in material handling rate. The minimum SDC of 0.47 l/cu.m. is shown for maximum material handling rate of 348 cu.m./h for dump trucks with lead varies from 2.2 km to 2.97 km. The variation of SDC with monthly composite production shows non-linear trend and is shown in Fig 2b. Statistical approach of benchmarking considers minimum SDC of past 3 years progressive data to benchmark diesel consumption in mine. The analysis of annual progressive SDC showing monthly minimum and maximum value is shown in Table 3.

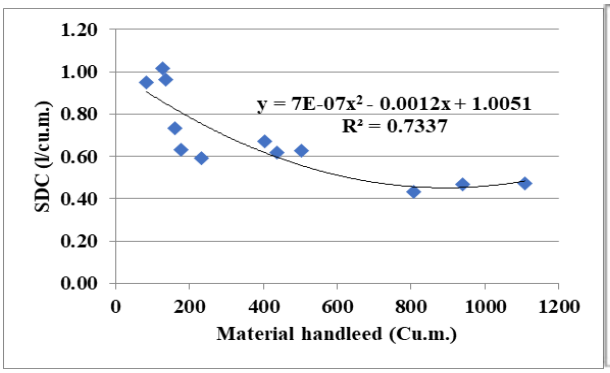

Fig 2a: Variation of SDC with total material handled

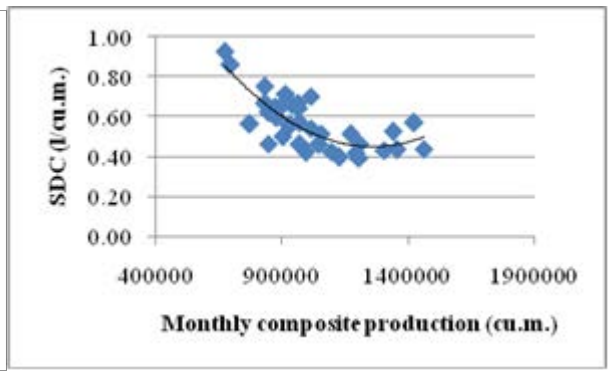

Fig.2b Variation of SDC of dump trucks with monthly material handled

Table 3 Analysis of progressive SDC of dump trucks for an opencast coal mine of SECL

Sample size:36 (monthly SDC); 03 (Annualized data of SDC)	SDC (l/cum)		
Year	Monthly Minimum	Monthly Maximum	Progressive
2012-13	0.60	0.93	0.69
2013-14	0.42	0.65	0.52
2014-15	0.39	0.66	0.47
Average	0.47	0.75	0.56

From statistical analysis, the minimum SDC of dump truck is 0.47 l/cu.m and average SDC is 0.56 l/cu.m. The progressive yearly variation of SDC is shown as Fig. 3a whereas the variation of SDC with material handled per hour is shown in Fig.3b from the actual measurement. The result of practical benchmarking is close to that by statistical approach. However, sometimes due to dynamic condition such as change of the haul road distance, material handles and operational practices statistical approach may not give accuracy in calculating the benchmark SDC. The disadvantage of statistical benchmarking is that it does not consider present operating conditions.

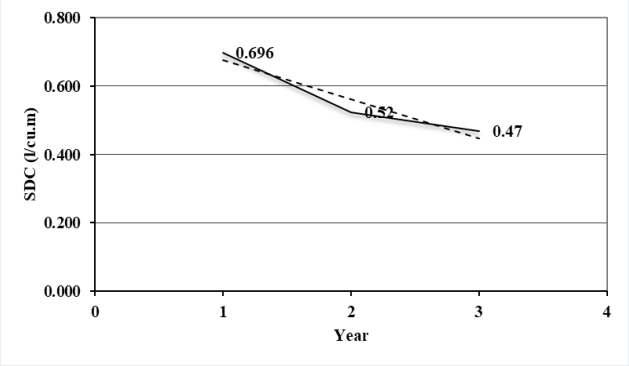

Fig 3a: Variation of progressive SDC

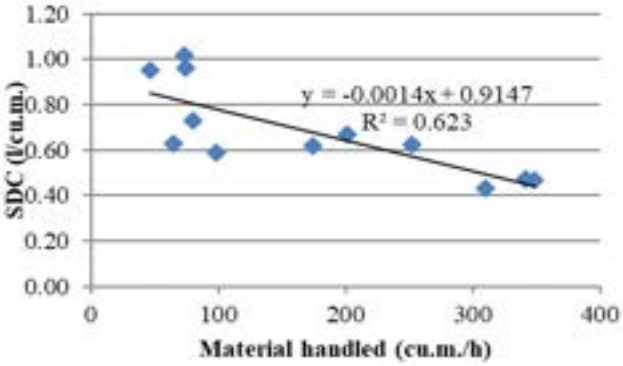

Fig.3b Variation of SDC of hauling with material handled

Statistical approach of benchmarking has also been applied for loading operation using electric shovel in large opencast mine. The annualized energy consumption and production data are used to calculate progressive SPC of the shovels operating in mine. Fig 4a shows the variation of SPC with composite production. The overall minimum SEC is then calculated to calculate benchmarking target for loading and hauling operation. Fig 4b shows the variation of overall SEC with composite production. Table 4 shows the minimum specific energy consumption of the loading and hauling operations. The minimum SEC is calculated as 17.76 MJ/cum in the year 2013-14.

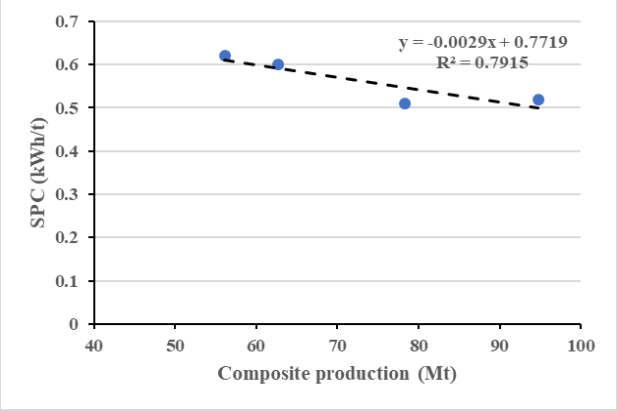

Fig 4a: Variation of progressive SPC with production

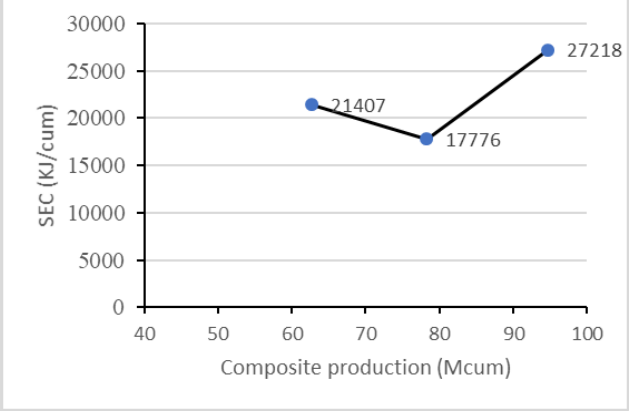

Fig.4b Variation of SEC of loading and hauling

Table 4 Analysis of progressive SDC and SPC of an opencast coal mine of SECL

	Energy performance values	
Mining operations		SEC (KJ/cum)
Hauling (SDC)	0.56	19756.8
Loading (SPC)	0.16	1651
SEC_{LH} (Year1)		21407.8
Hauling (SDC)	0.47	16228.8
Loading (SPC)	0.15	1548
SEC_{LH} (Year 2)		17776.8
Hauling (SDC)	0.7	24696
Loading (SPC)	0.44	2522
SEC_{LH} (Year 3)		27218

The result shows that both SDC and SPC decreases with increase in composite production in opencast mine whereas the overall energy consumption though increases with production, the minimum specific energy consumption target is assessed for lower production rate due variation in energy inputs and operating strategies for loading and hauling machines.

4.1. Best practices in opencast mines

The specific energy consumption of the best operating opencast coal mine for overburden handling taken from the literature is 26.9 MJ/cu.m.[12]. From the present benchmarking study the SDC of best operating coal mine with 92% overburden handling is 0.66 l/cu.m. for a large opencast mine and is equivalent to 25.4 MJ/cu.m. The present energy benchmark level of 25.4 MJ/cu.m. for Gevra opencast mine can be further minimized by improving operational practices and procurring new energy efficienct heavy earth moving machines like 240t dump trucks and optimising the number of dump trucks corresponding to the total numbers and capacity of electric shovels deployed in the coal mine. The benchmarking can be used for targeting and assessing the energy saving potential in opencast mining sector. A potential fuel saving of atleast 16 % is possible by comparing the minimum SEC with average SEC of the specific mine.

4.2. Energy saving potential

The fuel saving potential in the mine is estimated by comparing the minimum SEC and average SEC of the mine using Eq. (6) for bechmarking of a specific mine.

$$E_s = \frac{SEC_{avg} - SEC_{BM}}{SEC_{avg}} \quad (6)$$

The minimum SDC of 0.66 l/cu.m (25.4 MJ/cu.m) is obtained by comparing SDC of five opencast coal mines of different installed capacity. The capacity of the mines is variable and can be increased by increasing number of machines depending on the coal reserve of the mine. The diesel saving potential by comparing minimum SDC with average SDC is 16 %.

5. Conclusion

In the present paper, a statistical approach of benchmarking has been applied for calculating specific energy consumption (SEC) and is used as energy performance indicator for loading and hauling operations. The overall minimum SEC for loading and hauling operation is calculated as 17.7 MJ/cu.m.The benchmark SDC for of hauling operations is 0.47/cu.m whereas the benchmark SPC obtained for electric shovel is calculated as 0.15 kWh/cu.m. The mine specific model for benchmarking has been developed using linear regression method. There is a significant scope of diesel and power saving by use of this method in mine. A diesel saving potential of 16 % is estimated by comparing with benchmarking value and the overall saving potential of 19% is estimated on both loading and hauling operations in opencast coal mine. Though the result of

practical benchmarking is close to that by statistical approach, due to dynamic condition of mine operation such as haul road distance, material handling and operational practices statistical approach may not give accuracy in estimating the benchmark target. The disadvantage of statistical benchmarking is that it does not consider present operating conditions.

The statistical approach helps in quick estimation of benchmarking target for coal mines from the past data of diesel consumption, electrical energy consumption as well as composite production data of the mine. The benchmarking method can help in setting energy benchmarking target of the mine for continuous productivity improvement and energy saving in mine.

Abstract:

Cooling systems are becoming increasingly important around the world. While centralized heating systems have been around for decades, cooling systems tend to be something that is only kept for large buildings, and decentralized cooling has flourished and is becoming the first choice when it comes to comfort needs, disregarding the efficiency of larger systems.

In this work, TRNSYS was used taking advantage of the Wedistrict methodology to compare two different alternatives and analyze which technology fits better in a cold district solution. On one side, single-stage absorption chillers combined with solar thermal technologies (Fresnel) as its heat source, and on the other, compression chillers with high energy efficiency ratios combined with photovoltaic technologies were used.

The paper shows that the current technological state singles out the compression chiller as a more appropriate selection for variable demand systems, while leaving absorption chillers as a viable option for constant cooling demand systems where a high temperature heat source is available.

TRNSYS; District Cooling; Solar energy; Absorption chiller.

1. Introduction

The increasing temperatures throughout the world are leading to an expansion in cooling degree days (CDD), which leads to an increasing need for cooling systems worldwide. This trend is also visible in Europe, where the significance of CDD was previously overlooked while devising a cooling strategy. At present, CDD values are becoming difficult to ignore (Figure 1)[1].

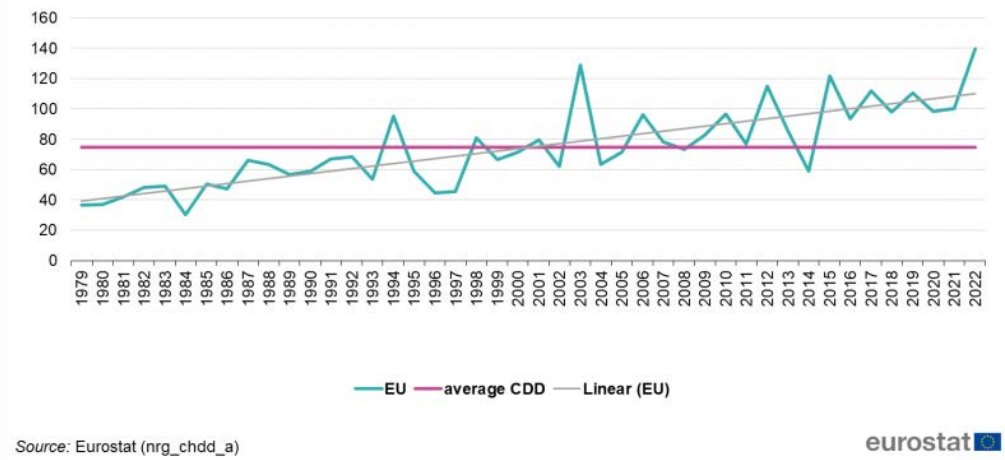

Figure 1. Cooling degree days statistics EU, 1979-2022.[1]

Two main cases have been analysed, the first one, photovoltaic panels have been used, and have been sized to be able to fully supply the compression chiller annually (Figure 2). In the other case, solar Fresnel panels have been sized to theoretically provide the energy needed for the conventional single stage absorption chiller, along with a natural gas boiler to ensure the correct inlet temperature for the chiller heat input (Figure 3).

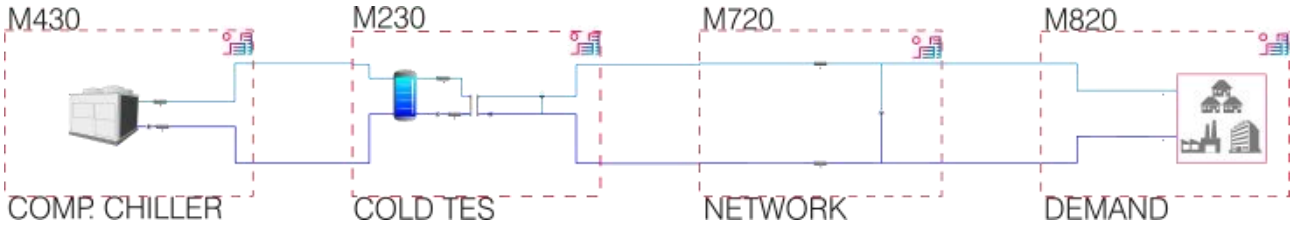

Figure 2. TRNSYS arrangement with tank.

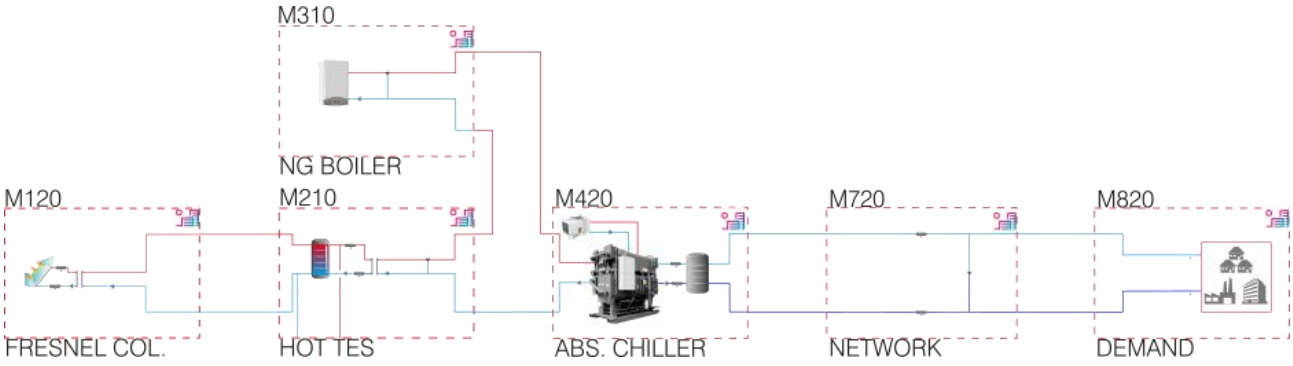

Figure 3. TRNSYS arrangement with absorption chiller with heat supply from solar energy plus boiler backup.

Different simulation approaches have been followed to arrive to correct plant sizes in order to compare technically and economically the results.

Both configurations have been simulated using TRSNYS (TRaNsient SYstems Simulation Program) following the modular methodology developed in the frame of the Wedistrict project [2]. Technical, environmental, and economic indicators have been calculated and analyzed [3].

2. Methodology

2.1. Software

TRSNYS (TRaNsient SYstems Simulation Program) software was applied in accordance with the modular methodology that was created specifically for the WEDISTRICT project.

This project studies the integration of innovative technologies for District Heating and Cooling (DHC) systems with an end goal of developing viable solutions for delivering fully renewable energy in climatization services [3].

The modular methodology is based in TRNSYS macros and decks. Macros are a series of TRNSYS types that are used together to reduce the number of connections to be done. The code to describe them has the letter "M" for "macro", followed by four numbers, the first three represent the code of the technology used, separated by the thousands in types of technologies (solar, storage, boilers, etc.), by the hundreds in different technologies between the same family, by the tenths in variations of the same technology. The unit is left in case the technology repeats itself in the same deck, due to the fact that TRNSYS, as many other software, does not allow variable name repetition.

WEDISTRICT macros have characteristics to improve the modularity and flexibility:

- Nomenclature: A standard nomenclature for macros, types, and variables
- Input and Output interfaces: Inputs and outputs variables are transmitted in and out of the macro by equation blocks. This method simplifies and reduces connections and allows replacing a macro by another more efficiently (Only a few connectors should be modified).
- Parametrization procedure: Parameters are variables that remain constant during the simulation time. A Python script has been developed to make this more fluent (from specific values calculate the majority of these parameters through correlations).
- Control strategy: Each macro has its own control strategy based on the technology represented. This method allows adding the same macro into different systems reducing the amount of control parameters to be set.
- Results: Each macro displays its own set of results and its internal calculations, such as energy and mass balance.

As an example, compression chiller macro has been taken (M4300). In this macro two different operation modes can be imposed, one in which the chiller works in series operation reaching an output temperature, and other, in which de chiller is controlled to work in parallel against a cold water storage to maintain a setpoint in the tank.

A simplified diagram is shown in Figure 4, along with its representation in TRNSYS. In the figure, heat flows are displayed in blue arrows (QCHI01 regarding the heat dissipated by the chiller, and QLsPI01 as the pipe losses), work flows are displayed in purple (WCHI01 as the power consumed by the electrical chiller and WPU01 for the pump), and mass flows with their corresponding temperatures are displayed in black arrows (MIn01/TIn01, MOu01/TOu01).

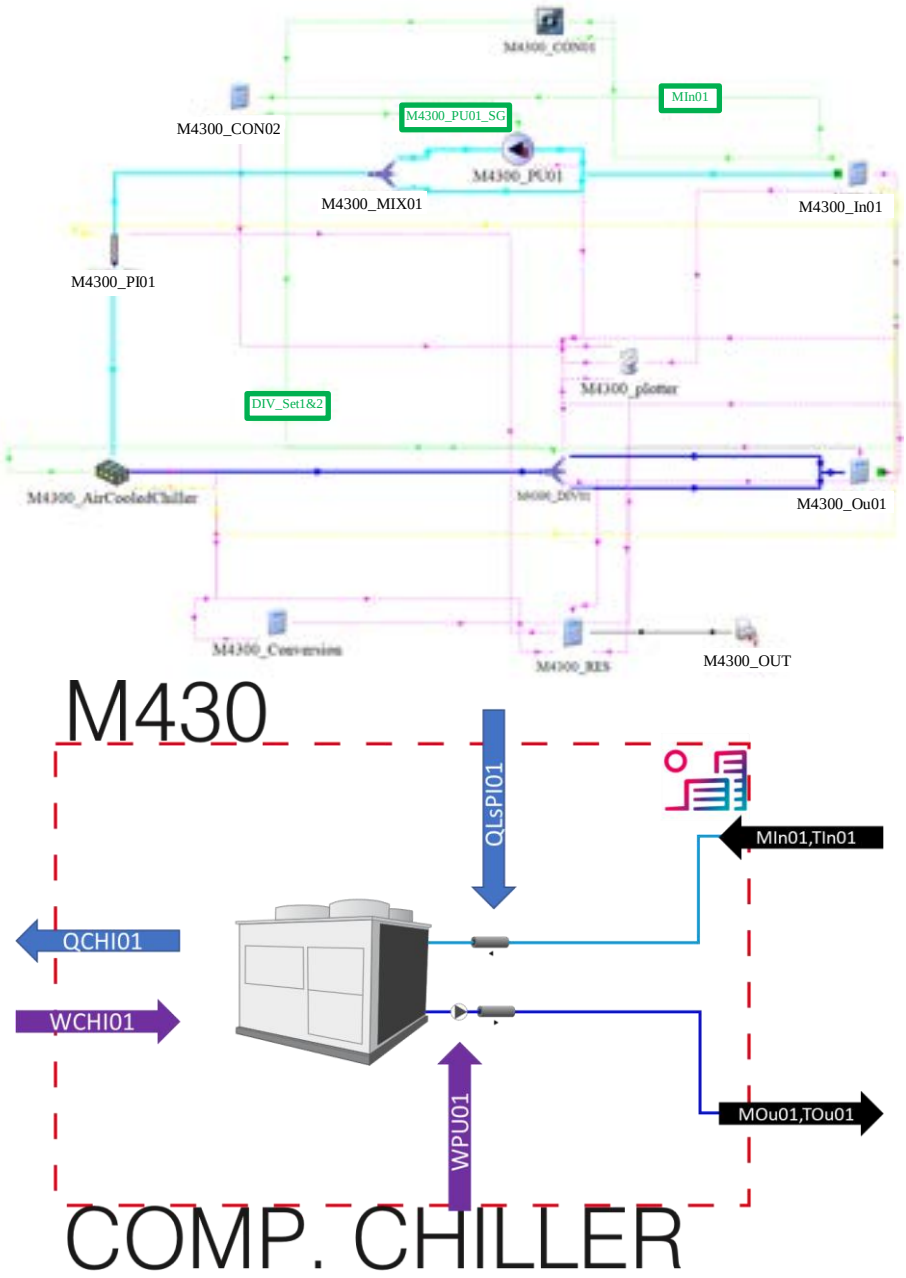

Figure 4. Compression chiller macro (M4300). Schematic diagram and TRNSYS translation.

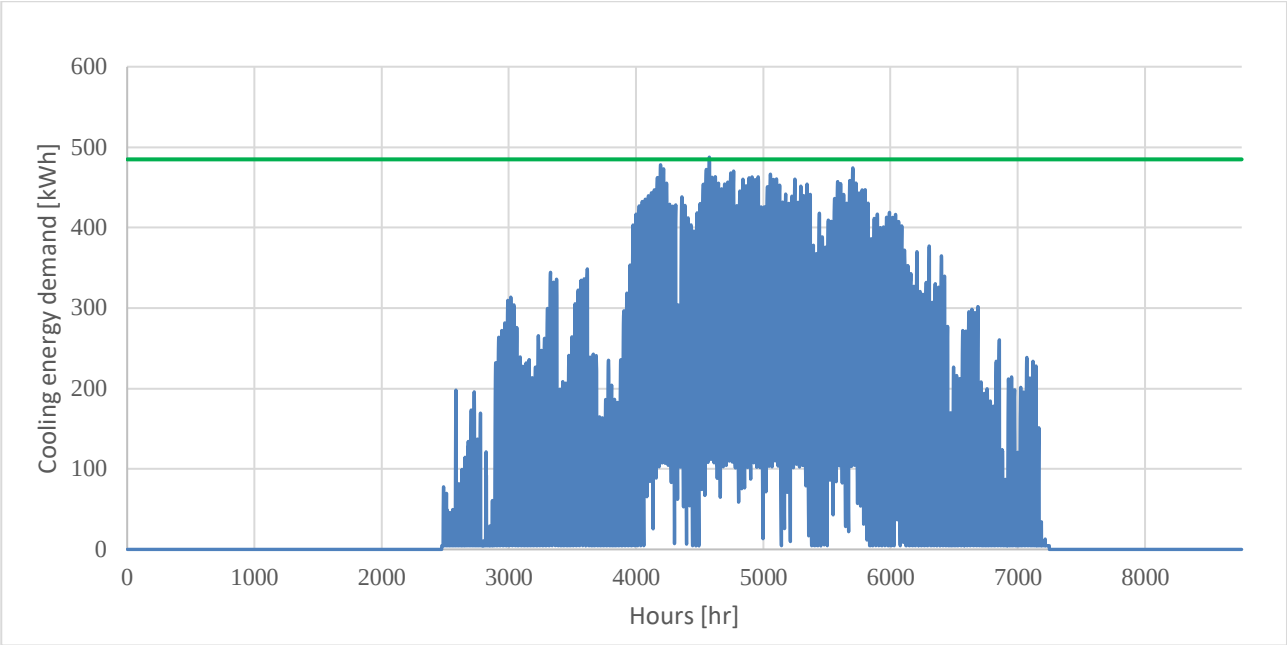
This methodology is used to develop macros which allow a faster generation of decks to be run by TRNSYS. After running the simulations, all results are read and KPIs (Key Performance Indicators) calculated through the use of a Python script.

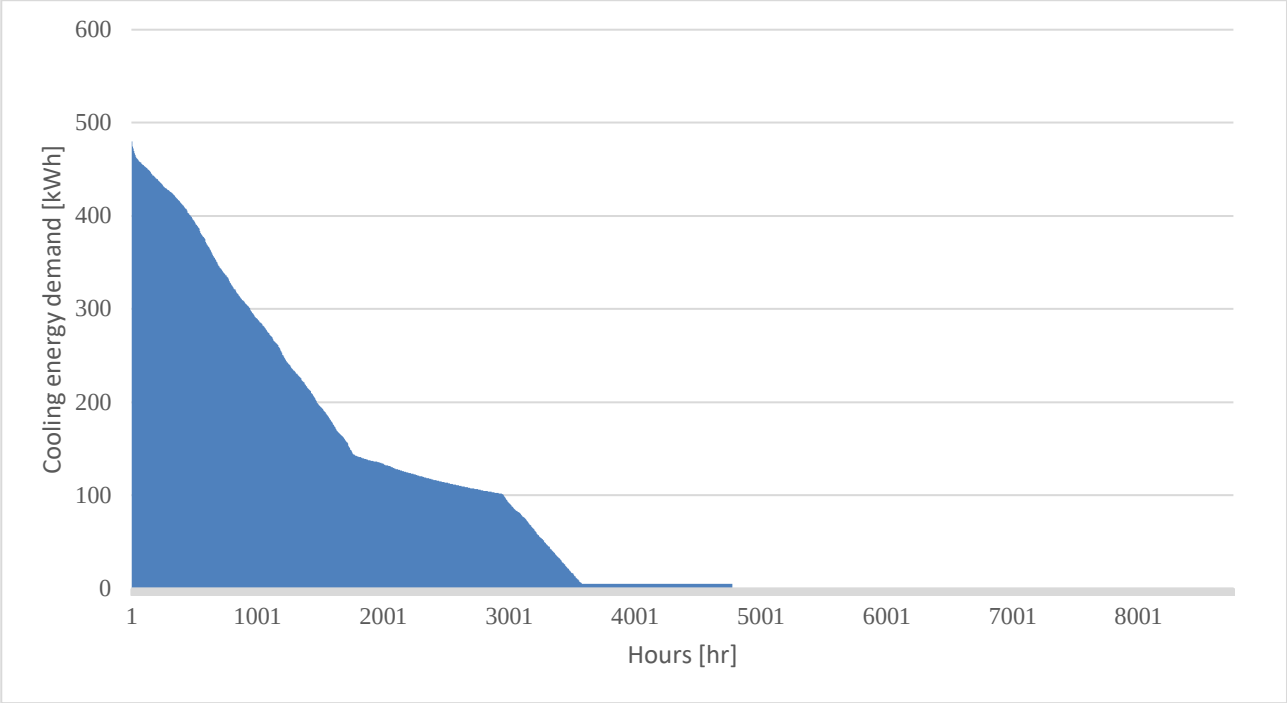
2.2. Location and Demand

This study has been carried out in Madrid where plenty of solar resource is available, and cooling demand is needed seasonally in summer.

Two demand profiles have been tested, a variable demand fixed by a yearly demand of approximately 733 MWh/y. And an experimental one, in which a constant value of 485 kW is considered.



(a)



(b)

Figure 5. Hourly demand profile studied (a) and monotonic curve of thermal loads (b) [kWh].

The hourly demand distribution and the descending monotonic curve, which indicates the application of various thermal loads in the system, can be observed in Figure 5 (a and b). These graphical representations are valuable for determining the necessary capacity that must be implemented.

2.3. Technologies Considered

The discussion in this paper intends to compare two diverse options of cooling generation, in which one of the main aspects to be addressed is the coefficient of performance (COP). While absorption chillers are known not to have high COP values due to their theoretical limitations, their main advantage is that most of their energy consumption is thermal (which compared to electric energy tends to be cheaper). On the other hand, compression chillers are found, where all their energy consumption is electrical. In this regard, a single stage absorption chiller has been used for this analysis which reaches an assumed COP value of 0.75. While for the compressor chiller a value of 3 was assumed [4].

2.4. Prices Considered

For electricity prices, the EU statistical website was used as source, and the last value available for Spain was selected (0.2298 €/kWh from S1,2022, for big consumers > 15000kWh) [5].

As not many reliable sources of pricing for technologies are available online, three different were considered [6–8], and a final value of 196€/kW was selected for the compression chiller and a 288 €/kW for the absorption chiller.

Other than that, values for Fresnel collectors were set in 190 €/m^2 and thermal energy storage (TES) were set in 260 €/m^3.

2.5. KPIs Definition

All KPIs have been calculated according to the scientific article referenced written for the Wedistrict project [2,3].

Mostly values on Levelized Cost of Energy (LCoE) and CO_2 emissions have been reviewed for comparison.

2.5.1 LCoE

The Levelized cost of energy (LCOE) evaluates the average net present value of energy expenditures during a system's lifespan. It is an important instrument for comparing various power generation technology options, particularly in situations where significant initial investments are required but operating costs decrease over time. This situation frequently occurs in systems that rely heavily on renewable sources.

The levelized cost of energy (LCOE) methodology involves the discounting of future expenditures and earnings to their current value in a designated base year, thereby enabling the determination of unit costs for generating energy. These unit costs represent the ratio between discounted lifetime expenses and projected net present value (NPV) of total energy output. In effect, they correspond to an average price that consumers would need to pay in order to cover all associated costs while yielding a rate-of-return equivalent to that defined by the chosen discount rate.

CAPEX calculations are done through the software, the value from the total system cooling capacity is also taken from the simulation results for this calculation. The rest of economic values are added in postprocessing by the script, fixing these values by the user.

$$LCOE = \frac{CAPEX \cdot CRF + OPEX_f + OPEX_v}{Q_C}$$

$$CRF = \frac{\{i \cdot (1+i)^n\}}{\{[(1+i)^n] - 1\}}$$

- $LCOE$: Levelized cost of cooling energy [€/MWh].
- $CAPEX$: Capital expenditure for the equipment [€/MWh].
- $OPEX_f$: Fix operational costs for cooling [€/year].
- $OPEX_v$: Variable operational costs for cooling [€/year].
- CRF: Capital recovery factor
- i: interest rate.
- n: project lifetime and number of annuities received.
- Qc: Cooling energy supplied per year [MWh/year].

2.5.2 CO_2 emissions

The concept of equivalent emission coefficient pertains to the quantification of non-renewable fuel-derived greenhouse gas emissions within a district heating and cooling system. It is important to note that carbon emissions generated by biofuels are not considered, while accounting for the ones related to extraction, transformation, and transportation processes. The calculation is as follows:

$$k_{CO_2} = \frac{\sum_i E_i \cdot k_i}{Q_C}$$

Where:

- k_{CO2}: CO2 emission coefficient (kg/ MWh).
- E_i: energy supplied by energy carrier i per year [MWh/year].
- k_i: Emissions coefficient of energy carrier i [kg CO2/ MWh.
- Q_c: Cooling energy supplied per year [MWh/year].

For CO_2 emissions the following table has been taken as seen in the reference [3].

Table 1. Default primary energy factor and non-renewable emission coefficient from ISO-52000 table B-16).

Energy carrier Delivered from distant		Primary energy factor			Non-renewable CO_2 emission coefficient
		Non-renewable	Renewable	Total	g/ kWh
Fossil fuels	Solid	1.1	0	1.1	360
	Liquid	1.1	0	1.1	290
	Gaseous	1.1	0	1.1	220
Biofuels	Solid	0.2	1	1.2	40
	Liquid	0.5	1	1.5	70
	Gaseous	0.4	1	1.4	100
Electricity		2.3	0.2	2.5	420
Solar	PV-electricity	0	1	1	0
	Thermal	0	1	1	0
Exported					
Electricity	To the grid	2.3	0.2	2.5	420
	To non EPB uses	2.3	0.2	2.5	420

2.6. Cases Evaluated

A first effort has been aimed to establish what appears to be the preferred technology by the users. The definitions on LCoE and CO_2 emissions have been established for the compression chiller and studies have been held as to determine how much improvement does the system get from the use of PV solar panels to provide electricity for the system.

Then the same indicators were established for the absorption chiller case, reviewing how much power is required as heat input for the system and how different variations on the supply affect the system.

3. Results

3.1. Compression Chiller

First a calculation of the system with the compression chiller has been made.

Table 2. Results from compression chiller system

PV capacity [kW]	Battery autonomy [kWh]	TES capacity Chiller [m^3]	Comp. Chiller capacity [kW]	Deviation Cooling demand [%]	LCOE [€/MWh]	CO_2 emission coefficient [kg/MWh]
165.00	495.00	30.00	485.00	-4.05	59.97	40.14

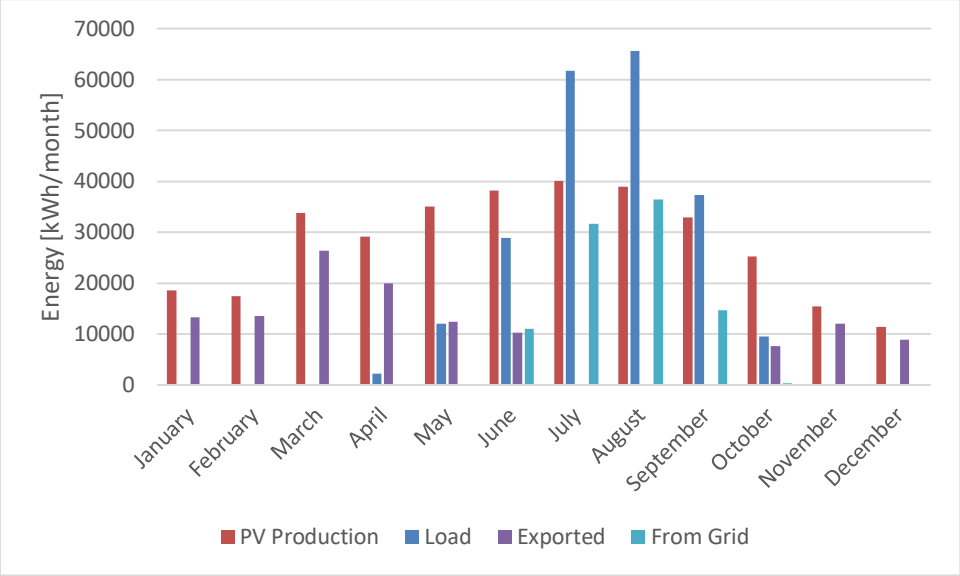


Figure 6. Photovoltaic production in analysed system and segregation [kWh/month].

From this first result we then took a step further to establish the same scenario without the PV panels, as to see the impact of these in the CO_2 emissions, and in the LCoE of the assumed network.

Table 3. Results from compression chiller system without PV panels.

TES capacity Chiller [m^3]	Comp. Chiller capacity [kW]	Deviation Cooling demand [%]	LCOE [€/MWh]	CO_2 emission coefficient [kg/MWh]
30.00	485.00	-4.05	87.98	129.84

These results show how LCoE values are improved by the installation of solar panels (31.8%), and how this investment reduces also the CO_2 emissions considerably (69.1%). This can be explained by the economic gain of exporting electricity throughout the year by the panels, and the reduction of the consumption from the grid, which has its assumed associated emissions (grid not completely green, Table 1).

3.2. Absorption Chiller

As for the compression chiller a first calculation has been made with the complete assumed system.

Table 4. Results from absorption chiller system.

Fresnel Collector area [m^2]	Hot TES capacity [m^3]	Boiler capacity [kW]	Abs Chiller capacity [kW]	Chiller Tank Vol [m^3]	Deviation Cooling demand [%]	LCOE [€/MWh]	CO_2 emission coefficient [kg/MWh]
1000.00	50.00	647.00	485.00	30.00	-5.94	205.67	604.75

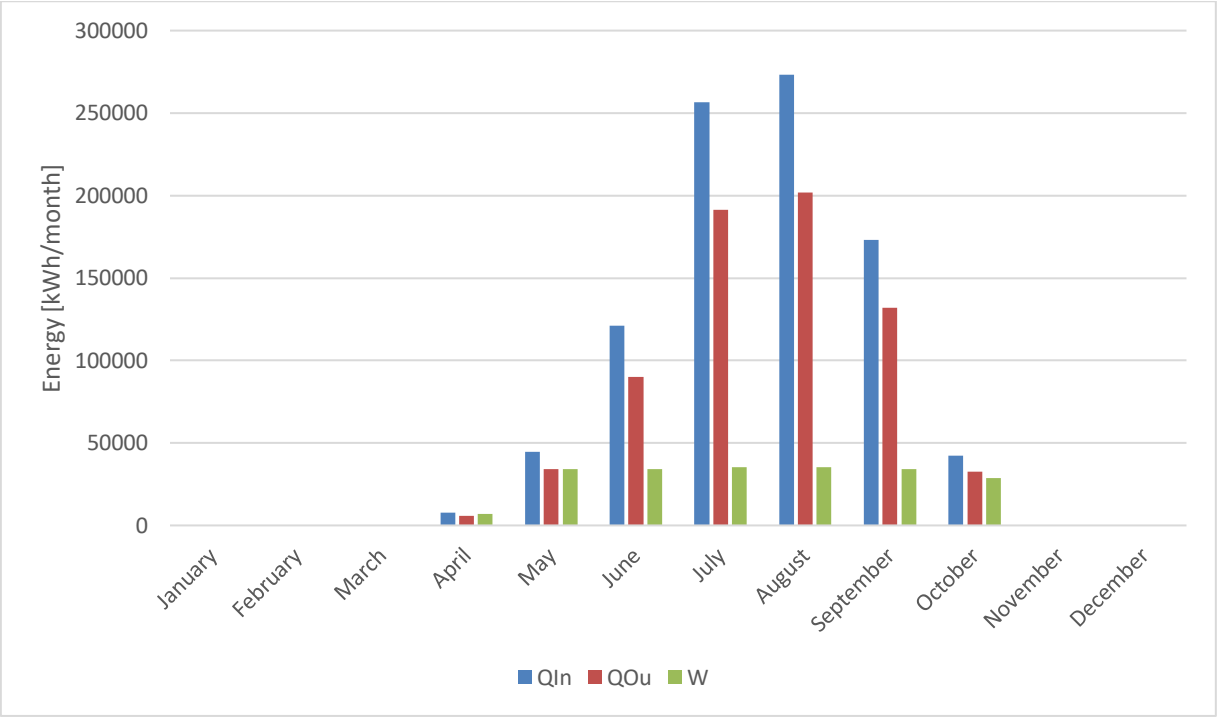

Figure 7. Absorption chiller energy flows [kWh/month].

From this first result we can see a gross difference from many different levels on the two principal KPIs compared:

To reduce the impact of the boiler production and its associated natural gas impact on the emissions we have assumed a scenario where this heat is provided by an existent net-zero emissions' source.

Table 5. Results from absorption chiller system reducing scope and emissions.

Fresnel Collector area [m^2]	Hot TES capacity [m^3]	Boiler capacity [kW]	Abs Chiller capacity [kW]	Chiller Tank Vol [m^3]	Deviation Cooling demand [%]	LCOE [€/MWh]	CO_2 emission coefficient [kg/MWh]
0.00	0.00	0.00	485.00	30	-5.94	122.51	181.00

The installation of the absorption chiller alone assumes a greater impact on the LCoE even without installing a full system to supply the heat. Given all these considerations further analysis seems inconsequential at this maturity stage of the technology.

The moment that this technology seems to flourish is when it works closer to its nominal operation point. It is interesting to compare the possibility of supplying a constant base value of cooling demand and see how this impacts the electrical consumption of both equipment.

3.3. Constant Case

A comparison of operations has been made for a constant demand equal to both equipment's nominal points. Considering that the energy supplied by the system to the absorption chiller still comes from an existent free net zero emissions source, while electrical consumptions have been taken into account.

Table 6. Results from absorption chiller with constant demand reducing scope and emissions.

Fresnel Collector area	Hot TES capacity [m^3]	Boiler capacity [kW]	Abs Chiller capacity [kW]	Chiller Tank Vol [m^3]	Deviation Cooling	LCOE [€/MWh]	CO_2 emission

[m^2]					demand [%]		coefficient [kg/MWh]
0.00	0.00	0.00	485.00	30	-11.17	35.49	57.03

Having considered nominal operation of the system and disregarded the price of installing solar Fresnel and the Boiler needed to supply the thermal demand (only considering electrical supply), absorption chiller shows a better cost and CO_2 emissions coefficient. But having made all these assumptions these results could be tied to too many considerations.

Table 7. Results from compression chiller constant demand, without PV panels.

TES capacity Chiller [m^3]	Comp. Chiller capacity [kW]	Deviation Cooling demand [%]	LCOE [€/MWh]	CO_2 emission coefficient [kg/MWh]
30.00	485.00	-4.05	86.70	129.84

On Table 7, it is visible that the electrical consumption of the chiller for this scenario yields a higher CO_2 emissions coefficient due to its electrical consumption throughout the year.

Table 8. Results from compression chiller constant demand, with PV panels.

PV capacity [kW]	Battery autonomy [kWh]	TES capacity Chiller [m^3]	Comp. Chiller capacity [kW]	Deviation Cooling demand [%]	LCOE [€/MWh]	CO_2 emission coefficient [kg/MWh]
165.00	495.00	30.00	485.00	-4.05	64.28	105.06

On Table 8, the improvement in LCoE found before due to the addition of PV panels in the variable case does not show the same impact, because panels do not generate the same amount of power throughout the year.

3.4. Discussion

From an economic standpoint, this system proves to be costlier for multiple reasons. Primarily, the implementation of absorption chillers is more financially burdensome when compared with compression chillers of equal capacity in terms of CAPEX (Figure 8). Additionally, since solar panels must be installed along with a natural gas boiler ensure diversity and generate heat input necessary for the absorption chiller's generator operation, these inputs punish severely, not only the LCoE due to these equipment CAPEX and operational expenditure (OPEX), but also, the CO2 emission coefficients linked to the production of said required heat input.

Although the absorption chiller operates efficiently during the peak months of July and August, utilizing only around 7% of its cooling capacity in electrical consumption, its lower coefficient of performance (0.75) compared to the compression counterpart (3) is significant enough to sway preference toward the compressor chiller option.

The aforementioned inclination is not upheld in situations where a consistent cooling necessity is obligatory for the system, as solar photovoltaic mechanisms do not yield an unchanging amount of electricity throughout every season (as shown in Figure 9). Therefore, absorption chillers show auspicious outcomes when considering that their energy supply originates from an already existent source.

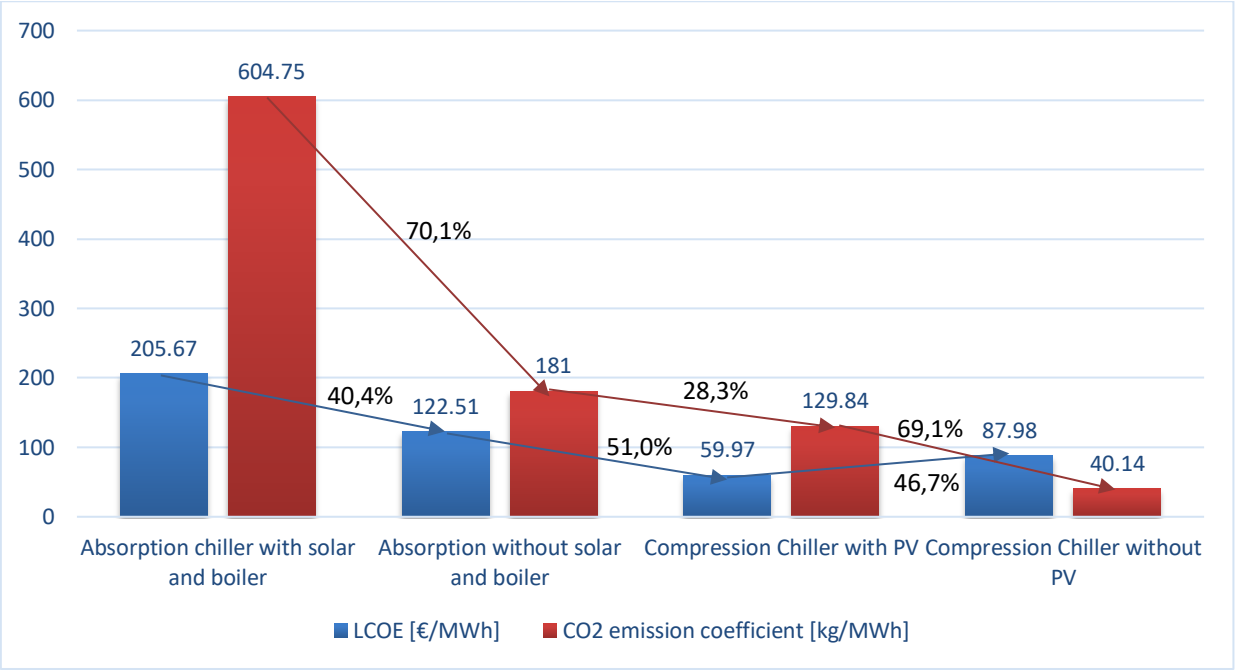

Figure 8. LCoE and CO2 emissions for variable demand cases and percentual evolution.

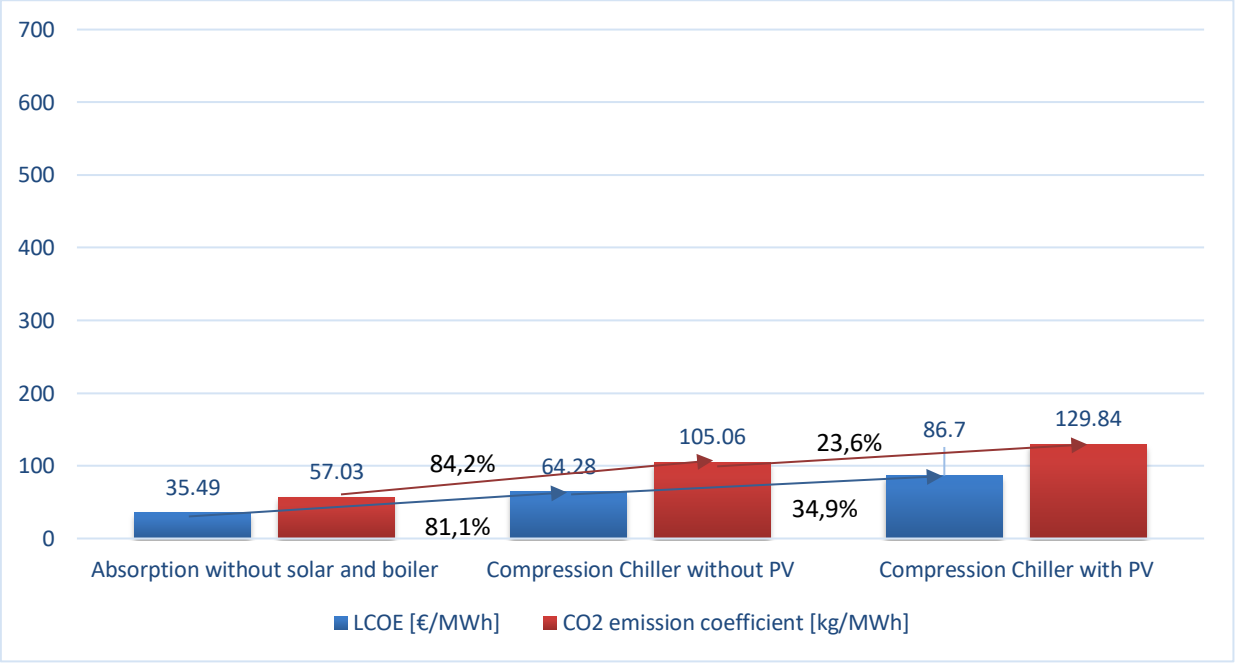

Figure 9. LCoE and CO2 emissions for constant demand cases and percentual evolution.

3. Conclusion

In terms of district cooling systems, the present circumstance limits options for technology selection. Presently, absorption chillers are viable if high-quality energy is anticipated to be wasted and their implementation can enhance system efficiency. However, when selecting a cooling system that will only supply a variable cooling demand, without any other interactions with other heating systems, the current technological state singles out the compression chiller as a more appropriate selection.

There is potential for utilizing the absorption chiller heat output as an energy source, considering that the outlet of the generator still can be rendered as a good energy source with temperatures around 85°C. This possibility presents itself as an intriguing subject of research from both financial and technical perspectives particularly when accounting for consistent cooling requirements such as those found in data centers.

Abstract:

The growing intensity of international commerce and the high share of total global greenhouse gas emissions by the maritime sector have motivated the implementation of regulations by the International Maritime Organisation to curtail large vessel emissions. Waste heat recovery is an effective way to improve ship energy efficiency, lower the temperature and amount of waste heat rejection to the environment, and therefore curb green-house gas emissions. In this article, existing and developmental on-board waste heat recovery technologies for maritime applications are reviewed. Emphasis is placed on the integration and performance of these technologies within the broader on-board energy system. Performance indicators are drawn from existing systems, experimental prototypes, and simulations, to quantitatively compare the different technologies in terms of power capacity, efficiency / coefficient of performance, heat source temperatures and specific cost of installation.

Keywords:

Energy; ECOS Conference; Waste heat recovery; Sustainability.

1. Introduction

It is estimated that the totality of vessels above 100 tons are responsible for approximately 3% of global greenhouse gas emissions [1]. Furthermore, shipping for international trade is expected to grow further in the immediate future [2]. Consequently, the International Maritime Organisation has set the objective of halving naval-related emissions by 2050 [3]. Engine waste heat recovery (WHR) is a possible pathway to decarbonising marine shipping. In large-bore two-stroke diesel engines, which are the propulsion method of choice in 96% of ships above 100 tons [4], approximately 50% of the fuel input is lost as waste heat through exhaust gases, cooling fluids and radiation [5]. On this basis, developing on-board WHR is a viable strategy to improve ship energy efficiency and curb sector wide global greenhouse gas emissions.

Table 1 Summary of marine WHR technological reviews in the literature, and the technologies discussed in each review and the present review.

	Shu et al. [6]	Singh et al. [4]	Xu et al. [7]	Zhu et al. [8]	This review
Turbo-compound systems	x	x			x
Turbochargers	x	x			
Absorption Refrigeration	x		x		x

Thermoelectric Generation	x	x			x
Organic Rankine Cycle	x	x		x	x
Steam Rankine Cycle	x	x		x	x
Kalina Cycle		x		x	x
Thermal Energy Storage					x
Isobaric Expansion Engines					x

WHR has been demonstrated as viable by Baldi and Gabrielli [9] who showed that WHR systems with 2- to 5-year payback times, reducing fuel consumption by 4% to 16% respectively, are achievable. Marine WHR

technologies have previously been reviewed by Shu et al. [6], and by Singh and Pedersen [4]. However, these reviews are not recent (2013 and 2016, respectively), and are discrepant on the classification and selection of WHR technologies. Shu reviews exclusively turbine based WHR technologies, including power cycles, Rankine cycle and various forms of Turbocharging (**Table 1**). Turbocharging always features in large vessels, and should arguably be classified as relevant to the engine technology and operation rather than part of the WHR system [10]. Furthermore, other WHR technologies exist, such as refrigeration systems, which are discussed in Singh's review, or thermal energy storage or isobaric expansion technology which are novel and have never been reviewed as marine WHR technologies. Some reviews have been published which focus on specific applications of engine WHR. Palomba et al. [11] evaluated the feasibility of applying WHR for powering on-board refrigeration and cooling systems on fishing vessels with some suggestions for system configurations and integration, while Xu et al. [7] specifically reviewed the available technologies for on-board refrigeration which were broadly categorised into absorption, adsorption and hybrid refrigeration system, with a partial focus on components. Zhu et al. [8] specifically reviewed marine engine WHR with bottoming power cycles, which consist of traditional Steam Rankine Cycles, Organic Rankine Cycles (ORC), and Kalina cycles. A summary of existing literature reviews focused on on-board engine WHR, and the discussed technologies is shown in **Table 1**.

1.1 Motivations & specific aims

Modern ships are evolving, and are being considered more and more as multi-energy systems, i.e. systems in which different types of energy (thermal, cooling, power, propulsion) and utility (clean water, steam) demands are designed to interact optimally with one another [12]. In view of this development and in the light of the existing literature landscape surrounding WHR technologies, the specific aims of this article are to provide a systematic, holistic, and up to date review of the current and developmental WHR technologies for marine applications and specifically the recovery of engine waste heat. Taken into account are the working principle, the possible integration to the marine energy system, and, when available, techno-economic performance measured in terms of efficiency / coefficient of performance, power capacity and specific cost.

2. State of the art of on-board WHR technologies

2.1 Waste heat recovery heat exchangers

A conventional on-board WHR method direct recovery from exhaust gases through a WHR heat exchanger, and directly provide for one of the on-board thermal energy demands. With a WHR heat exchanger system, exhaust gases flow in the hot side, and exchange heat with water or air flowing in the cold side. According to Baldi et al. [13] and Jouhara et al. [14], 5 such technologies can be highlighted for marine energy systems:

- **Economisers**: finned tube heat exchanger designed for low to medium temperature waste heat, aimed at heating boiler feedwater in view of steam generation in a separate piece of machinery.
- **Waste heat boilers**: medium to high temperature exhaust gases pass through the tubes of this heat exchanger, exchanging heat with water flowing on the cold side with the aim to generate steam.
- **Recuperators**: medium to high temperature exhaust gases pass the through the tubes of this HX hot side and exchange heat with the inlet air circulating in adjacent channels to provide for various on-board thermal energy demands.
- **Regenerators**: a type of heat exchanger with some thermal capacity to temporarily store thermal energy, with both hot and cold fluid asynchronously using the same channels. During a so-called hot phase, exhaust gases flow through the channels of the regenerator, storing heat into the heat exchanger's packing, generally a ceramic or refractory material. Cold fluid (air) is then circulated through the heat exchanger channels in a so-called cold phase to recover the stored heat.
- **Heat recovery steam generators**: a multiple-pressure heat exchanger system designed to produce high quality steam from high temperature exhaust gas waste heat. Such a system typically features three pressure levels: economiser, evaporator, and superheater.

2.2 Turbocompounding

Turbocompounding consists in utilising heat in the exhaust gas stream to power a turbine system and generate electricity. Turbocompounding is different from turbocharging, the latter being a method for recovering exhaust waste heat to compress the engine intake air. Advances in turbocharging technology have resulted in a surplus amount of energy in the exhaust gas stream compared to the requirements for intake air compression [4], encouraging further use of the exhaust gas waste heat potential through turbomachinery. In the best-case scenarios both turbochargers and a turbocompounding WHR system can be installed together to reach high WHR. According to MAN, one of the main manufacturers of turbocompounding systems [5] there are three options for turbocompounding, ordered here by increasing efficiency and complexity **PTG**: power turbine generator unit. A so-called power turbine directly converts exhaust gas energy to electricity, recovering a potential η =3-5% of fuel energy according to MAN. **STG**: steam turbine generator unit. Exhaust gas energy

is used to generate steam in an exhaust gas fired boiler (EFB). The energy contained in the generated steam is then used to power a steam turbine. Such as system can achieve a potential 5-8% fuel energy recovery.

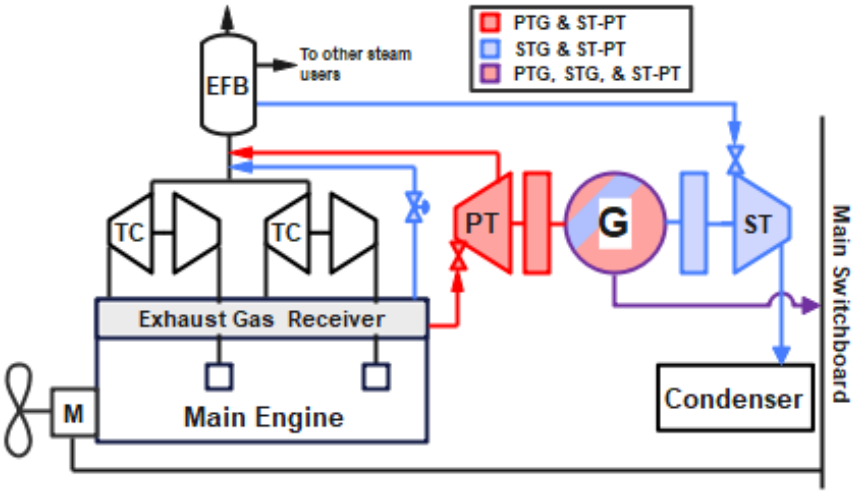

Figure 1 Schematic representation of turbocompounding WHR PTG system, STG system and combined ST-PT system.

ST-PT: combined steam and power turbine generator unit. Uses both preceding principles in a combined system with both turbines on the same shaft connected to the generator to potentially achieve 8-11% fuel recovery according to MAN, with a similar recovery ratio of approximately 10% for the Winterthur Gas & Diesel combined system [15]. These systems are shown schematically in **Figure 1**. In terms of maturity, turbocompounding is an established on-board WHR technology (technology readiness level~9) [13], favoured for its ease of installation and high retrofitting ability. To select the best turbocompounding system type, MAN recommend a PTG when the main engine power is below 15 MW, a STG for main engine powers between 15 MW and 25 MW, and the combined ST-PT for engine powers above 25 MW. **Table 2** shows typical specific installations costs and maintenance costs for the different types of turbocompounding systems. The data was synthesised by Olaniyi and Prause [16] from various turbocompounding WHR system manufacturers.

Table 2 Installation and maintenance costs for different types of turbocompounding WHR system, data originally collected in [16], costs actualized and converted from dollars to euros.

	Installation Costs [€/kW]	Maintenance Costs [€/year]
PTG	105	10,500
STG	320	21,000
PT-ST	420	32,000

2.3 Rankine cycles

Rankine cycles are a type of power cycle designed to convert thermal energy into useful mechanical power through an expander. The useful mechanical work is then converted to electricity via a generator. Thermal energy from the exhaust gases is used to evaporate a working fluid in the boiler (1 to 2). The working fluid vapour is expanded to the cycle's low pressure level in a turbine to produce useful work (2 to 3), then condensed (3 to 4), before being pumped to the cycle's higher pressure level (4 to 1) into the boiler, thus completing the cycle. The cycle presented in **Figure 2** shows a simple Rankine cycle layout using main engine exhaust gas as the heat source. Steam Rankine Cycles operate with water as the working fluid and thus require a high temperature heat source (T>200°C) [17], whereas Organic Rankine Cycles (ORC) use an organic working fluid with a lower boiling point to leverage lower temperature heat sources. Cycle performance is typically increased using modifications to the simple cycle such as regeneration, bleeding, and multiple loop cycles [18]. Regeneration involves a heat exchanger to extract residual thermal energy at the turbine outlet to pre-heat the working fluid between the pump and the boiler. Bleeding involves extracting part of the working fluid to preheat before boiler entry, and as a result a secondary lower pressure circuit which is expanded in a secondary turbine/expander. Multiple loop cycles involve two or more working fluids with different boiling points to leverage the multiple waste heat streams in marine energy systems. Most proposed systems for marine applications include one or several of these modifications. For example, Song et al. investigated the use of multiple waste heat streams as thermal energy source for a ~100 kW net power output ORC, with jacket cooling water for preheating and exhaust gas for the evaporation of the working fluid [19]. Lion et al. thermodynamically investigated a similar concept, except using hot scavenge air to preheat the working fluid and exhaust gas for evaporation [20]. Casisi et al. [21] modelled different ORC configurations for integration in marine energy systems: simple, regenerated and dual loop layouts. In these cases, the high temperature

cooling water circuit was used to preheat the working fluid. Rankine cycles have high technology readiness level ~ 8, with market ready systems being commercially available. Conventional ORC manufacturers are Ormat, Turboden and GE [22], with systems mainly targeted towards biomass, combined heat and power (CHP), geothermal and industrial WHR.

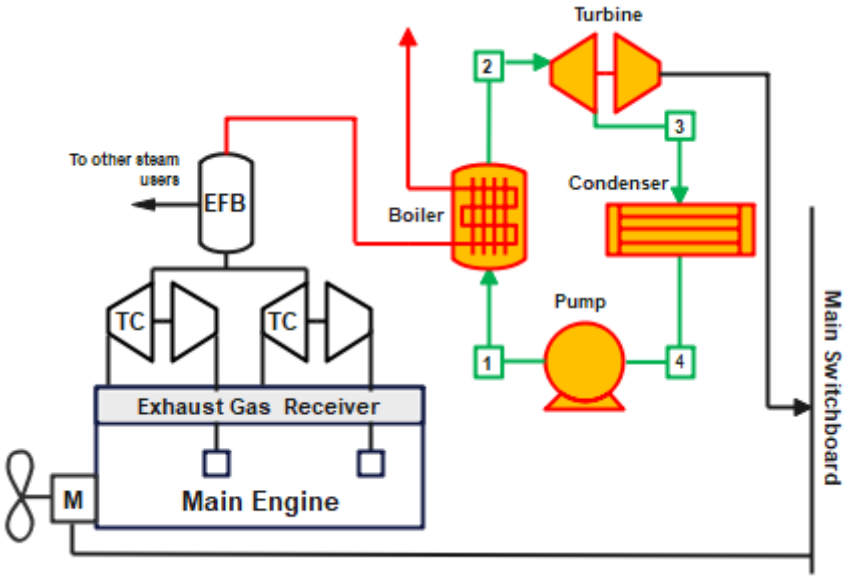

Figure 2 Schematic representation of a Rankine cycle WHR system using main engine exhaust gas as heat source.

Various manufacturers however offer ORC modules designed specifically for marine energy systems, such as Orcan-Energy's *Efficiency Pack* [23], Alfa Laval's *E-Power Pack* [24], or the Caltenix Mitsubishi partnership's *Hydrocurrent TM Organic Rankine Cycle Module 125EJW* [25]. The technical performance of some of these systems, both market ready and theoretical, is summarised in **Table 3**.

Table 3 Technical performance of marine ORCs (LT: low temperature, HT: high temperature)

Heat Source Temperature [°C]	Layout	Working Fluid(s)	Net Power Output [kW]	Efficiency	Ref
315	Basic	R123	625	16.38%	[26]
300 / 90	Dual Heat Sources	Cyclohexane	96	20.75%	[19]
300	Parallel ORCs	R245fa	101	10.20%	[19]
293.15	Regenerated	Benzene	396	22.00%	[27]
145	Regen.	Toluene	684	26.70%	[21]

Kalina cycles

Kalina cycles are a variation of the Rankine cycle, revolving around the evaporation of an ammonia-water mixture using the excess waste heat and operating an expander / generator train to generate electrical power [28]. The system was first introduced in 1983 as an alternative to ORCs, with higher efficiency and lower cost as the design objective. The crucial aspect of this cycle is that ammonia-water is a zeotropic mix, i.e., its boiling point changes with the respective mass fractions of the mix. Waste heat from the main engine exhaust gas is used to evaporate the ammonia-water zeotropic mix in the boiler. Working fluid vapour then flows through an expander connected to a generator, yielding electrical power transferred to the vessel main switchboard. Various process units internally improve cycle performance including heat recuperation and solution enrichment/separation processes. Detailed description of the working principle can be found in the original publication by Kalina et al. [28]. While the diagram in Error! Reference source not found. shows a single waste h eat source, exhaust gases, Kalina cycles are well suited to extract heat from multiple waste heat streams emanating from vessel diesel engine, such as preheating the zeotropic mixture with engine cooling circuits [29]. The performance and some main characteristics of various Kalina cycles for WHR are shown in **Table 4**. Data presented in this table were sourced mainly from theoretical literature studies, originally synthesised in [30]. The wide temperature range of heat sources from the WHR applications (98°C to 566°C), despite using the same working fluid (albeit in different mass fractions), and range of power outputs (21.7 kW to 8,600 kW), showcases the flexibility of the Kalina cycle in handling different waste heat sources. Efficiency of Kalina cycles tends to scale proportionally with plant size and is found in a similar range to Rankine cycles between 7.5% and 35%. The projected cost of Kalina cycles for various plant capacities is also shown in **Table 4**. The capital

cost for Kalina cycle systems above 1 MW can range from 1,000 to 1,500 €/kW, while for smaller systems, below 1 MW, significantly higher capital costs in the 2,000 – 3,000 €/kW range should be expected.

Table 4 Characteristics and techno-economic performance of WHR Kalina cycles, data originally synthesized in [30]**.**

Heat Source	Temperature [°C]	Power [kW]	Efficiency [%]	Cost [€/kW]	Ref
Coal combustion flue gas	150	320	12.3	2,000 – 3,000	[31]

Cement Plant	-	6,000	-	1,500	[36]

Thermoelectric generation

Thermoelectric generation (TEG) is a technology designed to directly generate electricity from a heat input using the Seebeck effect: a temperature gradient between two semi-conducting materials produces a voltage gradient proportional to the temperature different. TEG is particularly valued for its ability to continuously deliver electricity, its compacity and ruggedness in challenging environments: the first major field of application of TEG was the space industry. Today TEG is investigated for industrial WHR, including in marine energy systems [37]. TEG is at a technological readiness level where various commercial devices are available, their techno-economic performance being shown in **Figure 3**. The main drawbacks of TEG are low heat-to-electricity conversion efficiencies (below 5%) and low volumetric power output.

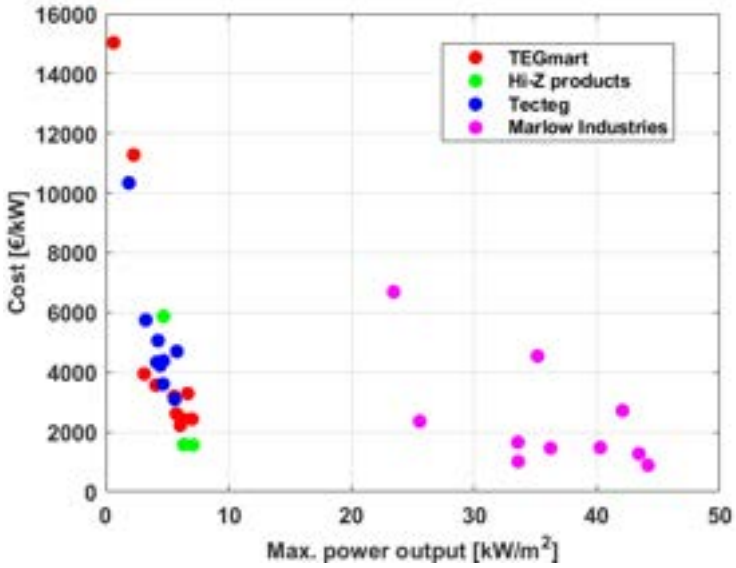

Figure 3 Commercial TEG modules techno-economic performance [38]–[41]**.**

Absorption refrigeration

The principle of absorption refrigeration revolves around leveraging the low boiling point of a refrigerant (typically ammonia). During this phase change the refrigerant will extract thermal energy from and cool down another fluid (typically water) yielding the intended refrigeration effect. A schematic representation of a simple single-stage absorption system is shown in the context of exhaust gas WHR in **Figure 4**. Cooling effect is produced in the evaporator where the ammonia evaporation process extracts thermal energy from a water flow which is sent to the vessel cooling load. Ammonia vapour then flows to the absorber to be absorbed to form a liquid solution, which is then pumped to a higher pressure towards the generator. The ammonia vapour is desorbed from the solution to a new vapour phase using water heated from main engine exhaust gases, and this vapour phase is then returned to liquid phase in the condenser, using sea water as cooling medium. The condensed ammonia phase then flows towards the evaporator, thus completing the cycle. Absorption refrigeration differs from conventional vapour compression systems for refrigeration, in that [42]:

- the vapour refrigerant is absorbed by a secondary substance to form a liquid solution before being pumped to a higher pressure. This process results in significantly less electrical work input compared to a vapour compression due to the much lower specific volume of liquid.

- the refrigerant is desorbed from the liquid solution using some thermal energy input before the condensation stage. Herein lies the main advantage of absorption refrigeration as it is a means to produce a cooling effect from a thermal energy source, thus making it highly relevant for marine energy systems with waste heat sources and potentially high cooling load.

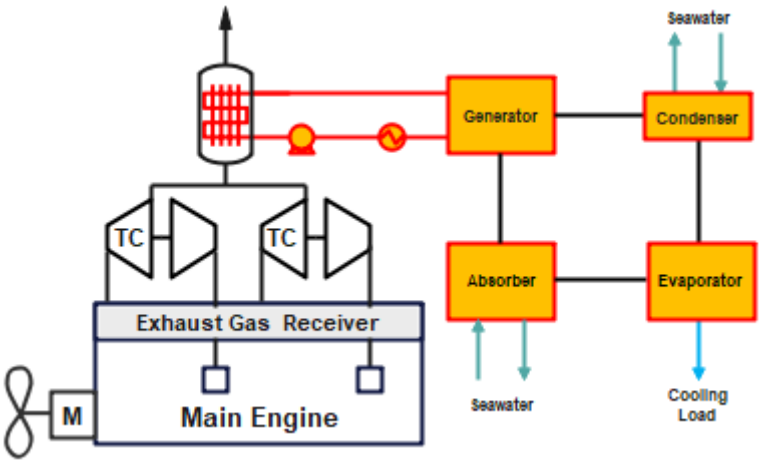

Figure 4 Schematic representation of an absorption refrigeration cycle WHR system using main engine exhaust gas as heat source.

While the system described is that of a single stage absorption refrigeration WHR system, various modifications and alternative layouts can help improve the performance. These alternative layouts include double stage, cascade and hybrid absorption / compression systems. The technical performance of various absorption cycles is shown in **Table 5**, while absorption refrigeration costs are shown in **Table 6**.

Table 5 Characteristics and performance of absorption cycles, data originally synthesised in [43]

Cycle	T_{evap} [°C]	COP	Working Fluid	Ref
Single-stage cascade	- 30 to 5	0.25 - 0.55	NH_3 - H_2O	[44]
Double-stage cascade	- 20 to 0	0.17 - 0.31	H_2O - LiBr // NH_3 - H_2O	[75]
Double stage	/	0.29	H_2O - NH_3	[47]
Absorption / Compression	- 10	1	NH_3 - H_2O	[80]

Table 6 Absorption refrigeration costing elements, data gathered from [50]

Design	Heat Source	Cooling Capacity (kW)	Installed Cost (€/kW)	Maintenance Costs (cts/kW/h)
Single Stage	Hot Water	175	1945	0.195
		1540	746	0.065
	LP Steam	4620	584	0.032
Two Stage	HP Steam	1155	973	0.097
		4620	713	0.032
	Exhaust Fired	1155	1070	0.097
		3500	648	0.032

Adsorption refrigeration

A cooling effect is generated with adsorption refrigeration by leveraging the boiling point of a refrigerant at low temperature to extract heat from another working fluid, a similar working principle to absorption refrigeration discussed previously. The principal difference is that the refrigerant vapour is then adsorbed onto the surface of a solid sorption material, rather than absorbed into a liquid solution. The adsorbed refrigerant is then separated from the condensed phase using a thermal energy input during a process called desorption. Typical adsorption materials (so-called adsorbents) include [51] silica gel and metal-organic frameworks.

Additionally, seawater can be used as the working fluid which can result in its desalination during the consecutive adsorption/desorption process; the relatively high boiling point of sea water (compared to traditional refrigerants such as ammonia) however limits the minimum temperature reached from the cooling process to that of chilled water (0°C to 5°C). A schematic representation of a two-bed adsorption refrigeration system with desalination function [52] is shown in **Figure 5**.

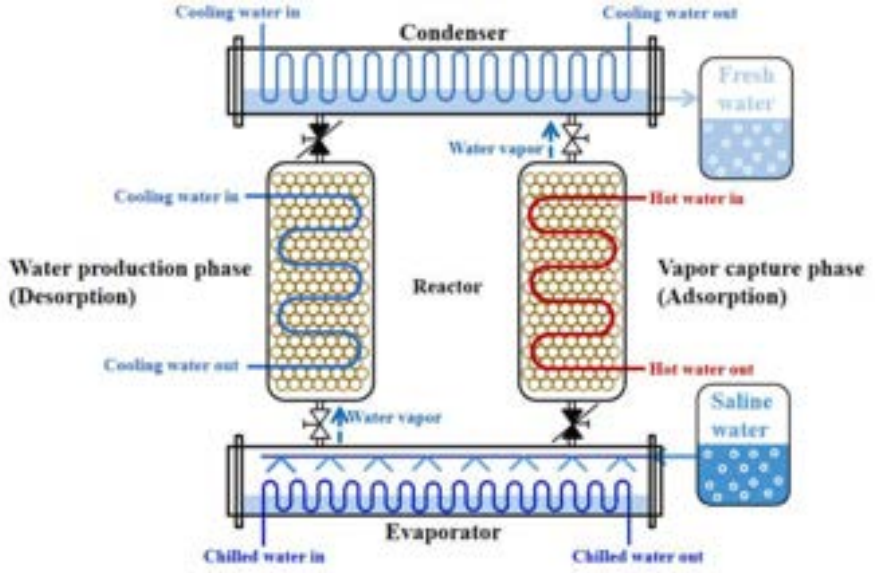

Figure 5 Schematic representation of two-bed adsorption refrigeration system [52]

Thus, this system can either be designed with a conventional refrigerant to generate sub-zero cooling, or with seawater as the refrigeration for chilling and desalination. The system shown in **Figure 5** is a two-bed system which is a rather simple configuration of this technology. Various modifications and more advanced configurations can be implemented to increase overall cooling power or rate of desalination. Three [53] and four [54] bed systems have been investigated, along with hybrid systems specifically designed for fishing vessel refrigeration [11] which combine adsorption refrigeration with conventional vapour compression systems. Adsorption refrigeration is a novel technology, thus techno-economic data is sparse. Costing elements for some adsorption chillers have been derived from analogous refrigeration technologies (absorption and vapour compression refrigeration) and are shown in **Table 7**. With the current state of the art, the maximum cooling power for adsorption chillers is around 100 kW.

Table 7 Cooling capacity and specific cost of various adsorption chillers.

Model	Cooling Power [kW]	Specific Cost [€/kW]	Ref
InvenSor LTC30 e plus	10 - 35	1,327	[55]
SorTech eCoo 2.0 Silica Gel IP20	16	1,188	[56]
Unnamed Silica gel / water adsorber	8	1,331	[57]

Isobaric Expansion Engines

Isobaric expansion engines (IEE) are a type of heat-to-mechanical power converter, based on a non-polytropic gas expansion process at theoretically constant pressure in a cylinder [58]. IEEs encompass various engine concepts such as Savery, Newcomen, and Watt pumps [59], Worthington direct-acting steam engines [60], and Bush thermo-compressors [61]. As seen from the provided examples, IEE is an old concept which has nonetheless received recent attention by technology makers due to the potential for useful work production from low temperature heat sources (as low as 40°C) and low temperature differences ($\Delta T = 30°C$), albeit with low efficiencies compared to other heat to work conversion technologies [62]. The latter of the two examples, Worthington and Bush-type engines have generated most of the recent interest; the Worthington engine is represented schematically in **Figure 6** in the context of WHR, where it is assumed that marine exhaust gases are used to generate steam (in the EFB) that undergoes the isobaric non-polytropic expansion process in the IEE. At the beginning the cycle, steam inlet valve **6** is manually opened, letting steam enter cylinder **1**, pushing piston **3** outwards and piston **4** inwards. During the entire stroke, steam enters at constant pressure with the inlet valve kept open, resulting in the so-called isobaric expansion. Cylinder **4** pushes the liquid out of cylinder **2** through the self-acting outlet valve **9**.

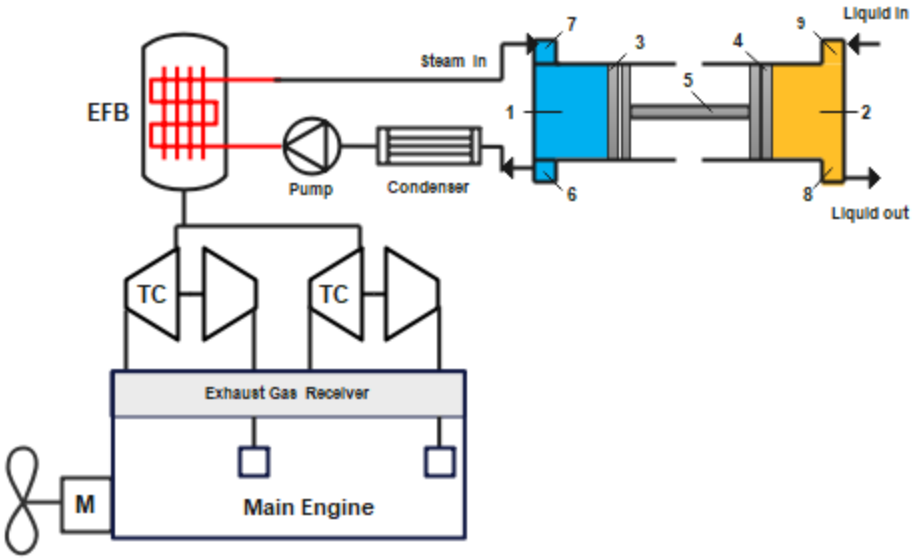

Figure 6 Schematic representation of the basic working principle of Worthington steam pump in the context of marine WHR.

When pistons **3** and **4** have fully displaced to the right-hand side, steam inlet valve **6** is closed, while liquid enters pumping cylinder **2** through the liquid inlet valve **8**, pushing piston **4** outwards and instigating the return motion of the engine stroke. Piston **3** displaces steam out of cylinder **1** through steam outlet valve **7** that is now opened until both pistons have fully moved to the left, thus completing the pumping cycle. It is assumed that the steam returning from the IEE is condensed (sea water used for cooling) and pumped back towards the EFB. The layout shown in **Figure 6** represents the simplest possible Worthington IEE. Extensive descriptions of more advanced IEE layouts can be found in [63]. For Worthington and Bush type IEEs, overall thermal efficiency can be found around 5%, for power deliveries below 1 kW, as shown in **Table 8**. The generated work can be used for a variety of on-board applications, such as powering pumps, compressors and other converters [58], or for water desalination [64]. However the simplest method may be to connect the IEE to a hydraulic circuit and generator [58].

Table 8 Performance characteristics of IEEs compared to thermal power pump (TPP). Data originally gathered in [62]**.**

	Cylinder Volume [L]	Cycle period [s]	Power [W]	Volumetric Power [W/L]	Efficiency [%]	Ref
TPP system	1.8	200	1	0.6	0.5	[65]
IEE-Bush	0.02	2.5	20	1200	6.4	[62]
IEE-Worthington	1	4	500	500	5.4	[62]

Thermal energy storage

Thermal energy storage (TES) is a technology designed to resolve the mismatch between heat availability and demand, particularly relevant for renewable thermal energy sources, namely solar, geothermal, and waste heat recovery. TES is classified into three distinct technologies [66], listed here in order of increasing complexity, cost, and energy storage density potential:

- Sensible TES (STES): heat is stored/released by increasing/decreasing the temperature of a solid or liquid [67]. STES materials include water, rocks, sand, molten salts, and metallic materials.
- Latent TES (LTES): heat is stored as the phase-change enthalpy of the melting/boiling process of a solid/liquid called phase change material (PCM). The reverse phase-change process is performed for discharge.
- Thermochemical energy storage (TCS): heat is stored/released as the reaction enthalpy of reversible exothermic/endothermic reactions. Typical thermochemical reactions for TCS include water sorption onto zeolite or other sorbents, hydration of inorganic salts, carbonation and oxide-reduction reactions.

The schematic representation of a thermal energy storage system integrated to a marine energy system is shown in **Figure 7**. TES is a passive WHR technology that doesn't directly convert waste heat to useful work but acts as a buffer to either store and release heat based on on-board demand or enable other WHR heat-to-X converters to operate with higher efficiency, such as power cycles.

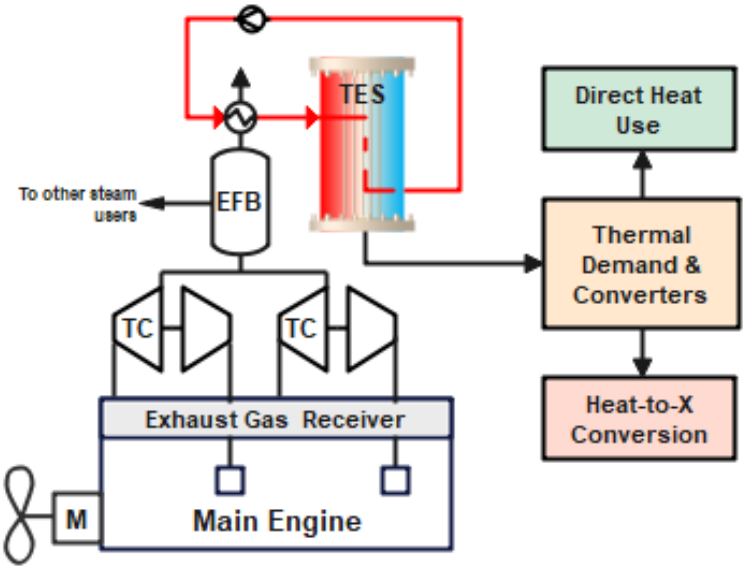

Figure 7 Schematic representation of the integration of TES to a marine energy system.

The system shown in the figure considers a single temperature level, with heat recovered from the exhaust gases. In real marine energy systems, TES has been envisioned for the storage of heat through a cascade of LTES systems with different PCMs each adapted to the temperature levels of the multiple onboard waste heat streams, potentially recovering 10% to 15% of fuel input as stored heat [68]; for the production of hot water on cruise ships to reduce by up to 80% fuel consumption in auxiliary boilers using a 1,000 m3 thermal oil-based STES [69]; for synergistically improving other WHR technologies, similarly to conventional WHR [70]. Excess heat stored in an LTES can be released at approx. 100°C to evaporate the working fluid in an on-board ORC [71]. An important design decision is how heat is transported to the TES and exchanged with the storage material. Typical techno-economic performance characteristics of various TES systems with these layouts are shown in Error! Not a valid bookmark self-reference.. STES generally displays low energy storage density (> 50 kWh/m^3), and TCS too low of a technological maturity, for realistic implementation in marine energy systems; thus, LTES can be considered as the most suitable TES sub-category for on-board WHR.

Table 9 Techno-economic performance of various TES systems, data originally synthesised in [72]**. ST: shell and tube, PB: packed bed, TT: tube-in-tank.**

Type	Material	Energy Storage Density [kWh/m^3]	Efficiency [%]	Volume [m^3]	Cost [€/kWh]	Ref
PB - LTES	$Li_2CO_3/K_2CO_3/Na_2CO_3$	66	80%	2	-	[73]
PB - LTES	$Li_2CO_3/K_2CO_3/Na_2CO_3$	115	61%	83,333	-	[74]
ST - LTES	Sodium Nitrate	-	-	77,161	65	[75]
ST - LTES	KOH	-	-	83,333	19	[76]

TT - LTES	Sodium acetate trihydrate	-	-	2,500	58	[78]

Conclusions

This article presented a systematic review of waste heat recovery technologies applicable to marine energy systems. The technologies were mainly characterised by their power capacity, efficiency / coefficient of performance, and specific investment cost. Furthermore, their applicability to marine energy systems for diesel engine WHR was discussed. It emerges from the review that:

- The turbine-driven heat-to-power technologies, i.e., turbocompounding systems and Rankine cycles, display the highest technological readiness level with market ready and proven systems, and highest potential power output each in the order of magnitude of at least 200 kW to 3 MW. These waste heat recovery technologies also have a high range of applicability since high electrical demand is likely regardless of vessel type and voyage.
- Kalina cycles typically show the same technical performance as Rankine cycles, but should still be considered as an unproven technology, with insufficient practical applications in conventional WHR let

alone marine waste heat recovery. Thermoelectric generation shows promising characteristics but low power outputs for individual modules severely limit economic viability.

- Through other technologies such as adsorption, absorption, and isobaric expansion engines, waste heat can be recovered and converted to other forms of useful work than electrical power. The suitability of the technology depends on the types of on-board energy demands which in turn depends on the vessel and voyage type. With their current technology readiness level however, only absorption refrigeration can deliver net power output in the same order of magnitude as the most powerful waste heat recovery technologies: 100 kW to 5 MW for absorption refrigeration, 8 kW to 35 kW for adsorption refrigeration, isobaric expansion engines are unproven beyond 1 kW.
- Thermal energy storage is in its own class of passive WHR technology, best used synergistically with other WHR technology to improve their performance by matching waste heat availability with on-board demands. Latent thermal energy storage is the best suited technology for on-board applications.

Abstract:

This communication presents the study of a new hybrid system consisting of a buried rainwater tank thermally activated through a water-to-water heat exchanger. This low-tech solution, little studied in the literature, performs the passive cooling of buildings and reduces domestic water network consumption (for non-potable uses). Firstly, experimental results obtained from two full-scale prototypes are presented. Then, numerical studies are discussed.

Keywords:

Building cooling; Geothermal energy; Measurement-simulation comparison; Rainwater collection; Thermal energy storage.

1. Introduction

With climate change, summer comfort and CO_2-emission reduction are two increasingly relevant topics. In this project, we are trying to develop a low-tech system allowing for the cooling of indoor spaces without using refrigerants or with a reduced energy expense.

The literature review shows a lack of detailed studies of such systems. The exploitation of experimental data of cold and hot water tanks connected to a thermo-active building system was treated by Kaltz [1], where the authors demonstrate that a 11 m^3 cistern could provide about 1000 kWh of cooling energy over a whole year. Simulation studies have been carried out by Upshaw [2] with the study of a non-buried rainwater storage tank. The approach considered the rainwater tank as a means of shifting the electrical peak load of an air conditioning unit. Sodah [3] simulates an open system with an aeration loop enhancing evaporative cooling but calculation is only monthly. While Gan [4], considered a tank with special design heat exchanger as a heat source for a heat pump (active system), which is also different from our approach. Marigo [5], also considered a ground coupled heat pump but the cold source is much closer to the rainwater tank we studied. The ground heat exchanger consists of helical shaped pipe in polyethylene immersed into a concrete-built water tank. The size of the tank and pipe are almost the same as our prototypes. To the best of our knowledge, the modelling of variable free-surface water storage and the related mass and heat transfers involved appears to be poorly documented.

To set up the model, the physical equations from both usual domestic water tanks and atmospheric reservoirs were combined, taking into account heat transfer between air and water. We hence aim here at establishing and validating an equation-based physical model, using the data of two full-scale prototypes in operation since July 2021.

In further works, the model will be coupled with a state-of-the-art building energy simulation tool in order to estimate the relevance of the system regarding summer comfort.

This work is organised as follows: first the principle of the system is explained, then the experimental setup and results are described and eventually a first version of numerical model and simulation is presented.

2. Main concept of the Rainergies system

The basis of the solution described consists in a new or existing buried rainwater tank, initially used for rainwater collection as non-potable domestic water and the relief of sewage networks. In France, the water resources management legislation locally enforces the water management at parcel level which could democratize the use of such rainwater tank. A helicoidal water-to-water heat exchanger (HX) is placed in the tank in order to take advantage of the heat storage capacity of water as a by-product. Thanks to an air-to-water heat exchanger connected to the ventilation supply duct, the tank delivers cooling energy to the building during summer [6].

In summary, the “Rainergies” system consist in following elements:

- A water tank for rain collection,
- A water/water coil heat exchanger immersed in the rainwater tank,
- A water/air heat exchanger placed after the supply air duct and connected to the immersed coil.

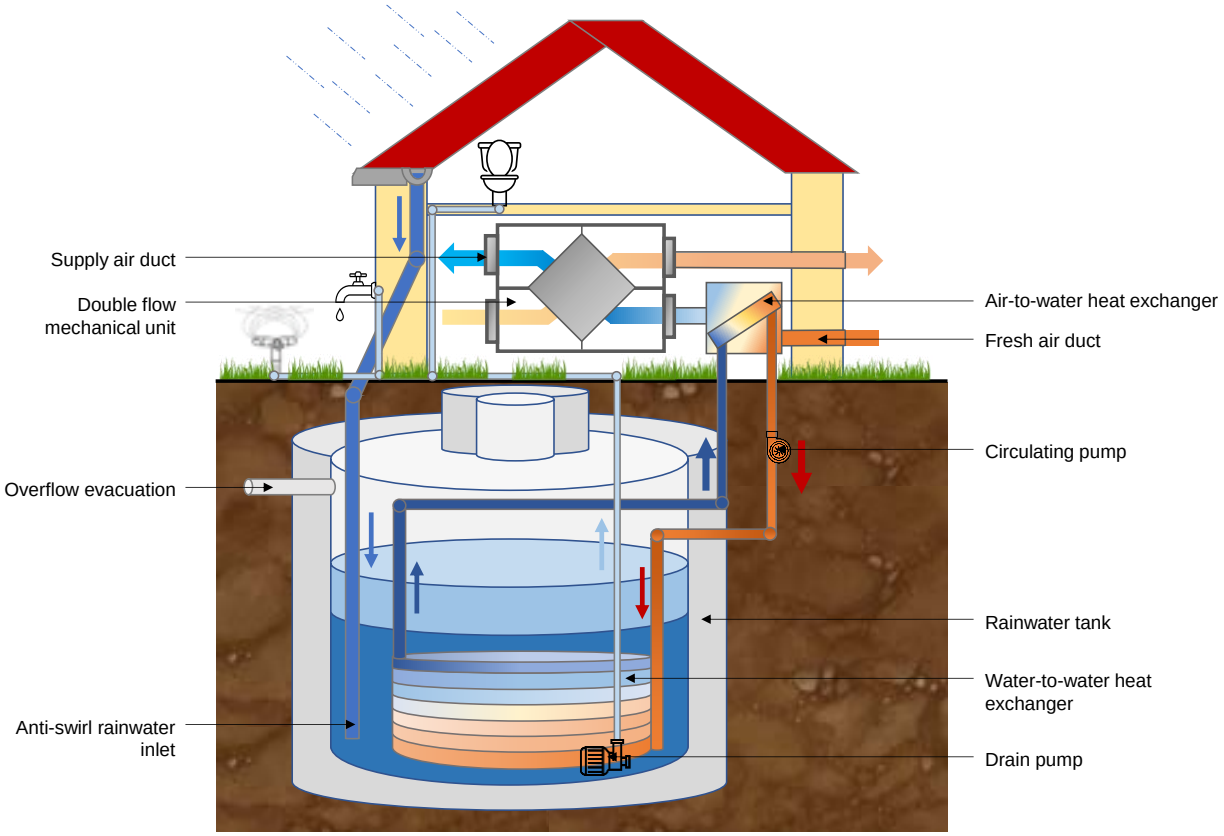

Figure. 1. Schematic diagram of the Rainergies principle (not at scale).

3. Experimental Study

3.1. Experimental set-up

Three Rainergies prototypes are installed in different locations in Alsace, France, in a semi-continental climate [7]. For the sake of conciseness, this article focuses on one prototype, located in Haguenau.

It consists of a 11 m^3 tank made of precast concrete with a coppered hundred-meter-long coiled heat exchanger. The surrounding ground is dry sand. A 1 kW cooling coil, placed before the double flow air handling unit, allows the heat transfer from the water loop to the supply air ventilation of a 150 m^2 family house which dates from the 1930’s but has been retrofitted lately to match current standards of the French building energy code.

Another prototype, also installed in a residential house, is very similar. The third system is located under a small office building with a larger tank of 25 m^3 and two immersed coils.

These prototypes will be the topic of a future communication, allowing to compare results with different setups (*e.g.* the position of the coil in the double flow mechanical ventilation) and ground properties (sandstone and groundwater flow).

3.2. Measurements

Presently, the Haguenau prototype is monitored with more than 25 sensors connected to dataloggers, with a minimum timestep of 10 min. The devices were installed in the summer 2021 and consolidated data is available since early 2022. The main measured data are:

- Water temperature stratification thanks to 5 fixed dataloggers evenly distributed over the height of the tank (0 m, 0.5 m, 1 m, 1.5 m, 2 m).
- Water level through total pressure of the bottom of the tank.
- Air temperature and humidity inside the tank.
- Temperatures at the air-to-water heat exchanger limits (both air and water).
- Meteorological data including rainfall, global solar radiation, air temperature and humidity.
- Temperature inside the buildings (at air vent and in the room)

3.3. Experimental Results

The results observed in winter operation mode and summer operation are encouraging.

During summer operation, as observed on Figure 2, the system can decrease the supply temperature of the ventilation by up to 13 °C, keeping indoor temperatures of the monitored houses under 27°C during the 2022 summer heatwave. The cooling energy between the 14th of May to 1st of September reached 455 kWh (considering an average ventilation flow rate). The average cooling power is 365 W but peaks of 1 kW were observed. Measurements show little variation of the air-to-water heat exchanger efficiency between [0.64 ; 0.88] with an average of 0.82 ± 0.16 which is consistent with the design value.

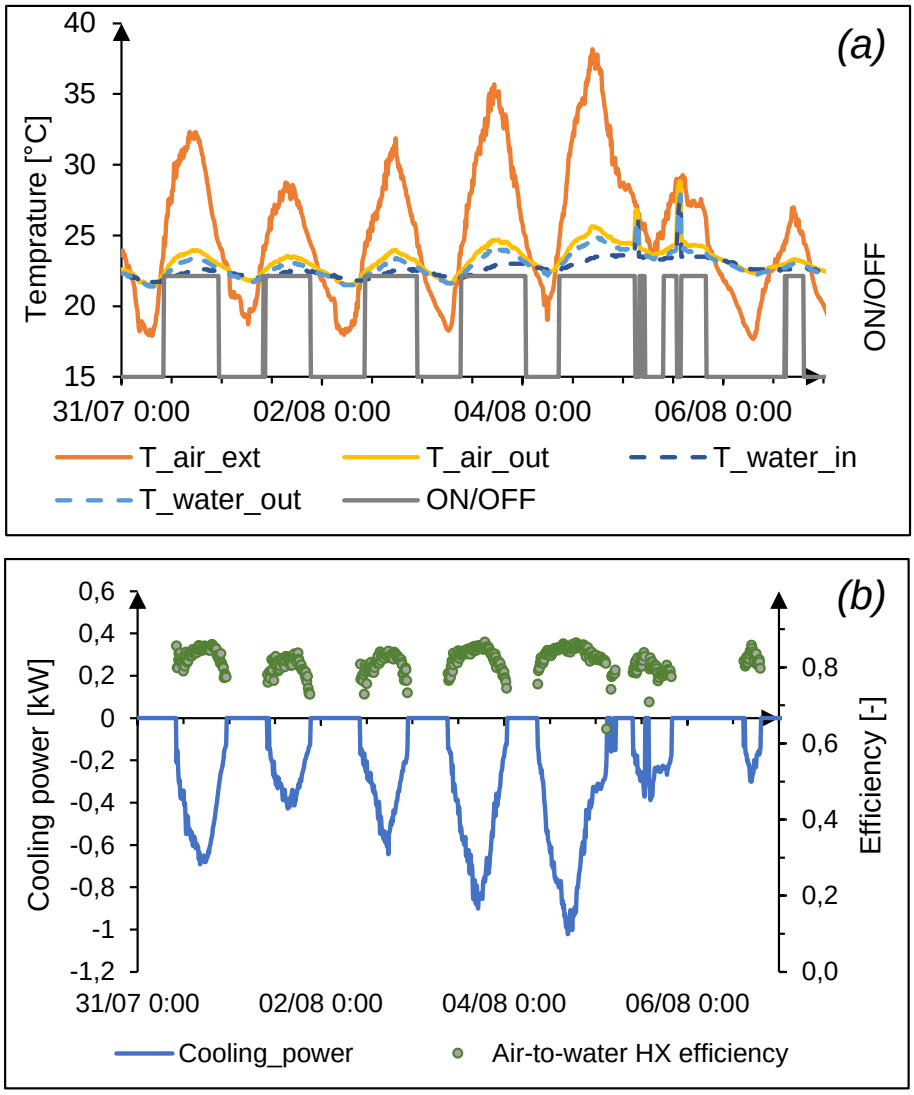

Figure. 2. Air-to-water heat exchanger, summer operation (a) and its cooling power produced and efficiency (b) (2022 – Week 31 – Haguenau).

In winter, it is also possible to use the energy in the tank for preheating before it passes through the double flow ventilation. This preheating is necessary to protect the ventilation elements from freezing in case negative outdoor temperatures. It is usually provided by an electrical heater. On the Haguenau prototype, this phenomenon was observed during 120 h over the winter period 2021-2022 (November 1st to March 15th), corresponding to ~ 39 kWh saved. The power supplied reaches 500W (average of 230W) and the air temperature was maintained above 0 °C despite outdoor dry bulb temperatures of - 6 °C (see Figure 3).

Thus, the system also allows for energy savings in winter (though in moderate quantities). Noticeably, winter operation allows to cool down the reservoir and its surrounding ground, which is beneficial for summer operation, as it participates to a seasonal energy storage.

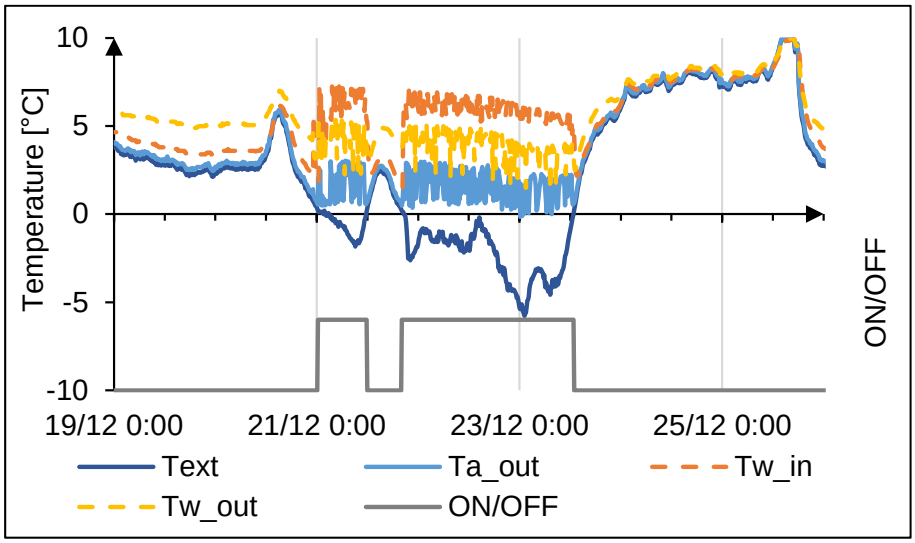

Figure. 3. Air-to-water heat exchanger, winter operation (2021 – Week 51 – Haguenau).

One of the difficulties of this project is to well assess the input parameters and their influence on the system behaviour. The experimental observation phase of the project can help to highlight and understand these events. For example, during rainfall the water temperature inside the tank is influenced by the quantity of rain but also its temperature (see Figure 3 – "T_Xm" meaning that the temperature sensor is at X m starting from the bottom of the tank) : during rainy events, for similar quantities water the temperature in the tank may drop significantly differently (up to 3 K). As this phenomenon is not observed after each rainfall, the hypothesis can be made that the temperature of the rain arriving in the tank is in cause. This parameter is difficult to evaluate, depending on pressure, air temperature but also probably of the roof surface temperature (harvesting surface) however recording the temperature inside the tank rainwater filter will allow in the future to validate the rain temperature model chosen.

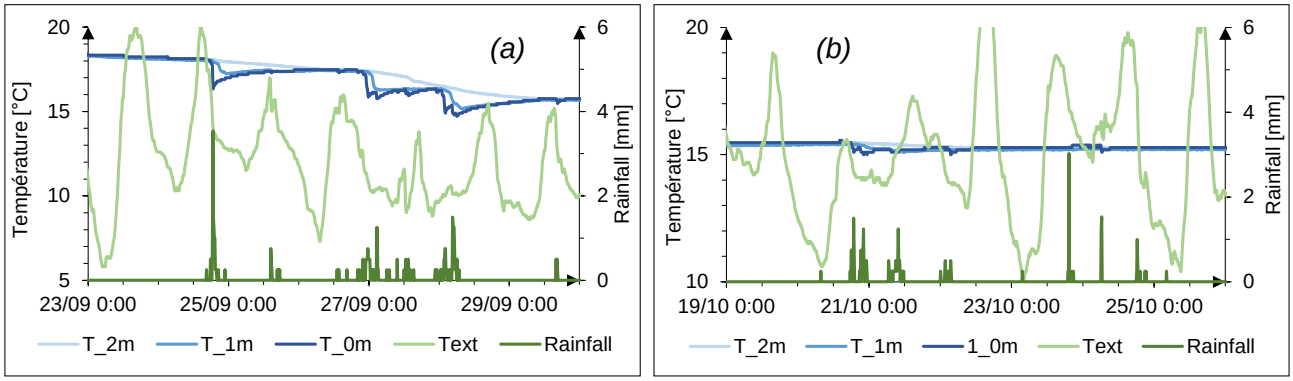

Figure. 4. Rainwater tank during rainy event with influence on the water temperature (a) and without influence (b) (2022 - Week 39 - Haguenau).

4. Numerical Modelling

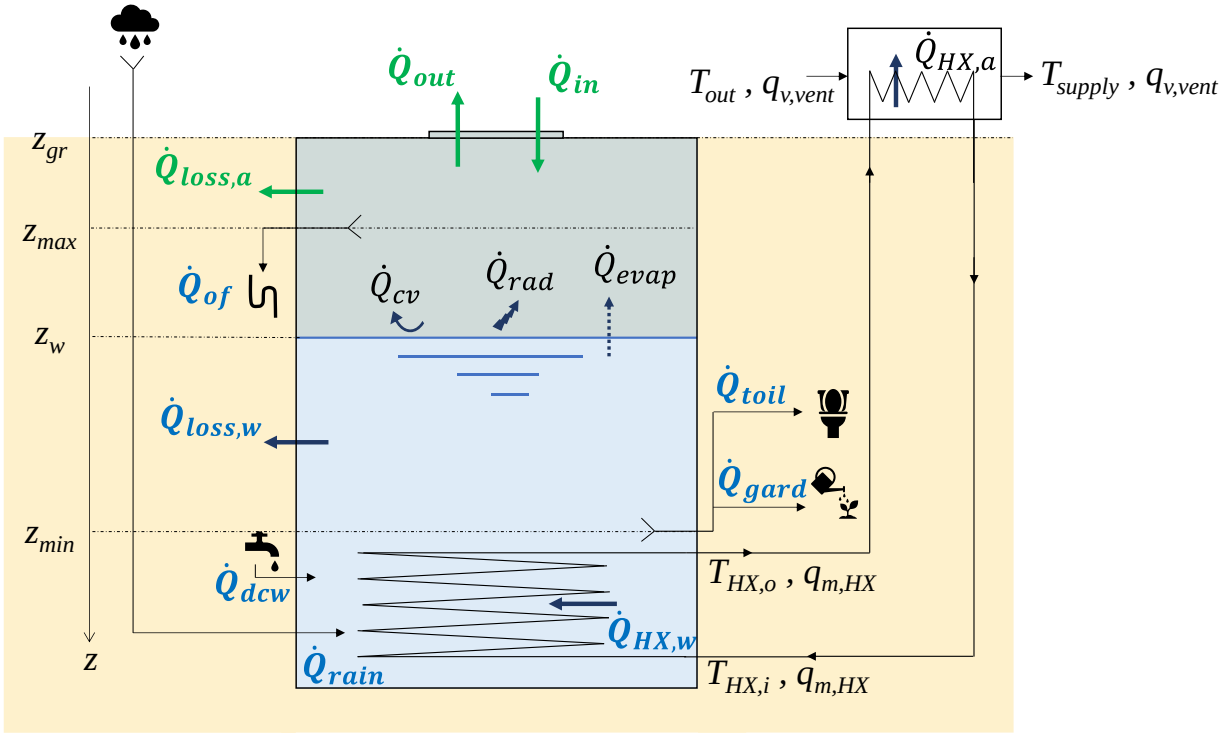

Figure. 5. System thermal balance.

4.1. Tank model

In first approach the tank is modelled with two temperature nodes, the ambient air temperature T_a (Eq. (2)) and the water temperature T_w (Eq. (1)), computed through the following thermal balances (a graphical representation of notations is given in Figure 5).

$$\rho_w c_{p_w} \frac{\mathrm{d}V_w T_w}{\mathrm{d}t} = -\dot{Q}_{loss,w} - \dot{Q}_{cv} - \dot{Q}_{rad} - \dot{Q}_{evap} + \dot{Q}_{HX,w} + \dot{Q}_{rain} + \dot{Q}_{dcw} + \dot{Q}_{toil} + \dot{Q}_{gard} + \dot{Q}_{of} \quad (1)$$

$$\rho_a c_{p_a} \frac{\mathrm{d}V_a T_a}{\mathrm{d}t} = -\dot{Q}_{loss,a} + \dot{Q}_{cv} - \dot{Q}_{out} + \dot{Q}_{in} \quad (2)$$

The different heat flows $\dot{Q}_X$ are detailed below, starting with the water node thermal balance.

- $\dot{Q}_{loss,w} = U_{w,gr} S_w \left(\overline{T_{w,gr}} - T_w\right)$ represents the convective and conductive losses from the water through the wall with $U_{w,gr}$ the heat transfer coefficient, taking into account the convection and conduction resistance, and $\overline{T_{w,gr}}$ the weighted mean temperature of the ground adjacent to water,.
- $\dot{Q}_{cv} = h_{c,\mathrm{a-w}} S_{w-a} (T_a - T_w)$ is the convective flux between the water and the air, with $h_{c,\mathrm{a-w}}$ the convection coefficient.
- $\dot{Q}_{rad} = h_{r,\mathrm{w-w}} S_{w-a} (\overline{T_{wall}} - T_w)$ stand for the radiative exchange between the surface water and the wall above it, with $h_{r,\mathrm{w-w}}$ the linearized radiative coefficient and $\overline{T_{wall}}$ the weighted mean temperature of the wall.
- $\dot{Q}_{evap} = q_{m,evap} L_v$ is the latent loss due to water evaporation, with L_v the vaporization latent heat and $q_{m,evap}$ the evaporation mass flow rate computed thanks to Hen's correlation [8].
- $\dot{Q}_{HX,w} = q_{m,HX} c_{\mathrm{p,gw}} \left(T_{HX,o} - T_{HX,i}\right)$ represents the heat flux extracted from the water-to-water heat exchanger.
- $\dot{Q}_{rain} = q_{m,rain} c_{p,w} T_{rain}$ is the heat flux due to precipitation and is treated as an advection flux. The same approach is used for the district cold water intakes, toilet flushing, gardening, or overflowing withdrawals represented by $\dot{Q}_{dcw}$, $\dot{Q}_{toil}$, $\dot{Q}_{gard}$, $\dot{Q}_{of}$ respectively.

The air node thermal balance is presented below.

- $\dot{Q}_{loss,a} = U_{a,gr} S_a (\overline{T_{a,gr}} - T_a)$ expresses also the convective and conductive losses through the wall but on the air side (similarly $U_{a,gr}$ stand for the heat transfer coefficient and $\overline{T_{a,gr}}$ the weighted mean temperature of the ground in contact with the air.
- $\dot{Q}_{out} = (q_{\mathrm{m,out}} + q_{m,leak}) T_a$ is an advection flux considering the air volume changes and the air leakage from the tank to the outside. $\dot{Q}_{in}$ is its counterpart but from the outside to the tank.

The inlet and outlet temperatures of the coil are computed through both equations of the air-to-water and water-to-water heat exchanger. As mentioned in the experimental results section, the air-to-water heat exchanger efficiency does not vary much, hence it is assumed constant which is also consistent with the forced convection that takes place in the exchanger. For the first simulations, the same hypothesis has been made for the water-to-water heat exchanger efficiency. The supply air temperature is determined by the equilibrium of the heat flow at the air-water heat exchanger.

4.2. Ground model

The ground is assumed to be homogeneous with constant properties not depending on the soil moisture. As the heat transfer is symmetrical according to the z axis, the 2D heat transfer equation in cylindrical coordinates was used:

$$\rho c_p \frac{\partial T}{\partial t} = \lambda \left(\frac{\partial^2 T}{\partial z^2} + \frac{\partial^2 T}{\partial r^2} + \frac{1}{r} \frac{\partial T}{\partial r} \right) \quad (3)$$

The numerical model for the heat equation is a discrete finite volume formulation of Equation (3). Depending on the volume location, thermal properties are adapted. A source term is added on the superficial node to consider the solar radiation. In this first model, the spatial discretisation is constant with 50 cm mesh, but it is intended that following models integrate a variable space discretisation with local refinements around the tank. The variation of ground moisture content is not modelled in this first model.

4.3. Solving Procedure

In order to solve simultaneously for the air, water and ground temperatures, the semi-implicit Crank-Nicolson numerical method was used as described by Walther [9]. It has the advantage of unconditional stability and is of second order in space and time.

5. Model validation

5.1. Simulation hypothesis

Input parameters, such as weather data or geometrical parameters, are extracted from measured prototype data. Glycol water mass flow and air ventilation flow are considered constant respectively at 0.14 $kg.s^{-1}$ according to the design value and 240 $m^3.h^{-1}$ according to one-off measurement values. Convection coefficients were assessed for steady state and kept constant throughout the simulation.

Marigo [5] using a previous study of Kusuda and Achenbach [10] explains that ground temperatures without thermal perturbations (*e.g.* geothermal probe or buried tank) depend on ground properties and outside air conditions (average annual air temperature and annual air temperature amplitude) :

$$T_{ground}(z,t) = T_m - A_T e^{-z\sqrt{\frac{\pi}{\alpha \tau_{year}}}} \cos\left(\frac{2\pi}{\tau_{year}} \left(t - t_0 - \frac{z}{2} \sqrt{\frac{\tau_{year}}{\alpha \pi}} \right) \right) \quad (4)$$

T_m is the annual average air temperature (°C), A_T is the annual amplitude of monthly average air temperature [°C], α is the ground thermal diffusivity ($m^2.s^{-1}$), τ_{year} is the annual periode (s) and t_0 is the date of the minimum surface temperature (s). Figure 6. shows the ground temperature variation as function of depth from the surface during the year, which is relatively stable at a 10 m depth. The ground temperature is therefore assumed constant at a depth of 10 meters below ground level (lower boundary condition). The soil temperature for $0 < z < 10$ m is initialised according to this model.

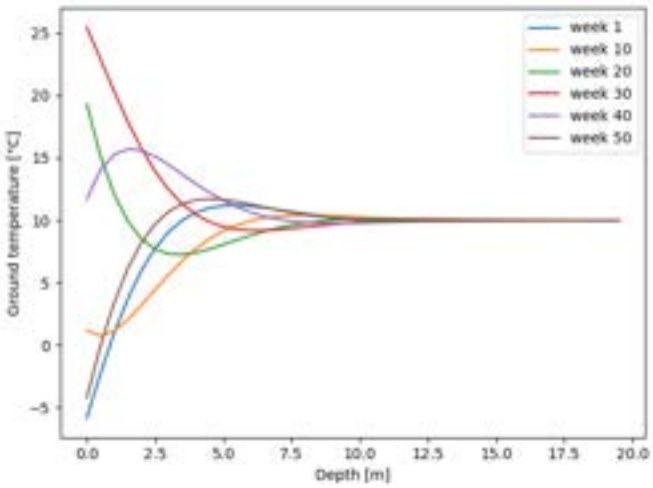

Figure. 6. Calculated ground temperature against depth for several week in Haguenau

The outdoor weather data are used as boundary condition for ground surface (temperature, wind and solar flux).

The input parameters are summarized below.

Table 1. Input parameters of the conducted simulation.

Parameter	value
Simulation parameters	
Timestep	600 s
Spatial step through z axis	0.5 m
Spatial step through radial axis	0.5m
Geometrical dimensions	
Tank diameter	2.5 m
Tank height	3 m
Roof surface	180 m²
Ground domain depth	10 m
Ground domain radius	10 m
Material properties	
Ground thermal conductivity	0.7 $W.m^{-1}.K^{-1}$
Ground heat capacity	850 $J.kg^{-1}.K^{-1}$
Ground density	1600 $kg.m^{-3}$
Heat transfer coefficients	
Water-to-water HX efficiency	0.7
Air-to-water HX efficiency	0.8
Water to tank wall convection coefficient	20 $W.m^{-2}.K^{-1}$
Air to tank wall convection coefficient	7 $W.m^{-2}.K^{-1}$
Air to water surface convection coefficient	6 $W.m^{-2}.K^{-1}$

5.2. Numerical results

The prototype setup was simulated over the summer period (from the 14/05/22 to the 31/08/22), using the boundary conditions described in previous section.

The simulation results obtained are presented on Figure 6, depicting the simulated versus measured water tank temperature (above) and the supply air temperature (below). This first model exhibits a correct behaviour in terms of dynamics of the phenomenon, although the magnitude of variations can possibly be fine-tuned.

Considering the simplifications made, the numerical results are very encouraging: the dynamics of water and air temperatures are respected and the simulated water-to-water heat exchanger inlet and outlet temperature and air supply temperature globally match the experimental data.

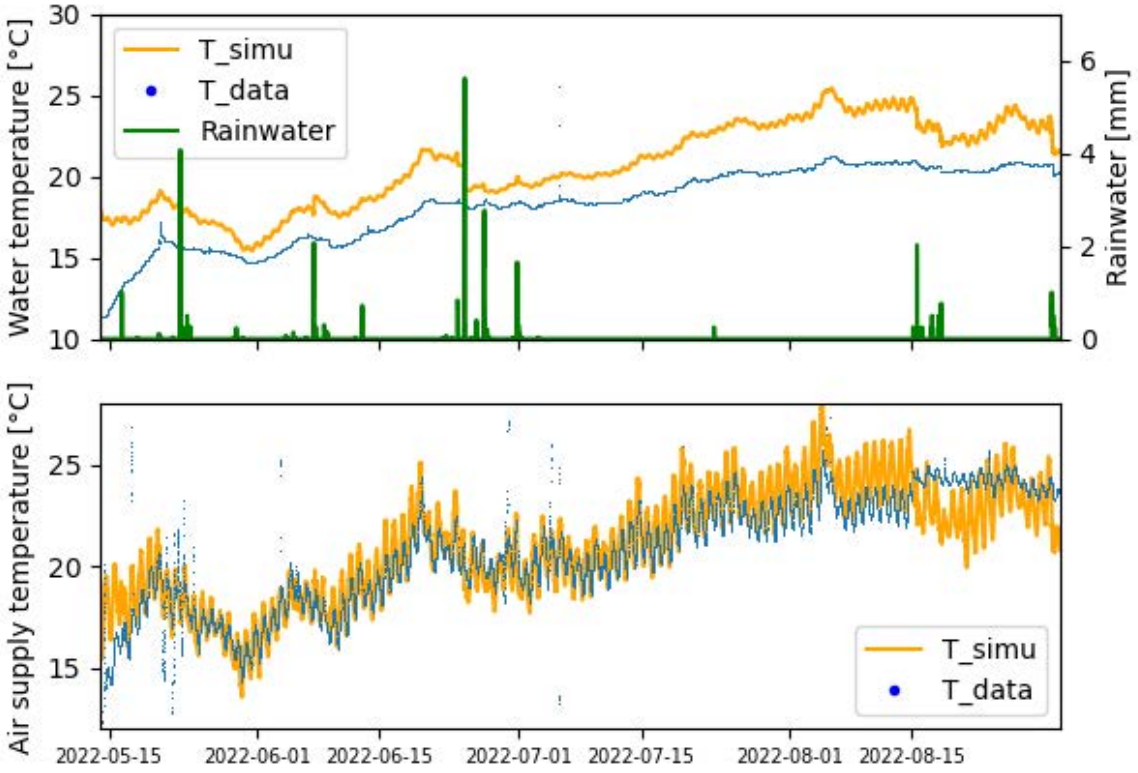

Figure. 7. Experimental and numerical data

Table 2. Root mean square error (RMSE) between numerical and experimental results

Analysed output	Root Mean Square Error (°C)
Air tank temperature	1.62
Water tank temperature	2.66
Inlet HX temperature	1.09
Outlet HX temperature	1.19
Supply temperature	1.22

In terms of RMSE, the preliminary simulation results obtained are as follow: the highest error is made on the tank temperature prediction (2.77 K) and errors of the order of 1.09 to 1.62 K are made on other temperatures.

In order to reduce the discrepancy between model and measurement, a sensitivity analysis of the model to its input parameters was undertaken.

5.3. Sensitivity analysis

In order to identify the influential parameters of the model, with the intention to obtain a better fit between model and measurements, a preliminary sensitivity analysis was conducted. We used Morris' [11] "one-at-a-time" sensitivity analysis method, taken up by Campolongo [12], which provides a ranking of parameters with an acceptable computational expense, given the involved simulation time (*id est* approximately 2 hours computation for 1 month simulated). The principle of Morris' method, nowadays widely used in the building simulation community, consists in computing the average elementary effect of the variation of one parameter at a time, usually for a dozen of repetitions. This was performed using the state-of-the-art SAlib python library.

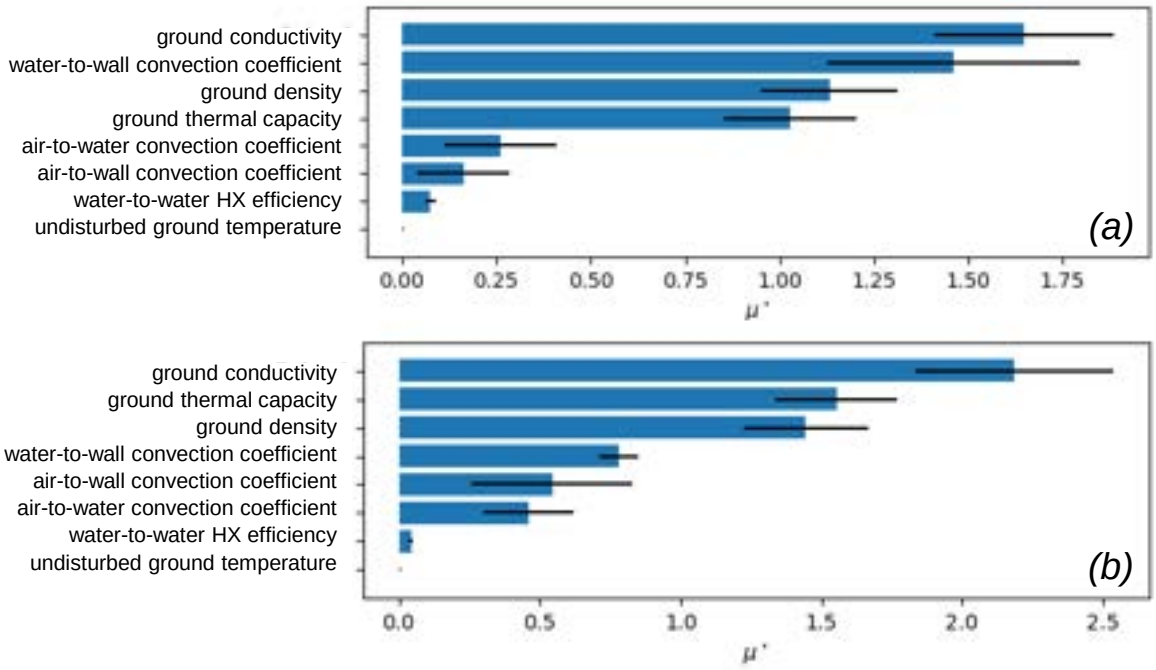

Figure. 8. Elementary effects of Morris's sensitivity analysis on the water tank temperature (a) and on the air tank temperature (b)

The investigation focusses on ground properties, thermal convection coefficients and the efficiency of the water-to-water heat exchanger.

The results obtained on the water tank temperature and air tank temperature are presented on Figure 7. Similar studies were also conducted on the inlet and outlet heat exchanger temperature and on the supply air temperature. The conductivity of ground, the thermal capacity of the ground and the density of ground are the three first influent parameters. The reservoir wall convective transfer coefficient of water is also influent on the water tank temperature.

The results show that following parameters are particularly influent on the outputs:

- All ground properties are significant on the water temperature output. Therefore, assessing those coefficients will be crucial for future work.
- The convection coefficient between wall and water, which calls for the numerical implementation of a temperature dependent correlation.

As a sequel, a parametric fit optimisation on the most influent parameters will be undertaken, with the aim of obtaining a better prediction of the measured temperatures.

6. Discussion

On the experimental side, the primary results exhibit good result with outside air temperature reduction of more than 10 K and cooling power reaching 1 kW. Noticeably, this system does not aim at replacing air conditioning, but it can reduce its use, especially in high-performance buildings. During winter, the prototype can pre-heat the air to protect the installation from frosting, saving the use of an electrical heater.

It is foreseen to conduct data acquisition within shorter timestep to try to better understand short-timed event such as rainfall and its impact on the rainwater tank temperature.

Regarding numerical aspects, ensuing the sensitivity analysis, a parameter fitting procedure will be lead in order to minimize the discrepancy between the model and measurements. Moreover, the models need improvement which have already been planned. The rainwater tank needs to integrate the water stratification and a better evaluation of air leakage which can strongly influence both air and water temperature. Thermal convection coefficients and water-to-water heat exchanger efficiency need also a finer calculation, *e.g.* depending on the air or water temperature instead of constant values. The time calculation will also be enhanced by changing the solving method and switching to a sparse linear algebra library. It will allow shorter time calculations and thus offer more options in terms of sensitivity analysis but also optimization.

7. Conclusion and perspectives

Coupling the model with a building energy simulation tool will allow in future works to optimize the controls and test the solution in different conditions (climate, …). It is also planned to explore the use of a dew point cooler that can provide extra cooling power by water evaporation into exhaust or supply air.

Moreover, with the rise of drought frequency, the applications of rainwater collection may widen, for example with the use of rainwater for laundry. This raises several new questions about the quality of the water stored in the tank. The water temperature increase may lead to microbiologic development, which can make the water unsuitable for certain uses (such as supply for washing machine). It is also possible for a biological film to develop on the heat exchanger leading to fouling and deterioration of its performance. This problem is not very common and deserves some investigation.

The applicability of such systems in real configurations, the performance prediction and the determination of design guidelines is obviously one of the objectives of the research conducted here, be it for commercial buildings or housing applications.

Abstract:

In general, any changes to room temperature for energy savings should not impact the occupants' thermal comfortability. Therefore, the thermal control strategy should meet the occupants' thermal comfortability expectations while exploring the energy consumption reduction strategy. The paper presents our preliminary work in developing "people-centered" energy-saving methods. The work starts with building a CFD thermal dynamic model of the room by using an actual kitchen as the prototype. The model can simulate and derive the temperature at any position within the room space and capture its temperature dynamics. Then, a target-tracking people-centered control strategy is proposed. With the occupant's motion and position changes, the model can calculate the room temperature at the point where the occupant is located. The objective of the control is to ensure the occupant's thermal comfortability. The initial simulation study indicates that the target-tracking control strategy could potentially save 23.32% more energy and greatly enhance the occupant's thermal comfort compared to a fixed-position sensor-based control strategy.

Keywords:

Thermal Comfort Control; Energy Efficiency; CFD; Thermal Dynamic Model.

1. Introduction

The UK government has set an ambitious target to reduce emissions by 78% by 2035 compared to the 1990 level [1]. A more ambitious goal is to achieve zero carbon emissions by 2050 [2]. To achieve this target, significant efforts must be made for decarbonizing power generation, heating, and road transportation [3]. Power generation from renewable energy sources has proliferated in the past ten years [4]. However, emissions from heating are almost unchanged. Without decarbonising heating, Net Zero goal has no way to be achieved as heating contributes nearly half of the energy consumption in the UK, in which 57% is used to meet domestic space heating and hot water demands [5]. Electric heating using power from renewable energy sources can promote heating decarbonization and proper electric heating management may support flexible grid operation to allow increased integration of variable renewable energy [6]. Heating electrification in coordination with power generation from renewable energy is considered as feasible way of emission reduction [7].

It is well known that conversion from electricity to heat has an efficiency of 100%. However, the utilisation of the converted thermal energy may not have 100% efficiency while in a heating system. For space heating, temperature distribution and air velocity affect the occupant's thermal comfort level which will lead the variations to energy consumed. A good control strategy for an electric heating system should satisfy the occupants' thermal comfortability while minimising energy consumption.

The room thermal models with high fidelity are essential for thermal comfort control strategies [8]. Room thermal models can be divided into three categories: white, black, and grey box models [9]. The white box model is based on the derivation of physical equations and assigning values to parameters in the model based on empirical knowledge [10]. Jradi et al. [11] developed a dynamic energy performance model for four buildings in Aarhus, Denmark, considering realistically measured physical parameters of components such as roofs, exterior walls, windows, doors, and floors. The model guides the analysis and evaluation of energy retrofits in buildings. The black box model is a purely data-driven model that uses artificial neural networks (ANN) to model the mapping of input parameters to desired output parameters [12]. Attoue et al. [13] proposed an ANN-based indoor temperature prediction model that considers the effects of solar radiation,

historical indoor and outdoor temperatures, and indoor and outdoor humidity on indoor temperature. The grey-box model is a hybrid model that uses physical knowledge to build a mathematical model and uses ANN to mine the relationships between a large amount of actual residential thermal data to obtain the values of the parameters in the model [14]. Hu et al. [15] developed a self-learning grey box room thermal model which uses indoor air and outdoor air temperatures to pre-estimate and scale the model parameters. Case studies show that the model can accurately predict indoor air temperature variations.

However, in these models, the temperature distribution in a space is normally assumed to be uniform. In this way, it is common for occupants to experience differences in thermal comfort in different parts of the room, with some areas feeling hot and others cold, which will affect the occupants' thermal comfortability and may be accompanied by an increase in energy consumption. Focusing on this challenge, this paper explores energy efficiency control strategies for occupant comfort enhancement based on a thermal dynamic model of the room.

The main contributions of the paper present: i) a thermal dynamic model could predict the temperatures of any position point in a room space is built; ii) a target-tracking energy saving control strategy to enhance the occupants' thermal comfortability is proposed; iii) a simultaneously evolving dynamic thermal models and occupant thermal comfort-oriented control strategies is implemented based on a co-simulation multi-platform.

2. Description of a target-tracking thermal comfort control system

The target-tracking thermal comfort control system is shown in Figure 1. The aim of the control system developed to achieve energy efficiency while maintaining the occupant's thermal comfort. Three parts form the control system: room CFD thermal dynamic model, occupant location recognition, and control strategy. The parameters and location of the electric heater are fed to the CFD model to simulate heat dissipation and transfer in the room as a heat source. Then, the room temperature distribution will be calculated and updated via the CFD simulation during each simulation time step. By this way, the temperature at different mesh point locations in the room can be obtained. The occupant location recognition is performed by synthesizing the sensors' data so the temperature of the occupant's activity zone can be obtained. The control strategy will be formulated to regulate the heat dissipation power of the electric heater. The study is based on INVENTOR and COMSOL software to build room CFD thermal dynamic model and on COMSOL and SIMULINK software to develop and simulate control strategy. The occupant location recognition part is achieved by an occupant random path generation model based on MATLAB software.

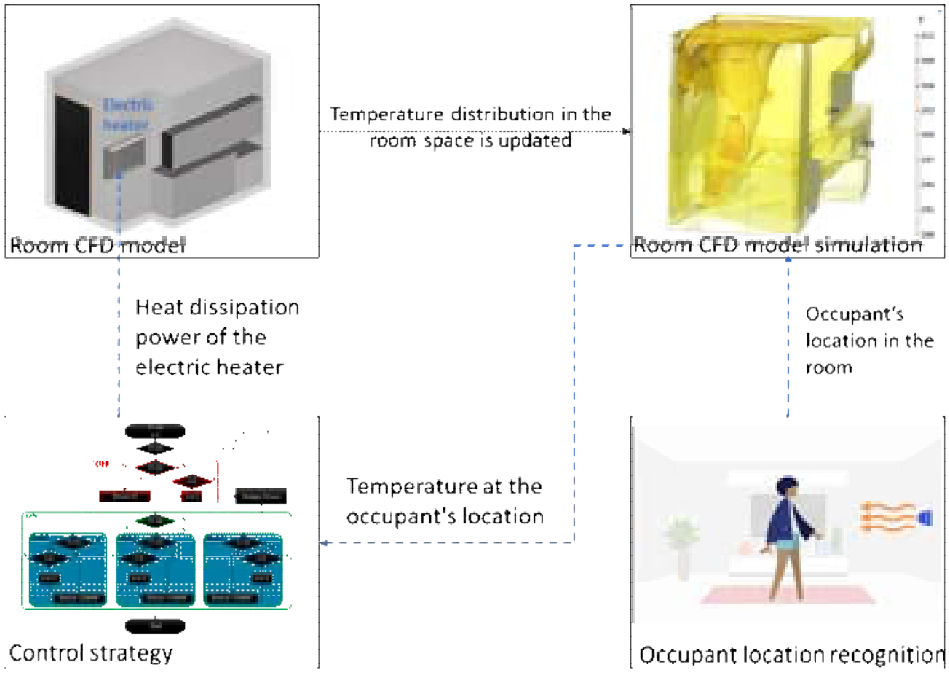

Figure. 1. Target-tracking thermal comfort control system illustration

3. Room CFD thermal dynamic model

Different from the current room thermal models assuming a uniform temperature distribution in the room space, the paper explores the room thermal dynamics and temperature distribution via a CFD simulation which will be performed with the information of room boundary conditions and the heat source (an electric heater in this study); the CFD model will be able to provide the temperature distribution for a different location in the room 3D space, and the resolution depends on the choices of mesh.

The CFD thermal dynamic model is built with the benefits of two software packages: INVENTOR and COMSOL. As shown in Figure 2(a), the laboratory kitchen is chosen as a base space for modelling. Use INVENTOR software to generate a 3D model of the room with consideration of the shapes and spaces of the interior furniture and appliances. The 3D room model is shown in Figure 2(b). The electric heater is the only heat source located in the room to heat up the space. The synchronization of this 3D room model in INVENTOR and COMSOL software is achieved via LiveLink for Inventor interface. In COMSOL, by assigning physical parameters to the components of the 3D room model and adding multi-physics field, the CFD model will obtain the temperature distribution inside the room space. Figure 2(c) shows the room CFD model mesh used in simulation.

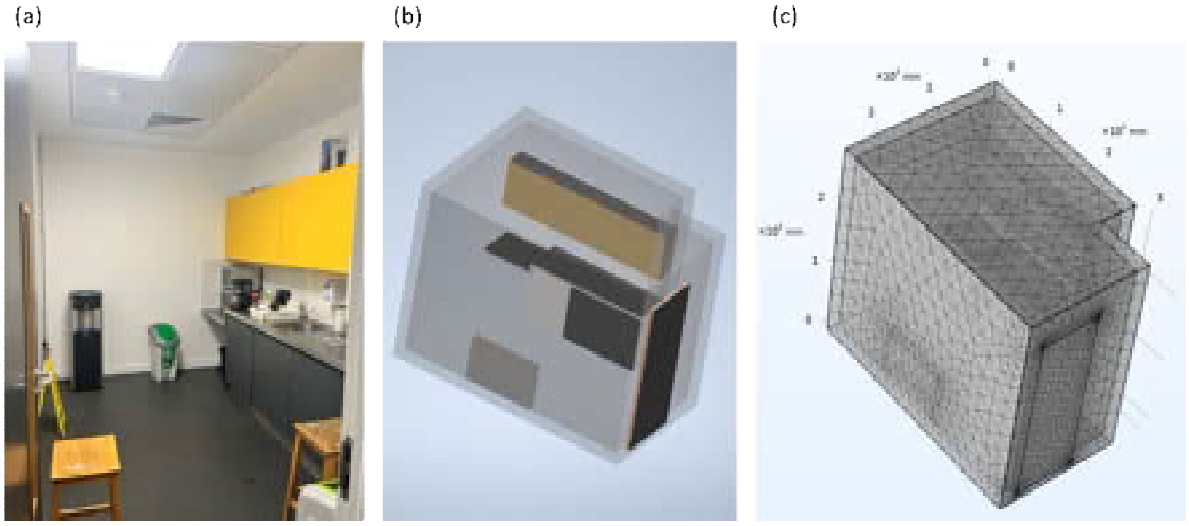

Figure. 2. a) The room, b) 3D model of the room, c) illustration of the room CFD dynamic thermal model mesh

In order to get the information about the temperature distribution inside the room space during the operation of an electric heater, multi-physics field simulations of coupled fluid flow and fluid-solid heat transfer are required in using COMSOL Multiphysics modelling. The laminar flow model is used to simulate the air flow in the room. The thermal model chooses using solid and fluid heat transfer physical fields. The total volume of the room is approximately 26.4 m^3. Physics-controlled mesh, shown in Figure 2(c), was generated automatically with element size set to coarse. The automatically generated mesh contains 127,313 domain elements, 15,887 boundary elements and 1,558 edge elements. Referring to the European National Building Code [16], heat transfer coefficients for the exterior wall and the door are selected to be 2.5 W/m^2K and 3 W/m^2K, respectively to represent the simulating scenario. The initial temperature is set as 10 ℃.

The input variable to this room CFD model is the thermal dissipation power of the electric heater. The state variable is the temperature distribution in the room space. By setting the thermal dissipation power of the electric heater, the temperature distribution in the room space will be updated at each simulation step.

4.Thermal comfort control strategies

A quantum series heater is investigated in this paper. This electric heater is an advanced product in the UK market. The heater used in this paper is model QM150RF, which has three electric heating modules, each operating at 1100 W and one fan, operating at 11W. The heater uses forced convection heat transfer to provide heat to the occupant. The electric heater is well insulated, the heat is released from underneath the heater, and a fan blows from underneath the heater to bring the heat into the room. In this study, the circuit of the electric heater has been modified so that it can now be heated at three levels of power: 1100 W, 2200 W, and 3300 W. The control strategy in this paper has been developed based on these three levels of power.

A commonly used temperature control strategy currently is thermostatic control. Based on the temperature data input from a fixed sensor to maintain the temperature near that sensor in a fixed interval, usually 21-25℃. Control strategies based on feedback from fixed temperature sensors are developed under the assumption that the temperature distribution within a room space is uniform. However, there is a large variation in the temperature distribution within the room space, which leads to erratic performance of control strategies based on fixed temperature sensor feedback. The CFD thermal dynamic model of the room developed in the third part of this paper can provide temperature variations at any location during the operation of the electric heater. LiveLink for Simulink interface enables the joint simulation of this CFD model in COMSOL and SIMULINK software. The development and simulation of the control strategy in this paper is based on the combined operation of SIMLINK and COMSOL software. The target-tracking thermal comfort control system proposed in this paper is shown in Figure 1. The heat dissipation power of the electric heater

is the control variable of the strategy and the temperature distribution in the room space is the state variable. The target-tracking thermal comfort control framework is present as follows:

$$\begin{cases} C(t) = f_{cs}(T(t)) \\ T(t) = S(t)|(x,y,z) \\ (x,y,z) = f_{olc}(t) \\ S(t+step) = f_{rtdm}\big(S(t), C(t)\big) \end{cases} \quad (1)$$

where, f_{cs} is the control strategy. $C(t)$ is the control variable at time t. $T(t)$ is the temperature at the occupant's location at time t; $S(t)$ is the state variable at time t, which is a function of the spatial coordinates. f_{olc} is the occupant location recognition model which is a time-dependent function. (x,y,z) is the occupant's spatial location. f_{rtdm} is the room CFD thermal dynamic model. $step$ is the simulation time step.

The control strategy is present in Figure 3. The control strategy development draws on the operating model of the actual electric heater. The operating states of an electric heater can be divided into two main categories, off and on. When the heater is on, it can be divided into three operating models, Mode 1 (power = 1100W), Mode 2 (power = 2200W), and Mode 3 (power = 3300W). The control strategy ensures that the temperature around the occupant is always between 21 and 25 ℃. Taking into account the time-dependent nature of heat diffusion and to avoid frequent start/stop of the electric heater, the control strategy is structured in a self-cycling manner for each mode.

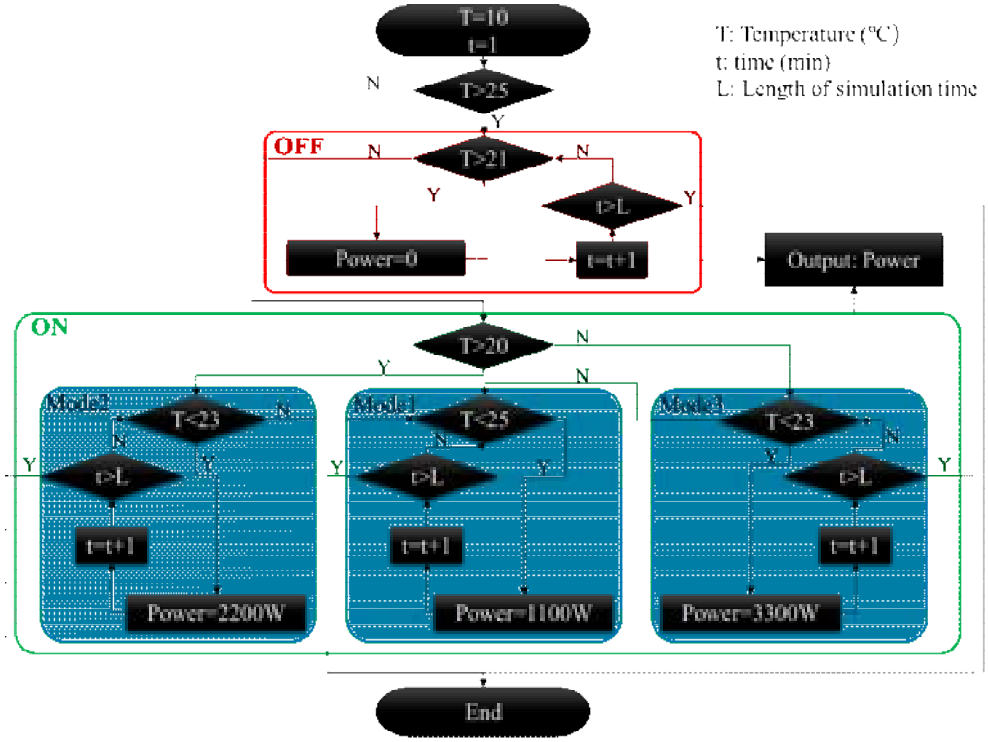

Figure. 3. Thermal comfort control strategy

In order to set the object of comparison, two fixed sensor-based control systems are designed for this study. These are, respectively, a control system based on a temperature sensor fixed to a doorway (TC@d), a control system based on a temperature sensor fixed near the heater (TC@h).

5. Results and discussions

This paper is based on a multi-software platform to complete the development and simulation of a CFD thermal dynamic model of the room and a target-tracking thermal comfort control strategy. The co-simulation flow is shown in Figure 4. During the co-simulation process, the synchronization the 3D room model on INVENTOR and COMSOL platforms via the LiveLink for Inventor interface. The interaction of the input and output data of the room CFD thermal dynamic model on the COMSOL and SIMULINK platforms is accomplished via the LiveLink for Simulink interface.

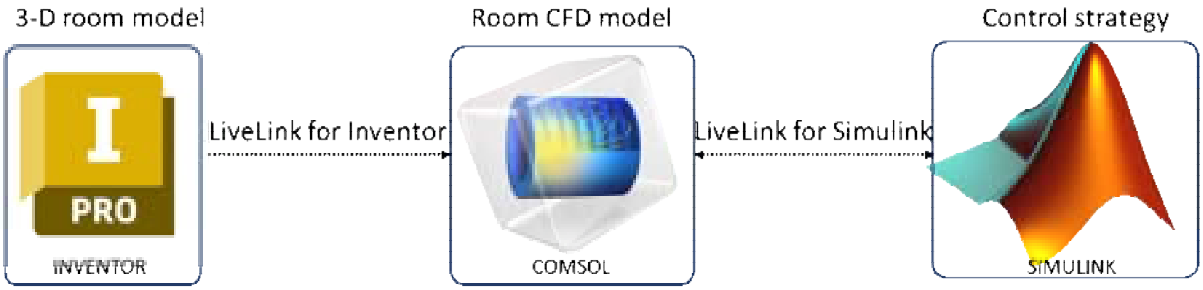

Figure. 4. Multi-platform co-simulation flow

This paper completes all simulations using a computer with an AMD Ryzen 5600H 3.30 GHz Processor, 16 GB of RAM, NVIDIA GeForce GTX 1650 GPU, and a 64-bit Windows operation system. Three temperature control strategies are simulated in this study, two based on fixed position sensor data feedback and the remaining on dynamic occupant activity trajectory temperature feedback. In the room CFD model, a plane one metre above the ground was set up as shown in Figure 5(a). Eight temperature probes were arranged on this plane, as shown in Figure 5(b). In this paper, the occupant's activity range in the room is divided into eight zones. The central temperature of the occupant's activity area is fed to the control strategy. The temperature at the occupant's activity area is always in a suitable range by selecting the appropriate control variables.

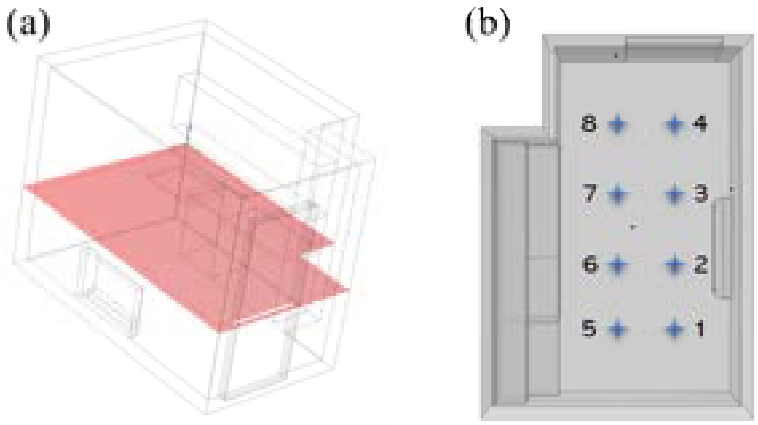

Figure. 5. Occupant activity zones: a) the plane, b) temperature probes

During the simulation, the occupant's activity trajectory needs to be given to verify the strategies' performance. After random sorting, one of the occupant's activity traces was obtained as: 6->3->7->8->5->1->2->4. It is assumed that the occupant spends a half hour in each zone. This paper adds two-time blocks of one hour each to this time location path. During these two-time blocks, the occupant leaves the room. Therefore, the final path obtained for the occupant's location over time is shown in Figure 6. This activity trajectory takes a total of 6 hours.

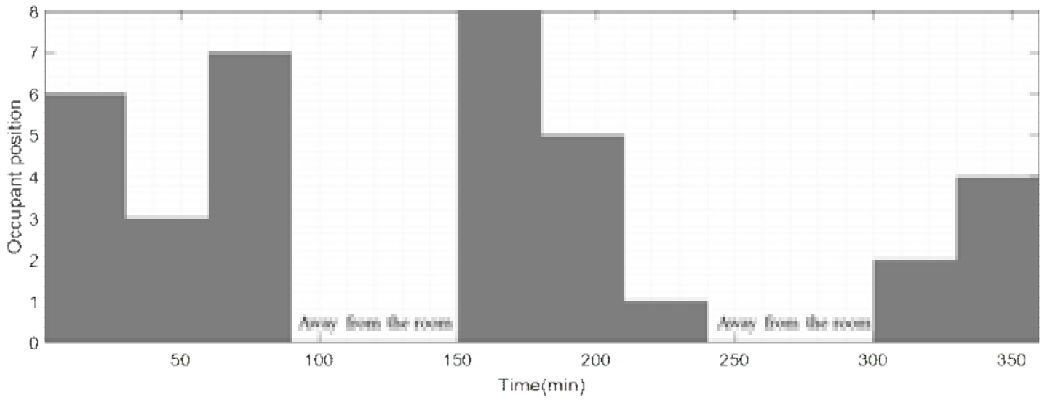

Figure. 6. Map of the location of occupant over time

A simulation analysis of three control strategies is carried out in this paper. These are, respectively, a thermal comfort control strategy for user target-tracking (TC@u), a thermal comfort control strategy based on a sensor fixed to a doorway (TC@d), a thermal comfort control strategy based on a sensor fixed near a heater (TC@h). Figure 7 shows the simulation results for the TC@u strategy. The position of the occupant

during each half hour and the temperature at that position before the occupant moves can be clearly obtained from the figure. The temperature at the occupant's location prior to movement is around 25 ℃. This shows that regardless of the temperature when the occupant enters this location, the TC@u strategy adjusts the temperature at the occupant's location to the set range, thus keeping the occupants thermally comfortable at all times.

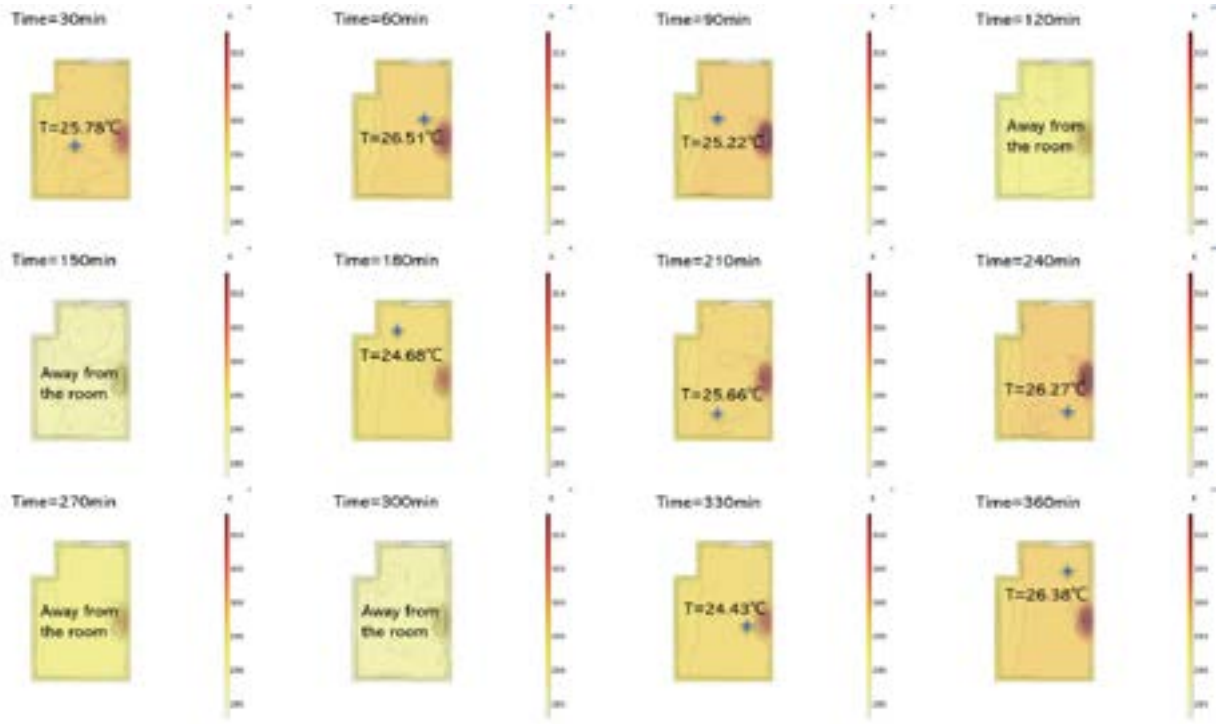

Figure. 7. The position of the occupant during each half hour and the temperature at that position before the position movement under TC@u strategy

Figure 8 shows the simulation results for the TC@h strategy. Prior to the move, the temperature at the occupant's location often exceeded 25 ℃, and even 30 ℃ in some locations. This shows that strategy TC@h does not guarantee the thermal comfortability of the occupants. Occupants tend to feel overheated.

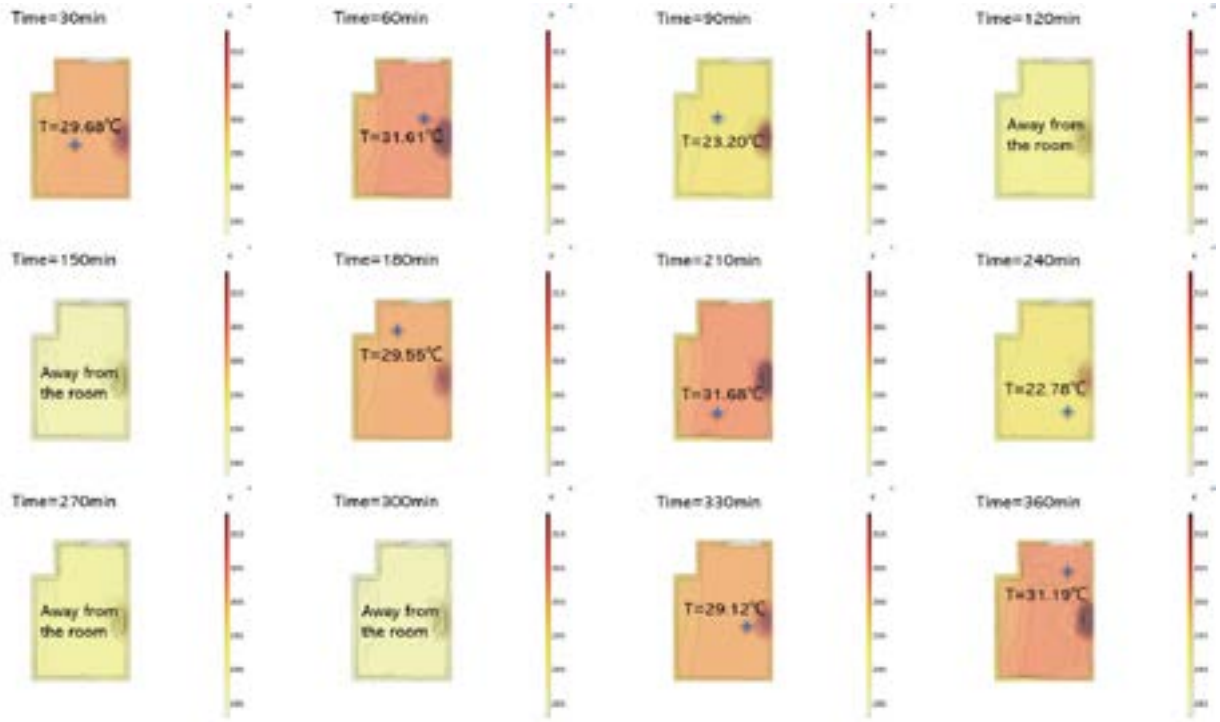

Figure. 8. The position of the occupant during each half hour and the temperature at that position before the position movement under TC@h strategy

The simulation result for the TC@d strategy is shown in Figure 9. Compared to TC@h strategy, the occupant's perception of the high temperature is much reduced in TC@d strategy. However, at 60min, 90min,

240min and 360min, the temperature around the occupant has reached 27 ℃, which has affected the occupant's thermal comfortability. Therefore, based on the simulation results in Figures 7, 8 and 9, TC@u strategy performs best in terms of occupant thermal comfortability.

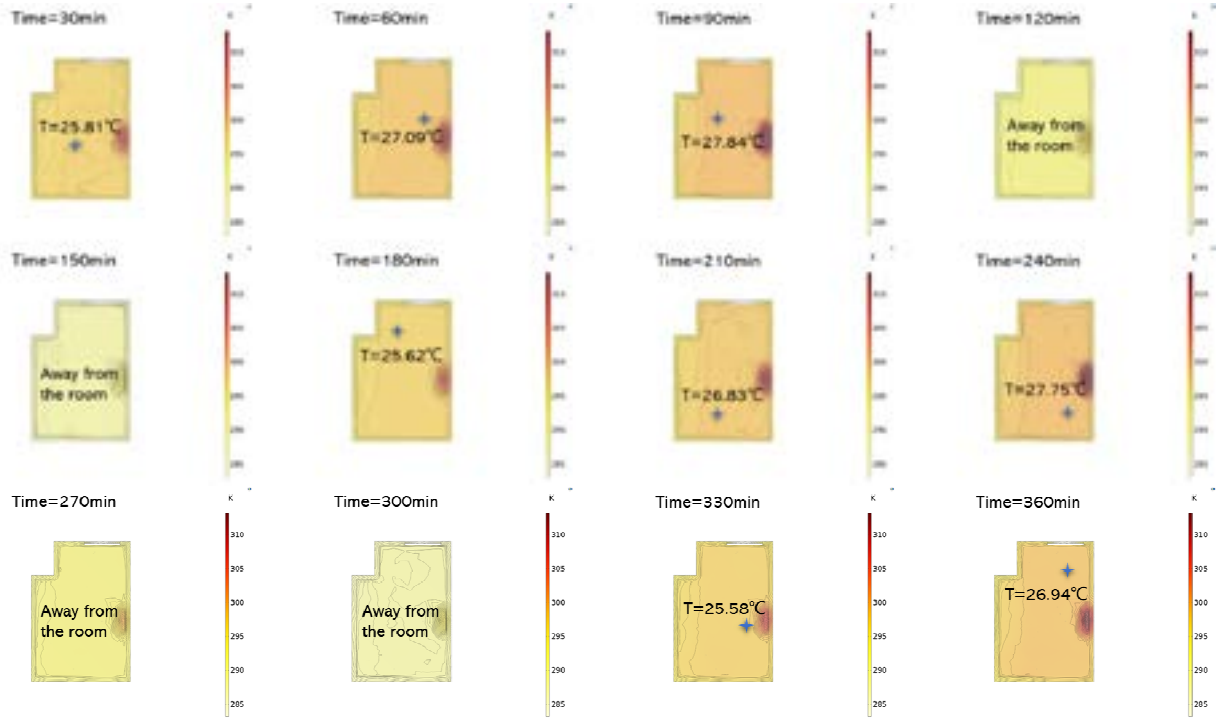

Figure. 9. The position of the occupant during each half hour and the temperature at that position before the position movement under TC@d strategy

Figure 10 shows the temperature variation for the three control strategies at the occupant's actual time location. Strategies TC@h and TC@d cause the occupant to be in the hot zone periodically, and the occupant tends to feel overheated. Strategy TC@u performs reasonably well, with the temperature at the occupant's activity trajectory remaining between 21-25 ℃ for most of the time. However, Strategy TC@u will occasionally experience high-temperature overshoot, as heat is a process quantity that will expand into the surrounding space over time. In subsequent studies, the control strategy needs to be tailored to address this high-temperature overshoot phenomenon.

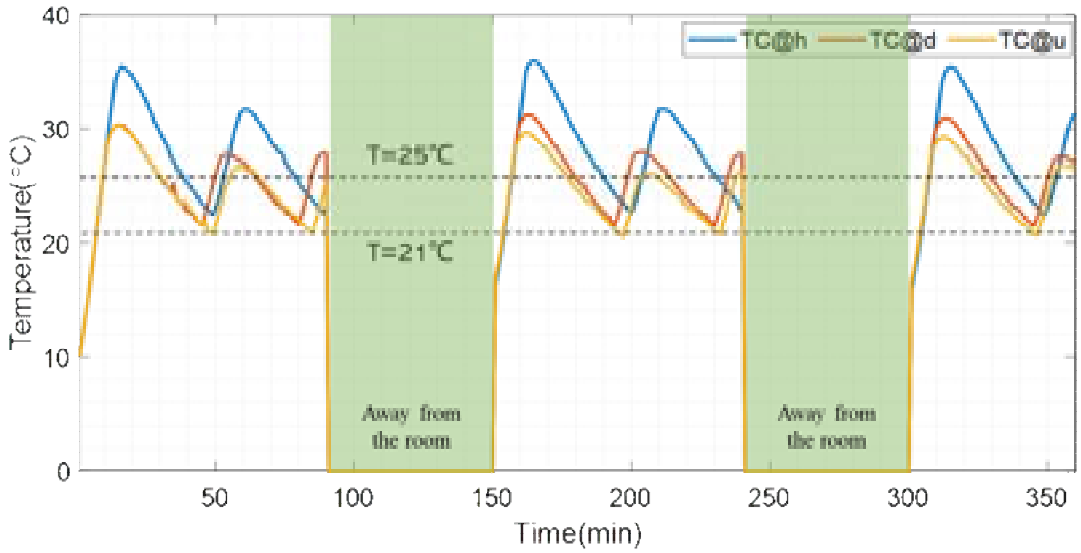

Figure. 10. Temperature at occupant activity trajectories with different temperature control strategies

In addition to comfortability, another indicator that occupants care about is the operating economy. The thermal energy consumption under the three temperature control strategies is shown in Figure 11. After six hours of operation, the energy consumptions under strategies TC@h, TC@d, and TC@u are 2.9887kWh, 2.5300kWh, and 2.2917kWh, respectively. Compared to strategies TC@h and TC@d, the economy of strategy TC@u is improved by 23.32% and 9.42%, respectively. Therefore, TC@u strategy ensures

occupants' thermal comfortability while reducing energy consumption. It is a promising strategy for energy-efficient temperature control.

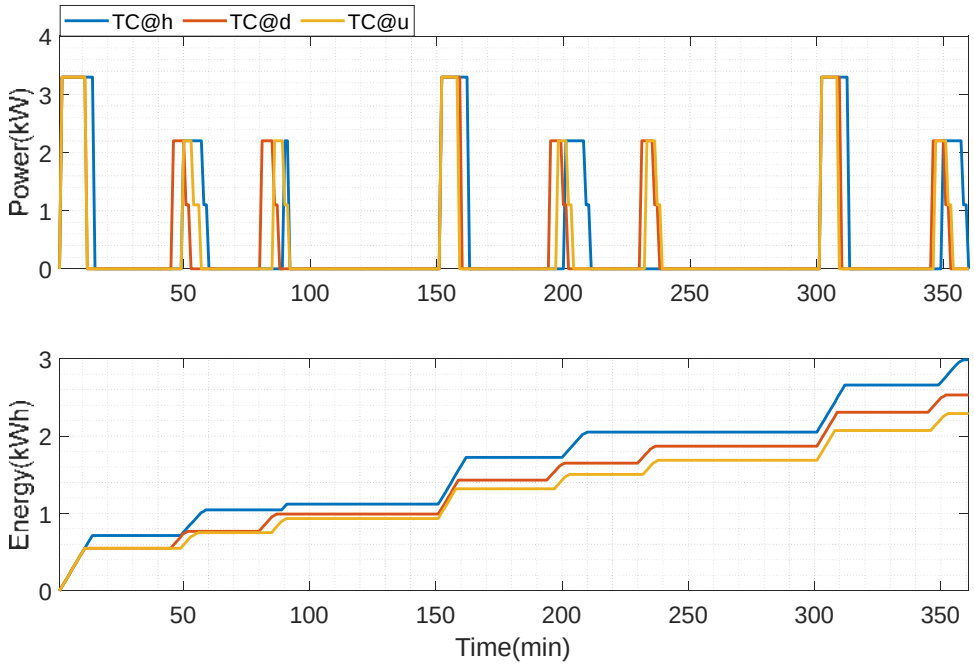

Figure. 11. Thermal energy consumption under different temperature control strategies

6. Conclusion

This paper built a room CFD thermal dynamic model based on the actual kitchen and an electric heater and then proposed a target-tracking thermal comfort control system based on this model. The strategy is developed and simulated through joint simulations on the COMSOL and SIMULINK platforms. The simulation results show that the strategy meets the thermal comfortability of the occupants while considering the economy.

Firstly, a 3D room model based on the INVENTOR platform was built based on the laboratory kitchen. The synchronization of this 3D room model on the INVENTOR and COMSOL platforms was implemented based on LiveLink for the Inventor interface.

Secondly, a room CFD model was created based on the COMSOL platform. The heat dissipation power of the electric heater is the input variable and the temperature distribution in the room space is the state variable. By setting the heat dissipation power of the heater to the model, the temperature distribution in the room space will be updated at each simulation time step.

Finally, a target-tracking thermal comfort control system is proposed and simulated by joint simulations with COMSOL and SIMULINK. The control system aims to achieve energy efficiency while maintaining thermal comfort. It mainly includes three parts: room CFD thermal dynamic model, occupant location recognition and control strategy. The simulation results show that this strategy both meets user comfort and operational economy compared with conventional control strategies.

Abstract:
Techno economic worldview of electricity demand considers and studies appliance ownership and usage as the primary determinants of electricity demand. In emerging economies like India, electricity demand from the residential sector is influenced by a host of other parameters like ability to pay, availability of quality electricity, climate, cultural practices, and specificities of building envelope. The study tries to understand the socio-economic determinants of residential electricity consumption in India considering the state of Uttar Pradesh as a case study. Panel dataset for a five-year period covering 25,690 households have been used for the study. The results indicate that seasonality, availability of reliable electricity, caste, rural or urban nature of the region and gender of the household head were important determinants of electricity demand. A fixed effects model was used for the estimation and was able to explain 80% of the variation in the dataset. The results are significant in two ways. First, they indicate that electricity consumption has to be studied considering its socio-economic context and not from a techno economic standpoint. Secondly, the results indicate that there would be considerable merit in including socio economic variables in the modelling and forecasting of electricity demand, as opposed to the present methods that extensively rely on time series modelling of actual demand.

Keywords:
Residential electricity; Electricity modelling; Econometric modelling; Fixed effects; Energy policy

1. Introduction

Electricity is a critical enabler of quality living conditions. Rapid electrification across developing countries across the last four decades has seen the share of residential electricity consumption in developing countries increase to about 30% of the total electricity consumption [1]. Residential Electricity Consumption (REC) is an aggregated output of individual choices by a large number of actors. It is affected by demand side factors like changes in population, household size, demography, disposable incomes, consumer preferences, energy efficiency measures, technological progress, consumer time use patterns, emergence of new end uses etc. Supply side factors like quality, reliability and affordability of supply could also influence the net electricity consumption of a household. Technological progress and diffusion of new technologies are also an important factor that contributes to the dynamic nature of electricity demand. While lighting with incandescent lamps have been replaced almost entirely with more efficient Light Emitting Diode (LED) lamps, new uses like induction cooking and electric vehicle charging are coming up. As consumers become prosumers, reduced dependence on grid-based electricity could lead to new consumption behaviors. The rapid growth, diversity and dynamism necessitate appropriate methods to study the same.

As of 2021, residential electricity consumption accounts for about a quarter of India's total electricity consumption. The sector has registered significant growth since the 1980s when electricity access to households became a policy concern. The average residential electricity consumption has increased from 18

units (kWh) in 1950 to 1028 units (kWh) in 2020 [2]. It has also been one of the fastest growing sector in the last two decades as shown in Figure 1.2 [3]. The increase in residential electricity consumption in the last five years are most notable. The rise has been attributed to specific factors like increase in the number of households with electricity access, increase in household incomes and increased appliance penetration among others [4]. In 2001, only 55 % percent of the households in India were electrified. By 2021, 99.93% of the households were been electrified [5]. While the increase in consumption has not been uniform across geographies and consumer segments, residential electricity consumption is evolving as a significant dynamic component of the electricity mix. Estimates by International Energy Agency (IEA) indicate that increased appliance ownership and demand for space cooling could increase the residential electricity demand threefold by 2040, from 2021 levels [1].

The fast growing residential electricity sector is also diverse and dynamic. Residential electricity consumption varies widely across states, regions within states and across socio economic groups. In 2018, an average household in Delhi consumed around 270 units (kWh) of electricity per month while the value was much lower for cities like Mumbai (110 units) and Ahmadabad (160 units) [6]. A similar diversity can be observed among states as shown in Figure 1.3. Annual per capita electricity consumption varies from about 700 units in Delhi to less than 100 units in Assam [2]. Such differences across geographies could be due to climatic factors, demographic determinants, socio economic conditions, specific policies etc. [7]. Top-down estimation of electricity demand considering macro trends tend to overlook such differences.

Thus, in a comparative sense, the other sectors of electricity consumption viz. a viz. commercial, industrial, agricultural and traction are better understood due to higher levels of concentration, regulation and documentation. These sectors might have dedicated expertise in managing consumption, the direction of residential electricity is influenced by a very large number of individual strategies (or lack thereof) of consumers who try to maximize diverse personal gains. Policies and plans to manage the residential sector need robust inputs on the future direction the sector. It is also necessary to understand the pathways of increased electricity consumption; to know the sections of the society and economy that have been benefited by the same and those that have been left out. Modelling can be defined as the method of quantifying output parameter as a function of a given set of input parameters [8]. Models of residential electricity consumption are used to determine future supply requirements, effect of a policy, technology or appliance use on overall consumption, evaluate the effects of competing policy scenarios etc. Accurate information about the characteristics of residential electricity use is necessary to plan supply, expansion and efficient use of electricity. Modelling of residential electricity demand is also significant for demand management policies.

1.1 Motivation

The dominating approach to modelling REC has been through the lens of economic elasticities and appliance ownership. Price and income elasticities of populations and regions have been the dominating nature of discourse undertaken to understand REC. In other cases, REC has been viewed as a techno economic question and modelling efforts have focused exclusively on appliance ownership. Both approaches view electricity consumption in isolation, while this study argues that there would be merit in considering the other drivers of REC. Electricity consumption, though realized through the end uses of electricity by appliances, is also affected by other social, economic, climate related and building envelope related factors. They could even be over riding and explain the nature of REC. Income, Gross Domestic Product (GDP), appliance ownership and past patterns of consumption are the most commonly studied determinant factors of REC [9]–[12]. This study is motivated by the question “What other social, economic and other factors could possibly affect residential electricity consumption?”

Past studies have discussed this question in detail, even with contradicting conclusions. Studies like Pachauri (2004), Tuwaitha (2014) and Perera et al. 2021 present consensus that income is perhaps the most important determinant of household electricity consumption. But analysis by CEA (2019) points out that the elasticity might be decreasing [13]. Thus, answering the question “how much does a household consume and why” requires broad based understanding and careful analysis. There has been many studies about the determinants of residential electricity demand in developing countries. [12] presents a review of forty-two studies and discussed the socio economic, dwelling and appliance ownership related factors affecting residential electricity demand in North America and Europe. The study identified a total of sixty-two factors that could potentially affect electricity consumption in households.

1.2 Objective

From the discussion, it is clear that socio economic factors are an important attribute affecting the residential electricity consumption. This paper attempts to understand the nature of this structural determinants of electricity consumption. The objective of the study is to understand the significance of the socio economic, demographic, building environment related, appliance ownership related and climate related determinants of residential electricity consumption, considering the case of India. The question has been approached by constructing a fixed effects model of REC using household level survey data from the state of Uttar Pradesh in India.

2. Literature Review

The review of literature focussed on identifying the studies that have modelled the residential electricity consumption (REC) in India. Studies were identified using a systematic search on three databases viz. a viz. Google Scholar and Web of Science. The most significant studies that are closely aligned with the scope of the present study are discussed in this section.

A study conducted by Laurence Berkely National Laboratory (LBNL) at Berkley University tries to model India's future using a bottom-up modelling approach. The study focuses on modelling the potential for emission reductions in various sectors of the Indian economy including the residential sector. The study considers rural and urban areas separately. Within each, end uses like cooking, water heating, air conditioning, lighting and residual were considered. Further, use of different appliances for the same end use was also captured. While the methodology presents better granularity, it considers the energy use and not specifically electricity use [14].

A large number of forecasting studies are aimed at projecting a future level of consumption. Attention has not been provided to choose of factors that are to be considered in the modelling process (the independent variables) and their weightages. The study aims to fill this gap by understanding the relative importance of factors that determine the household electricity use. A recent study by Basumatary (2021). tried to determine the determinants of household electricity consumption with specific focus on the effects of financial incentives from the government on consumption [15]. The study considers 322 samples from four districts of Assam and concluded that socio economic variables of a household does not necessarily affect electricity consumption. The study suffers from the limitation of limited sample size restricted to a small geography and is focused specifically in the effect of government incentives, but uses novel variables like wattage of connected appliances, number of living rooms, material for construction etc. making the model more realistic [15].

A recent paper by Cazenave and Pachauri (2021) follows a simulation based approach to model household electricity demand using income, stock of appliances and future purchases of appliances. Micro data and representative national survey data is used to model the household electricity demand for four countries of the global south: Ghana, Guatemala, India and South Africa. The study finds that appliance penetration possibilities vary for all the countries spending on country, appliance type, climate and income but with high and stable demand of electricity for entertainment in all the four countries considered [9]. Tewathia (2014) tries to determine the factors that affect electricity consumption of households in Delhi using variables like location, household income, stock of appliances, family size, household size, household awareness and time spent outside. Seasonal variations are accounted for by creating three distinct dependent variables for each season. The study found out household income, temperature and appliance ownership to be significant factors influencing the electricity consumption [16].

Cialani and Mortazavi (2018) tries to estimate price and income elasticities and the effect of GDP and climate on household electricity consumption in Europe using data from the period 1995 – 2015 [17]. Dynamic partial adjustment models, Generalized Method of Moments and Maximum Likelihood approaches are used for the analysis. The study concludes that price elasticities in the short run are small while income elasticities are relatively large [17]. [18] estimates the determinants of electricity consumption in Jordan using data from 1986 to 2015. The study uses six variables viz a viz GDP, electricity prices, population, urbanization, structure of the economy and aggregate water consumption [18]. A study by Singh et al., (2018) uses survey data from 1140 households to characterize the effect of climate and ownership of appliances on household electricity demand. It considers factors like electricity price, dwelling area, number of inhabitants and ownership of ACs, refrigerators and geysers but does not include socio economic variables like income [19].

Pachauri and Muller (2008) try to understand the relative importance of changes in household size, population, increase in connectivity and consumption per connection in rural and urban regions of India from 1980-2005. The study presents a macro level analysis with the lowest geographic scale being the state [20]. Narayan et al., 2007 uses annual time series data of G7 countries from 1978 to 2003 to estimate long run and short run

price and income elasticities of household electricity demand. The study specifically focuses on these two aspects to understand if the elasticities present an opportunity to introduce emission linked taxation [21]. Filipini and Pachauri (2004) uses three seasonal linear econometric models to understand the effect of variables like electricity price in rupees, kerosene price in rupees, LPG price, household income, area of the dwelling, size of the household and average age of the household. This was a pioneering study that moved away from using national level macro indicators and used unit level from 35,000 households from round 50 for the year 1993-94 from the National Sample Survey conducted by Government of India. The results indicated that electricity demand with respect to income was fairly inelastic in all the three seasons but household size and average age of inhabitants influence electricity consumption significantly [22].

Pachauri (2004) estimated the energy requirements of a household considering a large set of explanatory variables and using a double log functional model. It considered region of the country, nature of dwelling, rural / urban, food habits of the inhabitants, literacy levels, monthly expenditure, area of the dwelling, household size, age of the household head and nature of employment to determine energy needs. Though the study estimated energy needs including food and travel, it used household level data making it a bottom up study [23]. NSSO household level panel data was used to conclude that total income or expenditure level of an individual household was the most significant determinant of energy demand. The study also comments on the effect of dwelling size and the age of household [23]. Reddy(2004) tries to understand the economic and social dimensions of electricity use. [24] uses survey data from 1983-2000 to understand the differences in electricity use based on employment, income and locality for rural and urban households. The paper presents only a descriptive analysis to bring out the disparity in electricity consumption between categories of employment [24].

From the analysis of literature, it becomes clear that there can be more contributions to the area of modelling residential electricity consumption in India with respect to the approach and data used. Studies that try to determine the determinants of residential electricity consumption are seen to have limited use of determinant variables. Most studies focus on income and price elasticities of electricity demand. Other explanatory variables used include climatic conditions, rural or urban nature etc. There are no studies where all or a large number of these variables have been comprehensively covered.

3. Data and Methods

3.1. Dataset and variables

The present study used panel data from the Consumer Pyramids Household Survey (CPHS) conducted by the Centre for Monitoring Indian Economy (CMIE) [25], [26]. The survey data for the state of Uttar Pradesh with 25,690 sample households included has been used. Longitudinal data from 2014 to 2021 has been used for the analysis. The dataset contains socio economic, demographic, electrical appliance ownership and asset ownership information about the households, available for each month. The data was modified to two variables viz. a viz. season and cooling degree days (CDD). The season variables denote the prevailing season and calculated CDD of the area corresponding to the month of the data collection. The urban and rural datasets have been separated for analysis. The monthly expenditure of the household on electricity has been considered as the dependant variable as it is a reasonable proxy for electricity consumption. The data on monthly electricity consumption was not available. The dependant variables fall into five categories; socio economic attributes of the household, household demography, electrical appliance ownership, building envelope and climate.

3.2. Method

The study used fixed effects model to estimate the determinants of residential electricity consumption. Literature reviews revealed an almost standardised use of the log-log functional form of model specification, especially in cases where expenditure variables were involved [16], [20], [27]. A general empirical specification of residential electricity consumption can be written as shown in Equation (1)

$$E = F(SE, DF, EL, CL, BE) \quad (1)$$

Where E is the monthly residential electricity consumption, SE denotes the set of socio-economic variables, DF denotes the demographic variables, EL denotes the electricity consumption and appliance ownership related factors, CL denotes the climatic factors and BE refers to the set of building envelope related factors.

The functional form chosen for the study follows a log linear form as suggested by many past studies [9], [16], [19], [20]. The respective variables are explained in Table 1. The function for electricity consumption of households can be represented as shown in Equation (2)

$$Log\ (EM) = \beta_0 + \beta_1 log\ (ME) + \beta_2\ CC + \beta_3\ LT + \beta_4\ RU + \beta_5\ AH + \beta_6\ SH + \beta_7\ PH + \beta_8\ TV + \beta_9\ RF + \beta_{10}\ CO + \beta_{11}\ AC + \beta_{12}\ SN + \beta_0 CD + \beta_{14}\ TW + \beta_{15}\ TR \quad (2)$$

Where ME is the monthly expenditure of the household across all categories, CC refers to the caste category of the household, LT refers to the status of literacy of the household head, RU refers to the rural or urban location of the household, AH refers to the age of the household head in years, SH refers to the size of the household (number of people regularly resident in the house), PH refers to the hours of power availability, TV refers to the number of television sets owned by the household, RF refers to the number of refrigerators owned by the household, CO refers to the number of air coolers, AC refers to the number of air conditioners, SN refers to the season corresponding to the particular data point, CDD refers to the cooling degree days (used as a measure of air conditioning demand) and TW and TR refers to the type of roof material and type of wall material of the household respectively.

Table 1: Description of explanatory variables

Dimension	Variable	Description
Socio Economic (SE)	Log (Me)	Log (Monthly expenditure of the household)
	CC	Caste Category
	LT	Literacy (Yes / No)
	RU	Region type (Urban / Rural)
Demographic Variables (DF)	AH	Age of household head
	SH	Size of the household
Electricity Consumption and Appliance Ownership (EL)	PH	Power availability (Hrs / day)
	TV	No. of Televisions
	RF	Number of refrigerators
	CO	Number of air coolers
	AC	Number of air conditioners
Climatic Factors (CL)	SN	Season
	CDD	Cooling Degree Days (CDD)
Building Envelope (BE)	TW	Type of roof
	TR	Type of wall

A fixed effects panel data model was used to estimate the coefficients. The fixed effects model takes into account the fact that individual units are repeatedly surveyed at a fixed frequency over a period of time and hence retail some intrinsic characteristics.

4. Results and Discussion

To determine the determinants of REC, a fixed effects panel data regression model was employed. The determinants of rural and urban areas were also analysed separately using the same method. The descriptive statistics of the determinant variables used for the study are provided in Table 2. The correlation between the determinant variables was ensured to be less than 0.7 to avoid auto correlation. The results of the fixed effect regression model are described in Table 3. The results indicate that the non appliance ownership parameters have a significant influence on REC. The results establish socio economic, climatic, building envelope related and demographic determinants of residential electricity consumption. We find that the socio-economic variables explain about 70% of the variation in REC. The results are significant as they expand the horizon of research on determinants of REC beyond the conventional factors like elasticity and appliance ownership.

4.1 Socio Economic Factors

The monthly expenditure of the household has a significant influence on the consumption of electricity. The elasticity is positive at 0.505 indicating that one unit increase in the expenditure level of the household would lead to about 0.50 units increase in their expenditure on electricity. Different studies like Pachauri (2004), Singh et al. (2018) and Tiwari (2008) have shown positive impact of expenditure on electricity consumption but with lower elasticities [19], [22], [28]. A number of studies have used income as an explanatory factor and calculated the income elasticity of REC. For the present study, the use of income data was limited by the quality of income data. Expenditure of the household is indicative of the income level of the household as well as its purchase choices. Thus, it is an important determinant of REC.

Caste has been identified as a social grouping that affects the access to quality services in India. The results indicate that the caste category of the household is a significant determinant of its access or use of electricity. The variable caste category used in the study classifies the households to five categories viz. a viz. Upper caste, Other Backward Castes, Scheduled Castes and Scheduled Tribes in addition to a fifth category of households that did not specify the caste or category to which they belong. The Upper Castes refer to a social group which have historically been owners of land and were endowed with political capital. The Other Backward Classes (OBCs) is a group of different castes and some minority religions which have historically been considered the middle classes. The scheduled castes, about 16% of the national population is a term used to collectively denotes groups belonging to the lowest rung of the caste hierarchy. The scheduled tribes constitute the tribal or indigenous communities. Caste represents historical and current disadvantages and can be considered a metric of inequality. While the upper castes include the traditional land owning and prosperous groups, the prosperity can be considered to decrease across the board from Upper Castes to Scheduled Tribes. Past studies like Bhattacharya & Saxena (2017) had studied the effect of caste, tribe and religion on energy access and found that such social structures remain significant despite years of affirmative action and the households belonging to scheduled tribe and scheduled caste communities had significantly poorer access to electricity and LPG for cooking. The results are in line with the findings as scheduled tribe households can be seen to have lower electricity consumption even after controlling for other exogenous factors. Households with a literate head of the household has been shown to have higher electricity consumption than others by many past studies. The results of the present study support this claim.

Table 2: Summary statistics of variables

Variable	N	Min	1st Quintile	Median	Mean	3rd Quintile	Max
Monthly Expense on Electricity	13,85,278	95	300	400	451	560	1,392
Total Monthly Expenditure	13,85,278	376	7,115	8,865	9,421	11,065	10,15,514
Age of household head	13,85,278	7	41	48	49	57	108
Power Availability (Hrs/Day)	13,85,278	1	16	19	19	22	24
No. of Televisions	13,85,278	0	1	1	1	1	3
Number of refrigerators	13,85,278	0	-	1	1	1	3
Number of air coolers	13,85,278	0	-	1	1	1	5
Number of air conditioners	13,85,278	0	-	-	0	-	3

4.2 Demographic Factors

The age of the household head can be seen to have a positive and significant but very small effect on residential electricity consumption. Similarly, size of the household has also been determined to be a significant variable. Smaller households can be seen to have positive impact on REC while households with higher number of members are seen to have a negative coefficient, which is counter intuitive and against the results of some past studies. The negative effect of higher household sizes on electricity consumption could be due to the socio-economic nature of the study area. In rural and urban areas, joint families with higher number of

household members could belong to the economically weaker sections and reside in small households or in slums. This could be a possible reason for the negative coefficients.

The results from the present study indicate that households in the urban areas have a higher electricity consumption than rural areas. Singh et al. (2018) has used household level survey data from about thousand households in different climatic zones of India to understand the different factors influencing residential electricity consumption. The study found a negative price elasticity of demand and weak influence of demographic factors. The study also showed that urban households belonged to a class of its own and had higher electricity consumption than rural households. Similar results were obtained by Basumatary (2021) and Pachauri (2021) [9], [15]. Thus, it can be concluded that households in the urban region have higher REC. The difference could be due to longer hours of electricity usage, larger number and diversity of appliances, better power quality, higher incomes or structural differences in lifestyle choices.

4.3 Electricity Consumption and Appliance Ownership (EL) Related Factors

Power availability is an important supply side constraint that has been found to have significant effects on REC. As indicated in Table, the average power availability in the study area was only 19 hours. This could be due to scheduled load shedding or unscheduled power outages. Power outages limit the ability of the consumer to use the appliances and hence reduce the REC. It has also been found to reduce the propensity of consumers to but appliances as indicated by Agarwal et. al [29]. Households might also engage in “electricity / energy stacking” whereby they use secondary sources of electricity to achieve higher level of services that are not provided by the primary service. For instance, households may employ a Solar Home System (SHS) or avail electricity from a mini grid to use electricity for the time when the central grid is unavailable or unreliable. In the case of India, change of policy direction along with increased expansion of electricity infrastructure has resulted in significant improvement in power availability. The results indicate that as the supply side constraint of power availability eases, it would act as a catalyst for increased electricity usage.

Appliance ownership has been identified by many past studies as the most significant factor in the bottom up modelling of REC [8], [12], [18], [20]. The results from the present study indicate that refrigerators have the highest positive influence on REC with a coefficient of 0.06. This could be attributed to the fact that refrigerators are a high wattage equipment that is used throughout the day as opposed to other appliances like air conditioners or televisions that are used for specific number of hours. Studies like Huang (2020) and Chunekar (2018) have noted that electricity use by refrigerators often go unnoticed and could contribute most significantly to energy savings through efficiency improvement [7], [30]. Among other appliances, air conditioners and air coolers have been found to have significant positive influence on REC. However, the results from the fixed effects model indicate that the number of televisions owned by a household can have a significant but negative effect on REC, which is counter intuitive and against the findings of previous studies like Agarwal (2019) [29]a. This needs further enquiry.

4.4 Climatic Factors

The Cooling Degree Days (CDD) is a measure of how hot the temperature of a particular region has been compared to a reasonable standard comfortable temperature. They essentially capture the need for air conditioning and hence, is an important determinant factor for estimating REC. The present study shows that the CDD has a significant but negative influence on REC with a very low coefficient. This could be due to two reasons. One, the study area has very low penetration of high wattage air conditioning equipment like air conditioners. Thus, cooling demand might not be converted to the end use of air conditioning, utilising electricity. Secondly, the critical threshold value of comfortable temperature to be used for the calculation of CDD for the region had been chosen as 22^0C in line with a previous study [31]. This could be an under estimation for a region with an average temperature of 35.61 ^{0}C in 2021 [32].

Similar, seasonality has been found to be an important determinant of REC. The study area has a hot humid summer and harsh winters. The results indicate that the summer months have higher consumption of electricity while compared to the rainy monsoon months (used as reference). This could be attributed to the increased use of fans or other room conditioning appliances. The winter months are associated with a significant but highly negative coefficient indicating reduced electricity consumption demand. The increased REC during summer months has been reported by previous studies like Singh et. al. (2018) and Tewathia (2014).

4.5 Building Envelope

Analysing the results about building environment, we find that concrete walls (which has been used as the reference category) can be seen to have the highest significant and positive effect on REC. Walls made of wood, stone and sheet have significant but negative influence on electricity consumption with coefficients of (-0.404, -0.226 and -0.260). Houses with walls made of mud or thatch are also found to have lower electricity consumption. A similar trend can be seen in the case of roofing material. Concrete roofs have been found to have the highest positive influence on REC while roofs made of thatch and sheets have significant negative influence on REC.

4.6 Limitations and scope for future research

While the present study is novel in the use of large scale, current and representative data, there could be several significant improvements. The anomalies found in the present results like the negative effect of television ownership opens up more room for research. The study has conclusively shown the relevance and significance of non technological factors in influencing REC. While the effects of factors like caste have been quantitively been estimated, there is considerable scope in understanding the exact pathways through which socio economic and demographic variables affect REC. For instance, questions like “why does households belonging to the scheduled tribes have a lower electricity consumption than other households?” could be explored. Further research would reveal if it is a problem of affordability, lack of access to appliances, poor quality of power supply or other institutional factors. Similarly, the age composition of the households have been found to have significant effects on REC. Huang (2021), Chen (2017), Huang (2020) and Jones et. al. (2015) has reported decreased REC in households with presence of elders. Further research could probe the actual pathways through which these effects happen.

4. Conclusion

The present study has tried to understand the non technological factors that act as determinants of residential electricity demand. While the overarching focus in researched literature was on modelling price elasticity, income elasticity and time variability of demand, the present study tries to account for socio economic, demographic, climatic and building envelope related factors in addition to electricity availability and appliance ownership. The study used panel data from household surveys in the state of Uttar Pradesh, India. The results indicate that many of these factors are significant. Monthly expenditure level of the household and caste category affect REC. Literacy and age of the household head have also been found to have significant effects on REC. Summer season is associated with higher REC while the effect of Cooling Degree Days (CDD) on REC requires further study. Households which use concrete for roofs and walls have been found to have higher levels of REC compared to those that use tiles, sheets and thatch. The present study validates the need to look beyond the narrow frame of appliance ownership to understand the driving factors behind REC.

Abstract:

In this work, a proof of concept design for a poultry meat farm is studied. The design aims to be climate-neutral and energy-flexible by applying different technologies such as PV panels, PVT panels, BEO field, and high and low-temperature heat pumps. In order to size these systems, the farm's required heating, cooling power and (de)humidification rate has to be estimated, which is the focus of the current paper. For this purpose, a model was created in the Python environment. Based on the building's current design, expected weather conditions throughout a model year, and the required conditions for the chickens' well-being, the heating and cooling loads are calculated. The analysis does not yet take into account which technology is used to supply the heat as the sizing will be done based on the results of this analysis. In addition to the 'standard' climate requirements, some pens will be used to study the behaviour of the chickens during alterations in the temperature and humidity of the pen. These tests are predefined and the HVAC installation should be able to handle these test conditions as well. The results of the model can be used as a guideline to size the different HVAC systems. However, as the model is based on assumptions and simplifications, a sensitivity analysis was performed as well. This analysis shows that the conductive losses are small compared to ventilation and infiltration losses. The air changes per hour of the farm have a great impact on the total required heating and cooling power. Therefore, attention should be given to the air-tightness of the chicken pens to reduce the required installation size.

Keywords:

Energy-use; Poultry farm; Energy neutral; model.

1. Introduction

The sustainable development goals, adopted by the United Nations, are a set of 17 interconnected goals aimed at addressing global challenges such as poverty, hunger, inequality, and climate change. The second goal, "Zero Hunger," recognizes the need for sustainable agriculture to provide adequate food for a growing population while reducing the negative environmental impact of current agricultural practices.

Sustainable agriculture aims to achieve food security and enhance livelihoods while conserving natural resources and minimizing negative effects on the environment. To achieve this, it is essential to adopt low-carbon technologies in agriculture to reduce greenhouse gas emissions, improve resource-use efficiency, and promote biodiversity. Poultry farming, which is a vital component of the agricultural sector, has a significant role to play in achieving sustainable food production.

The ever-increasing demand for poultry products [1] due to the relatively low climate impact compared to other meat variants has put pressure on farmers to increase production. However, this increase in production must be achieved using renewable methods that minimize environmental impact. In this context, several studies [2-6] have been conducted to explore low-carbon technologies that can be implemented in the poultry farming industry to reduce greenhouse gas emissions and promote sustainable practices. However, not all technologies can be applied in all regions or for all power requirements.

Therefore, this study seeks to contribute to the development of sustainable poultry farming by focusing on a methodology to predict the required heating and cooling demand of a new poultry farm design. This methodology is essential to ensure that the heating and cooling systems used on the farm are appropriately sized, leading to energy efficiency and a reduction in greenhouse gas emissions. The findings of this study

can help farmers and policymakers make informed decisions about the design and implementation of sustainable heating and cooling systems in poultry farming which are currently not often used within this sector, ultimately contributing to achieving the second sustainable development goal of the United Nations.

Information on the dimensions and requirements for the poultry farm were provided by ILVO, a Flemish research centre [7]. This farm will be used to conduct detailed research with respect to a plethora of factors, ranging from feed composition, feed management, and animal well-being to emissions, impact of climate control, and energy flexibility of the stable depending on electrical grid conditions.

2. Modelling methodology

2.1. Standard boundary conditions

A new poultry farm has been designed to house up to 14,000 chickens. The goal is to construct this new farm in an energy-flexible and climate-neutral manner as a proof-of-concept. To achieve this, the required heating, cooling, humidification, dehumidification, and ventilation rate has to be estimated based on the required optimum conditions for the chickens and the outside weather conditions. The design temperatures and humidities are presented in Table 1 based on the age of the chickens within the pen expressed in days. On the days not mentioned in Table 1, the values are obtained by interpolating between the two adjacent values.

Table 1. Climate set point and minimum ventilation rate within the stable depending on the age of the chickens.

Chicken age (days)	Average weight (g)	Temperature (°C)	Relative humidity (%)	Minimum ventilation rate (m³/kg/h)
0	45	34	55	1.5
3	90	34	55	1.4
7	180	31	60	1.3
14	470	27	70	1.1
21	920	25	70	0.9
28	1480	22	70	0.8
35	2110	22	75	0.7
42	2770	21	75	0.7

Another important input characteristic to the developed model (see section 2.4) is the heat and humidity produced by the chickens themselves. The following equations, in function of the average chicken weight, are used for this:

$$Q_{chicken} = 10.62 \cdot m_{chicken}^{0.75}, \quad (1)$$

$$m_{vapour,chicken} = -17.7 \cdot m_{chicken}^{2} + 200 \cdot m_{chicken} + 22, \quad (2)$$

where $Q_{chicken}$ is the heat produced per chicken in watt, $m_{chicken}$ is the average mass of a chicken (at a certain age) in kilogram and $m_{vapour,chicken}$ is the amount of grams of water vapour produced by a chicken in a day.

The ventilation rate which can or should be applied in the farm has prescribed minimum and maximum values. The minimum ventilation rate depends on the chickens' weight and is also represented in Table 1. The maximum ventilation rate is 4 m³/kg chicken/h. This norm is quite high compared to other animals due to the high heat production of poultry. A second limitation to take into account is that the ventilation rate should always be sufficient to keep the carbon dioxide concentration beneath 3000 ppm. As the prescribed minimum ventilation rate already is always higher than the ventilation rate posed by this limitation, the carbon dioxide concentration is not taken further into account. The actual applied ventilation depends on the applied climate control. The climate control considered in this work is based on temperature solely and is illustrated in the next graph. It should be noted that this strategy holds when the outside temperature is lower than the temperature inside the pens. The target temperature (TT) inside the pen is allowed to vary between a certain range (defined by T0 and T1) without applying external measures. When the temperature drops below T0, which is already at a minimum ventilation rate, the heating system is turned on. When the temperature increases beyond T1, the temperature is controlled by increasing the ventilation rate. At a certain point (at T2), the temperature cannot be reduced enough by solely increasing ventilation flow rate. When the temperature exceeds T3, active cooling is applied to lower the temperature inside the pens.

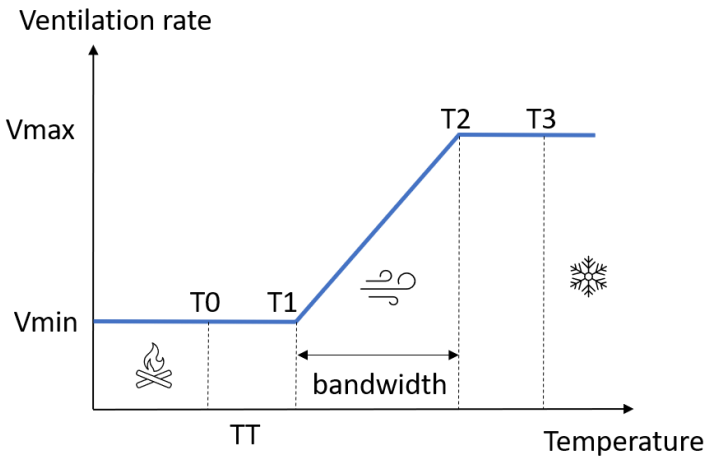

Figure 1.: Applied climate control in poultry farm.

2.2. Special boundary conditions for heat and cold stress tests

The temperatures and relative humidities from Table 1 represent the requirements for the chickens under 'standard' stable conditions. However, sometimes, extreme conditions have to be applied to the pens in order to create a 'stressful' environment for the chickens. This way, the researchers of ILVO can perform heat and cold stress tests and investigate the influence of these conditions on the chickens. The conditions for the heat stress tests are as follows (in function of the age of the chickens):

- Day 3-6: 24h at 40°C and RH 65%
- Day 7-25: 12h/day at 39.5°C and RH 65%
- From day 26: 8h/day at 36°C and RH 70%

The conditions for the cold stress tests are:

- Day 1-6: 24h at 24°C and RH 40-50%
- Day 7-13: 24h at 15°C and RH 40-50%
- Day 14: 24h at 13°C and RH 40-50%
- Day 15-26: 24h at 13°C and RH 50-55%

These conditions only have to be applied in 3 (adjacent) compartments of the 9 compartments, and have to be reached within 2 hours. Also, the return to standard conditions has to happen within 2 hours. 720 chickens are present in all 9 compartments. While 3 compartments are put under the stress test conditions, the other six compartments follow the standard conditions mentioned in section 2.1.

2.3. Layout of chicken farm

Table 2. Thermal resistances.

Type and location	Value [m²K/W]
Convection external side wall	0.02
Convection internal side wall	0.25
Convection floor	0.25
Convection ceiling	0.25
Conduction external wall between compartment and outside	7.77
Conduction internal wall between compartments	2.62
Conduction internal wall between compartment and air lock	2.52
Conduction internal wall between compartment and food compartment	2.52
Conduction internal wall between food compartments	2.43
Conduction external wall between food compartment and outside	1
Conduction ceiling	4
Conduction floor	4.17
Conduction roof	3.2

In addition to the required climate, the dimensions and layout of the modeled stable also have an important impact on the final results. The stable is divided into 9 compartments, which can each contain up to 1555 chickens. Three compartments make up one department, with each their own air conditioning unit. Next to these compartments, food compartments are located which separate the chicken compartments from the outer walls. Additionally, an attic is located above the chicken compartments. The design has predefined interior wall, exterior wall, floor, and ceiling construction materials and thicknesses which are used in the model to calculate conductive thermal resistances between two adjacent areas. The convective thermal resistances are calculated with constant convection coefficients, which are taken conservatively based on the default values of TRNSYS 16 TRNBuild [8]. The thermal resistances are listed in Table 2 and a sketch of the compartment layout is illustrated in Figure 2.

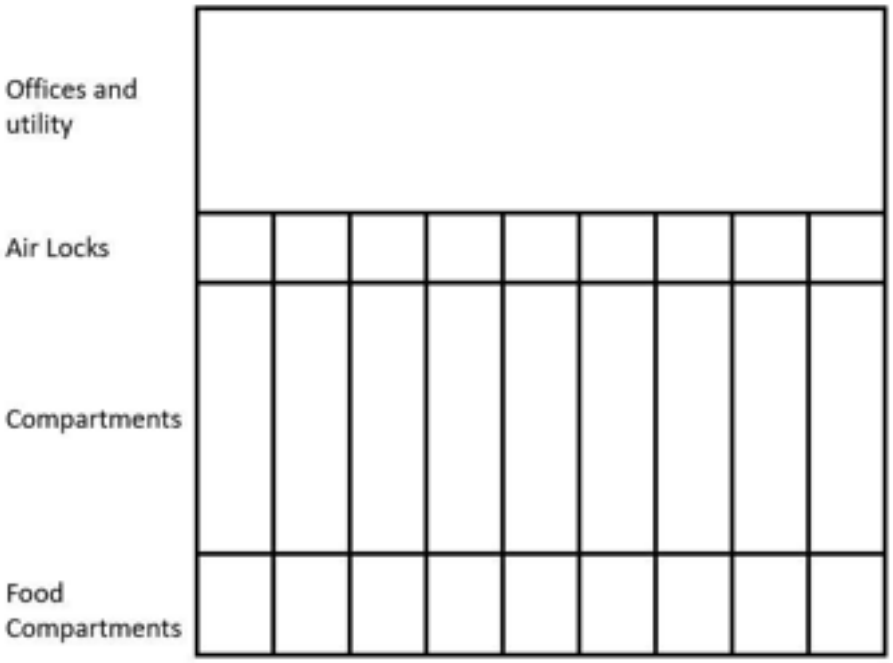

Figure 2. Sketch of the layout of the poultry farm consisting of nine air-locks, chicken compartments, and food compartments as well as a room for offices and utility.

2.4. Model strategy

For the modelling, which was done in Python 3.7 [9], the poultry farm was divided into 19 zones: 9 chicken compartments, 9 food compartments and the attic. For each zone, three balances were calculated: an energy balance, a mass balance (w.r.t. the air supply) and a moisture balance. In the zones containing chickens, the heat and vapour production by the chickens was taken into account, as well as the heat conduction to adjacent chicken zones, food compartment, attic, air-lock, ground and outdoors. In addition, direct solar gains due to six installed Solatubes [10] per chicken compartment, were also added. Lastly, the contribution of the heat and vapour transferred through ventilation and infiltration of air was included. For the food compartments, the conduction is similar to the chicken compartments. However, there are no internal (heat or vapour) gains, no ventilation and no Solatubes. When simulating the attic, only conduction to chicken compartments and the outdoor environment is taken into account.

For simplicity, the infiltration losses are taken into account by assuming a constant infiltration rate in the model. This is expressed by certain ‘air changes per hour (ACH)’. It is assumed the fresh air in the chicken compartments is coming from the food compartments. This same infiltration rate, in its turn, is coming through cracks and crevices from the outside environment. As a default, 1 ACH is taken, and the influence from this assumption is evaluated later on.

Two ventilation strategies are considered, which influence the energy balance. The first one dictates that the target temperature and humidity inside the chicken compartments are always maintained. In this strategy, the ventilation rate is put to the minimum value, and additional heating or cooling is applied to reach the target temperature. In the second strategy, the control depicted in Figure 1 is applied. Here, different temperatures than the target temperature are allowed (within a certain range) before heating or cooling is needed. This will have a significant impact on the required heating and cooling load. In the model, this problem is solved iteratively by searching for the temperature and ventilation rate combination where the required (sensible) load is minimal. As a default, the minimum ventilation strategy is applied. In section 3.4.2, the influence of applying the second strategy is discussed.

The heat losses to the air-lock are dependent on the temperature of the air-lock, which is unknown. Therefore, this temperature was assumed to be at the average temperature of the compartments and outdoors, with a minimum of 18°C. As the attic and food compartments do not have a target temperature, the temperature in these compartments is solved iteratively based on reaching an energy balance between the heat losses and the heat gains. In addition, a minimum temperature of 18°C is set in the food compartments.

3. Simulation results with fixed outdoor conditions

3.1. Steady-state cooling and heating loss calculations

In the calculations presented in this section, the outdoor temperature is fixed at certain values, varying from -10°C to 35°C. The outdoor relative humidity is fixed at 50%. The heating and cooling loads were calculated for different chicken occupations (both in age and number). 1555 chickens per compartment represents the maximum capacity of the farm, 720 chickens per compartment represents the standard occupation. Table 3 gives an overview of the sensible loads, expressed in kW, for the entire poultry farm. Positive values indicate heating, negative values indicate cooling. For standard occupation conditions, the maximum sensible heating load is thus 141 kW, the maximum cooling load is 157 kW.

Table 3. Heating and cooling loads (sensible) (in kW). RH (outside) = 50%.

		Number of chickens per compartment	
Outdoor temperature (°C)	Age (d)	720	1555
-10	0	107	113
	14	111	136
	28	120	168
	42	141	216
0	0	81	86
	14	75	88
	28	70	89
	42	74	101
10	0	55	58
	14	39	40
	28	19	16
	42	17	-30
20	0	30	31
	14	4	-8
	28	-31	-71
	42	-59	-128
30	0	7	7
	14	-29	-54
	28	-79	-149
	42	-124	-242
35	0	-5	-6
	14	-46	-77
	28	-104	-188
	42	-157	-299

The highest heating load corresponds to older chickens, however, this is strongly dependent on the outdoor conditions as well. In addition, the higher the number of chickens in a compartment, the higher the load. This finding is a result of the allowed ventilation rate and the chickens own heat production. The load for one department (so three compartments) is, by approximation, equal to 1/3rd of the total load. In reality, the demand of compartments located near the outdoor environment will be different to the ones more in the center, due to the heat losses to the environment.

3.2. Analysis of the energy balance

In this section, the results from section 3.1 are investigated in more detail by zooming in on the energy balance. In particular, identifying the dominant heat losses allows for reducing these by adjusting the farm design. The results presented in this section are based on the simulations for a stable with 720 chickens per compartment at an age of 42 days, as this age resulted in the highest cooling and heating loads according to section 3.1. The trends observed are however also applicable to the other occupation combinations. In Figure 3, the energy balance in winter (i.e. -10°C outside) for the entire stable is depicted, divided into energy input (left) and energy output (right). The input contains the heat production of the chickens, the heat gains because of the Solatubes and the required heating. The output contains the ventilation and infiltration losses (to the air-locks) and the conduction losses.

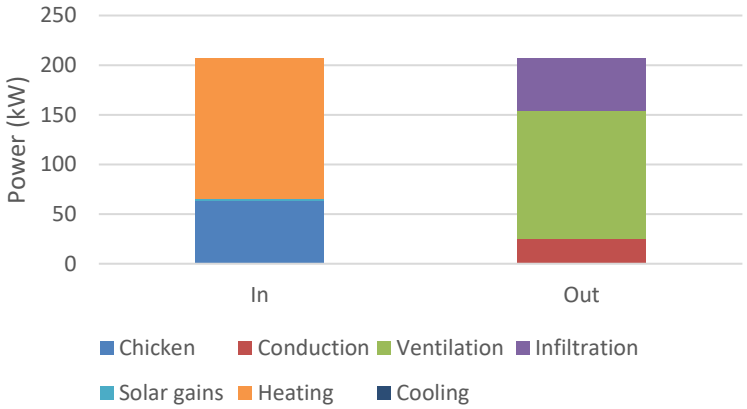

Figure 3. Energy balance (sensible) in winter (-10°C) for entire stable (720 chickens/compartment at 42 days old). RH (outside) = 50%.

Based on this figure, it can be concluded that the Solatubes mainly serve as light source, but do not really contribute to the heat balance. It should be noted that the impact of the incident solar radiation on the remainder of the roof and outer walls is not taken into account in the calculations, as the impact will be limited. The expectation is that when incorporating these, the conduction losses through the attic and outer walls will likely decrease, as they will be at a higher temperature than considered in the current simulations.

The conduction losses are also small compared to the ventilation and infiltration losses. The ventilation rate accounts for 62% of the total losses. This is the largest component for the oldest chickens, which is also likely the reason why the maxima occur for these ages as seen in Table 3. Therefore, if technically possible, the required heating load could be strongly reduced by incorporating an energy recuperation system on the ventilated air.

The conduction losses from Figure 3 are split up into each heat loss stream in Figure 4. The largest share of conduction losses is through the ground. This might be the result of some assumptions and simplifications that were made, as the ground is a difficult part to model due to the influence of floor heating and additional insulation. However, as the overall influence of conduction losses on the total heat balance is limited, it is expected that the applied model for the ground does not have a significant influence on the main results.

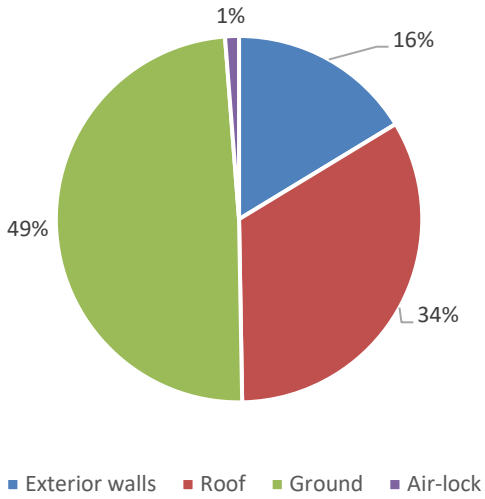

Figure 4. Distribution of conduction losses (sensible) in winter (-10°C) for entire stable (720 chickens/compartment at 42 days old). RH (outside) = 50%.

A similar analysis as described above was made for conditions during summer (i.e. 30°C outside). The results for the energy balance are given in Figure 5. The heat gains due to the Solatubes and the heat generation of the chickens are still the inputs. However, under these conditions, the ventilation, infiltration and conductive heat streams are also inputs as the outside temperature is higher than the target temperature. The largest share is the heat produced by the chickens themselves, ventilation is the second largest share. The only energy output is the cooling load.

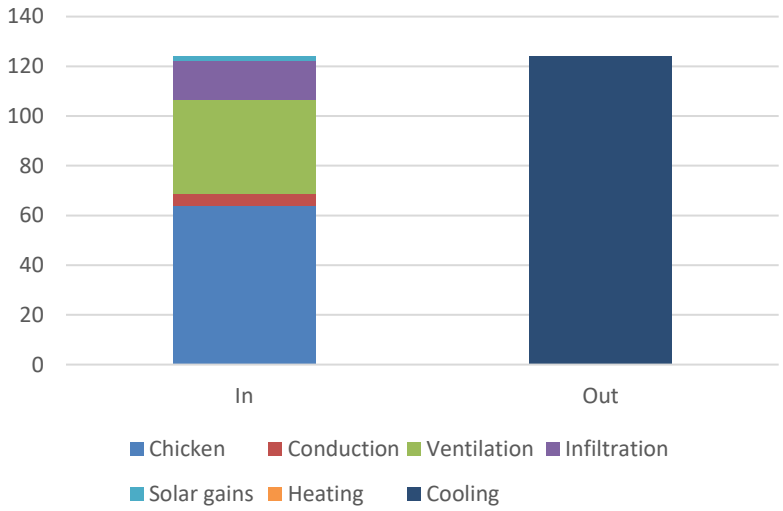

Figure 5. Energy balance (sensible) in summer (30°C) for entire stable (720 chickens/compartment at 42 days old). RH (outside) = 50%.

3.3. Required loads during stress testing

3.3.1. Heat stress tests

The heating loads for the three compartments put under the heat stress test conditions (as described in section 2.2) are illustrated in Figure 6. The heating loads are expressed in function of the age of the chickens and the outdoor temperature. The gap at day 25 is due to the change in setpoint condition as mentioned in section 2.2. As expected, the highest heating loads correspond to the lowest outdoor temperatures. For an outdoor temperature of 30°C or 35°C, no heating is required when the chickens are older (negative values in the graph). In these cases, there is cooling required, although reduced compared to the standard conditions. The maximum requirement for a heat stress test at 0°C outside temperature does not exceed the required heating power of one department at -10°C which is 47 kW. This is 1/3rd of 141 kW as can be seen in Table 3 for 720 chickens per compartment. So no additional capacity has to be installed.

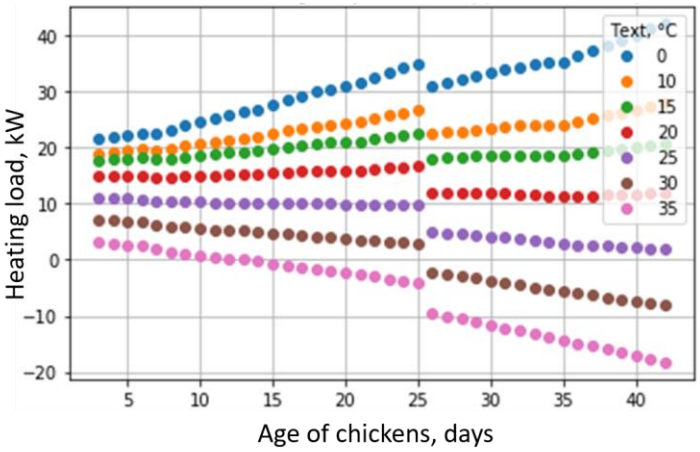

Figure 6. Heating load (sensible) for one department put under heat stress (720 chickens/compartment). RH (outside) = 50%.

3.3.2. Cold stress tests

The cooling loads for the three compartments during the cold stress tests are plotted in Figure 7, again in function of outdoor temperature and the age of the chickens. The gaps in this figure are once again a result of the change in setpoint condition as listed in section 2.2. The cooling load increases with an increase in outdoor temperature. At the lower outdoor temperatures, heating is required (indicated by the positive values) although reduced compared to the standard conditions. Once again, for the cold stress test conditions at an outside condition of 20°C, the required cooling power for one department is not exceeded for the standard conditions of one department at 35°C outside temperature.

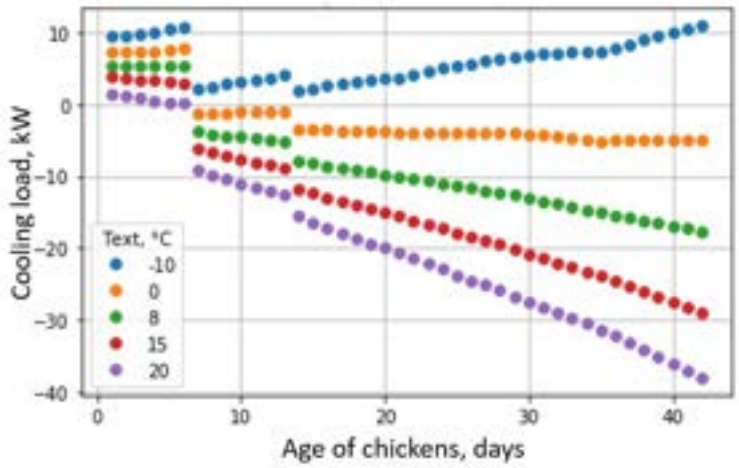

Figure 7. Cooling load (sensible) for one department put under cold stress (720 chickens/compartment). RH (outside) = 50%.

Combining the above mentioned results with the results presented in Table 3 (but rescaled to 6 compartments instead of 9) gives the total heating or cooling load of the entire farm during the periods with stress tests. It should be noted that these values are stationary loads, i.e. loads required to maintain the target temperature inside the compartments. However, in order to reach these temperatures within the required timeframe (2 hours), additional power is required, which can be based on dynamic calculations. As long as these tests occur at corresponding weather conditions, i.e. heat stress tests around summer time and cold stress tests around winter time, no additional power should have to be foreseen (compared to the values mentioned in Table 3) to be able to achieve the predefined conditions.

3.4. Sensitivity analysis of simulation parameters

In the calculations discussed above, several assumptions were made in the model. In this section, the influence of some of these assumptions on the results are investigated. A closer look will be taken at the air tightness of the farm and the applied ventilation strategy. The heating and cooling loads are recalculated with a different set of parameters, for the maximum and minimum loads during winter (-10°C outside) and summer (30°C outside) for 720 chickens per compartment.

3.4.1. Influence of air tightness

As already mentioned in section 2.4, a default value of 1 ACH was applied in the simulations. The next graph illustrates the influence on the results when the infiltration rate is either halved or doubled. The influence on the cooling load is rather limited compared to the influence on the heating load. This is also illustrated by the energy balances presented before (Figure 3 and Figure 5). During winter conditions, when heating is necessary, the infiltration rate has a large relative contribution in the energy balance. However, during summer conditions, when cooling is required, the infiltration rate has a less dominant contribution. Overall, a good air tightness is important as it drastically impacts the heating load.

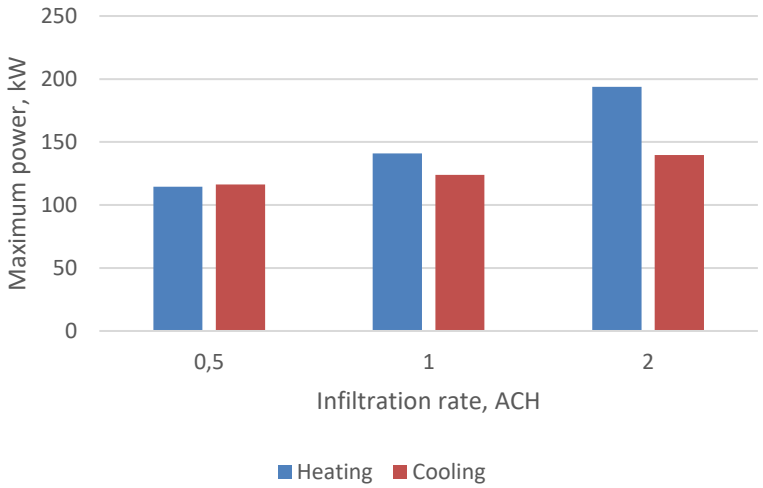

Figure 8. Influence of air tightness on (sensible) heating load (winter, -10°C) and cooling load (summer, 30°C) for the full stable (720 chickens/compartment at 42 days old). RH (outside) = 50%.

3.4.2. Influence of applied ventilation strategy

As a default, in the previous results, the minimum ventilation strategy was applied. In Figure 7, the influence of the choice of bandwidth in the strategy depicted in Figure 1 is investigated. In case cooling is required, first, 'free cooling' is used until the maximum ventilation flow rate is reached before active cooling is applied. The bandwidth "zero" means that the target temperature (TT) is always reached. For the "small" bandwidth, there is a 0.5°C tolerance on the target temperature (meaning T0 and T1 from Figure 1 are 0.5°C below and above TT, respectively). The bandwidth itself (difference between T1 and T2) is set to 2.5°C. This means that for this case, active cooling is started when the temperature is 3.5°C above the target temperature. The bandwidth "large" corresponds to a tolerance of 1°C on the target temperature and an actual bandwidth of 5°C, so active cooling will be started when the temperature is 7°C above the target temperature. From Figure 9, it can be seen that the influence of the ventilation strategy on the heating load is limited. This is because the tolerance on the temperature to apply heating is small in every case. For cooling, the tolerance is a lot higher. Only in a limited amount of cases, the outdoor temperatures will be 7°C higher than the target temperature, thus eliminating the need for additional cooling in a lot of scenarios.

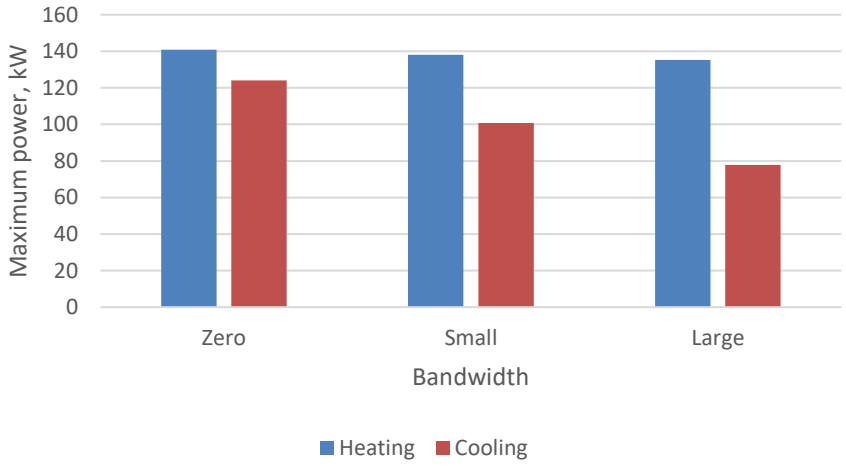

Figure 9. Influence of ventilation strategy on (sensible) heating load (winter, -10°C) and cooling load (summer, 30°C) for the full stable (720 chickens/compartment at 42 days old). RH (outside) = 50%.

3.5. Influence of outdoor relative humidity

The outdoor relative humidity has almost no impact on the sensible load but it does drastically change the total load through the latent heat requirements. Figure 10 shows the maximum humidifying and dehumidifying flow rate in function of the outdoor relative humidity. For humidification, this maximum occurs at the lowest outdoor temperature (-10 °C) and chickens of 14 days old. These values are almost constant as the saturated humidity ratio at this temperature is very low, resulting in only small changes of water content within the air flows. The maximum dehumidification flow rate occurs at the highest tested outdoor temperature (35 °C) and chickens of 42 days old. This value is more strongly dependent on the relative humidity as a similar change at this outdoor temperature represents a larger change in humidity ratio. At low relative humidities, dehumidifying is not necessary in any scenario. But at high relative humidities, the dehumidification has to balance the water vapour production from the chickens, infiltration flow rate, and ventilation flow rate, thus resulting in high required flow rates.

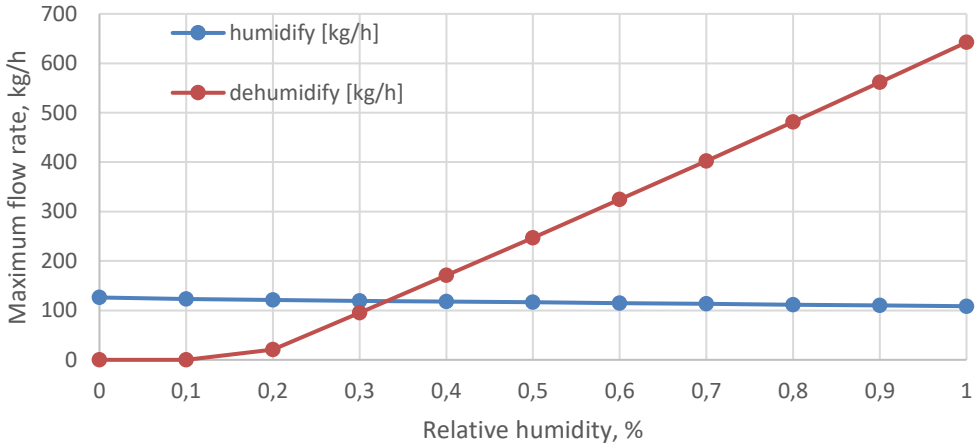

Figure 10. Influence of the outside relative humidity on the maximum required (de)humidifying flow rate for the full stable (720 chickens/compartment).

4. Simulation results over an entire year

Lastly, four simulations run over an entire year are compared based on representative weather data of the planned building location. The weather data is from a past year with measurements for every hour. The typical load for the planned farm is 720 chickens in each compartment, which grow over a period of 42 days. Before the next cycle of chickens occurs, an empty period of 10 days is required. A full cycle thus takes around 52 days. Four profiles are used to study the impact of when this 52 day cycle starts throughout the year. In the four different profiles the new chickens were introduced on days 1, 11, 26, and 40 of the year, where the rest of the occupancy is determined based on the 52 day cycle. The results of these simulations are presented in Table 4. There is some impact on the required heating and cooling depending on when the cycle is started. Some outliers are possible, as for example, the cooling demand for profile 2 is noticeably higher. The total cooling and heating loads presented in Table 4 also include the required cooling and heating to dehumidify, by cooling the air below the dew point and afterwards heating the air back to the required inlet temperature. The high cooling load in profile 2 is therefore also likely a result of the high dehumidification within this profile as a result of the unfortunate matching of this profile with a harsh weather period. It would thus be a good practice to try and match the 10 days empty period with harsh weather conditions if these are known sufficiently in advance.

Table 4. Simulations over a year for a representative weather year.

		Profile 1	Profile 2	Profile 3	Profile 4
Total heat load	MWh/y	521.1	519.2	523.5	515.4
Sensible heat load	MWh/y	286.8	284.4	288.3	285.2
Total cooling load	MWh/y	88.0	106.2	94.3	78.4
Sensible cooling load	MWh/y	29.0	35.0	34.7	26.5
Max total heat load	kW	191.0	174.0	180.9	184.7
Max sensible heat load	kW	126.7	101.1	105.5	119.7
Max total cooling load	kW	221.6	253.5	227.0	222.7
Max sensible cooling load	kW	92.4	97.6	115.9	97.0
Total humidification	kg/y	304,649	300,165	306,645	300,710
Total dehumidification	kg/y	57,540	69,647	59,092	49,346
Max humidification flow rate	kg/h	105.3	111.5	107.8	98.6
Max dehumidification flow rate	kg/h	149.8	171.1	139.0	158.3

5. Conclusion

In this paper, a model was developed to estimate the heating and cooling demand, irrespective of the HVAC system, for a proof-of-concept chicken farm that would house a maximum of 14,000 chickens. During standard chicken occupation with 720 chickens per compartment, for a total of 6,480 chickens, the stable would require a maximum of 140 kW of heating load and 157 kW of cooling load depending on the weather conditions. These maxima occur for the oldest chickens of 42 days old. The main conduction losses of the stable are primarily through the floor and secondly through the ceiling. However, the implementation of underfloor heating could have a drastic impact on floor conduction losses. In the overall balance, the conduction losses are neglectable in comparison to the ventilation and infiltration losses. The air tightness of the chicken pens, however, is an important factor in the required heating power and sufficient effort should be taken to lower the air changes per hour of the air-conditioned stables. This stable will also be used to test the impact of stressful temperatures and humidities on the chicken's behaviour. The HVAC unit should also be able to handle these conditions. As long as these tests align with the reigning weather conditions, such as heat stress tests in summer, then there should be no additional power required to achieve the wanted stress conditions. The results of this model will help in sizing the required HVAC installations of the proof-of-concept chicken farm, leading to increased energy efficiency and reduction in greenhouse gas emissions.

Acknowledgments

We would like to thank ILVO for asking the research question about the energy requirements of their new poultry farm design. Additionally, we want to thank the research foundation Flanders for their contribution through FWO grants 1SD9723N (Xander van Heule) and 1SA3722N (Jera Van Nieuwenhuyse).

Abstract:

Energy system optimization models (ESOMs) often contain time coupling constraints, some of which couple short time frames as of daily storages or load changes of components, while other constraints couple longer periods like seasonal storages, peak load prices, or upper bounds to overall yearly CO_2 consumption.
Those ESOMs have binary constraints for minimal loads, efficiency curves, or discontinuous energy prices that are relevant for the short-term operation of the equipment. Calculation times for solving a whole year or longer as a coupled MILP problem are in many cases too high for practical applications that normally should not exceed one hour. Typical decomposition strategies to reduce calculation times are often designed for subclasses of energy system models and are not generally applicable. In order to have a generalized approach to solve these models efficiently, we investigate strategies that are based on a problem specific relaxation of integer constraints and downsampling of the input time series of the models.
A rolling horizon strategy is proposed that relaxes and downsamples the time steps from the end of the rolling horizon to the end of the year to consider the operation during the rest of the year. In order to reduce the error of the relaxation, binary constraints are reformulated to get the best LP approximation of the original MILP model. Using this rolling horizon strategy, models that are almost unsolvable as coupled MILP can be solved efficiently and very robustly and deliver a result that is feasible for the original problem and very close to the optimum of the original problem.

Keywords:

Energy system optimization; Time-coupling constraints; LP-relaxation; MILP; Downsampling.

1. Introduction to solving time-coupled energy system optimization

The optimization of the design and operation of energy supply systems plays an important role in the decarbonization of the industrial, commercial, and communal sector. Due to the vast number of new technologies and the interactions between different kinds of energy (sector coupling), designing and operating energy systems is a complex task which in most cases requires mathematical optimization models. Although some decisions can be made using simulation models, energy system optimization models (ESOM) are much more flexible and versatile to handle different kinds of decisions and target functions. Linear programming (LP) or mixed integer linear programming (MILP) has evolved as the state-of-the-art method to do these kinds of optimizations, although the problems themselves are often nonlinear. The complexity of these kinds of models is high if spatial, temporal, and/or technological dimension is high [1,2].

Many references in scientific literature deal with capacity planning of energy systems of countries [3,4] or even networks of more than one country [5,6]. Because electricity is very hard to store and has to be produced at the same time it is consumed, most of these models focus very much on electricity supply. In this paper, we focus on smaller sized energy systems, for example in industry, commercial buildings, or communal quarters. In contrast to countries or continents, those energy systems have an almost negligible spatial resolution. The technological options and temporal resolution on the other hand are often more versatile than in ESOMs for geographically large networks.

Optimizations are modeled as quasi-stationary states of operation for every piece of equipment and every point in time. Typical resolutions are hourly or quarter-hourly for a whole year or even longer. In cases where

the energy suppliers and demands are separated spatially and the energy distribution (grid) is also relevant, a spatial structure of the energy system can be taken into account as well.

In this paper, we focus on models that take hours to solve due to the coupling of time steps by storages or other effects. From a practical standpoint, these models are often considered unsolvable, as for some real-world applications it is not possible to wait for so long. The aim is to solve these models in less time by solving simplified models with results very close to the original model. Other scientific work often focuses on certain kinds of time-coupling variables or equations and propose very good solutions to solve these ESOMs very closely to the original full model. Many of these publications use the target function value of the replacement models as quality measure for the methodology. An overview of different approaches to tackle complexity in ESOMs is given in [1] and [7]. In this work, we want to evaluate the operation of the equipment as well, because for practitioners this is an important criterion to decide whether a solution makes sense.

1.1. Non-scientific requirements in energy system optimization

In this work, we focus on non-scientific use cases of energy system optimization. The GFaI develops a software toolkit called TOP-Energy for the optimization of industrial and communal energy systems [8,9]. The constraints to the methodology discussed here arise from customers and reflect practical considerations like economic constraints or usability constraints.

A very important boundary condition of solving time-coupled ESOMs in a consulting use case is the time to solve the model. Energy consulting projects often have a scope of one or two months and include data acquisition, modeling, scenario optimization, scenario comparison, and presentation of results. It is necessary to solve several models per day, so the time to solve one model should not exceed one hour.

Another important criterion is the comprehensibility of the results. Parameter variations should result in a reasonable change of the solution. This affects parameters like the gap of the MILP solver. Very high gaps can lead to solutions that are close to the optimal solution but are not explainable anymore. The operation of the energy system in the result should be reasonable. This is especially important for design optimization, in which errors in the target function may affect certain time points disproportionately and make them look wrong. This has happened in real world problems in the past and is a problem for the credibility of the ESOM itself.

Some applications exploit the convex nature of some constraints relative to the target function. Electric feed-in for example, usually does not need a constraint that forbids buying and selling electricity at the same time, as prices are usually pointing in the direction of minimizing feed-in. Practical applications nonetheless are very generic and can't exploit the seeming complexity of the constraint. Changing the target function from operating costs to CO_2 emissions for example changes the convexity, but is a very common feature in real-world models.

1.2. Idea of the paper

The idea of the paper is to propose a method that can handle all kinds of relevant time-coupling constraints in models of typical industrial or communal energy systems without exploitation of certain convex parts of the model or behavior of technical components. Some decomposition approaches only work for a subset of ESOMs. We are trying to use a very general approach that is based on a relaxation of binary variables and a downsampling of the time series rather than a decomposition. We do not want to use Benders or Dantzig-Wolfe decomposition because they rely on a very specific mathematical structure of the problem that cannot be guaranteed in every case. In order to get a reasonable mode of operation for every device in the final solution, the previously relaxed binary variables have to be set to 0 or 1 in a later stage of the optimization. By doing this, the solution presented to the user is feasible for the original problem.

We propose a multi-stage optimization approach, in which the first couple of stages determine the design variables and the peak power prices, and the last stage uses a rolling horizon with a relaxed look-ahead in order to calculate results that fulfill all constraints of the original problem. The complexity of the original problem is thus reduced by relaxation of binaries and downsampling of the input time series in a way, that the difference between the original and the downsampled time series is as small as possible.

In order to improve the quality of the relaxed solution, problem specific substitute formulations are used for specific binary variables. They are used to replace piecewise-linear functions and SOS1 formulations for feed-in prices in a way that the difference between the binary formulation and the LP formulation is as small as possible.

2. Structure of optimization problem

2.1. Mathematical structure of the design and operation optimization problem

The mathematical formulation of the optimization problem was stated similarly in many cited publications. We look for a generic formulation, which works for many energy conversion units (electricity, heat, cooling, steam, compressed air), many operational side conditions (minimum part load, minimum runtime, ramp-up behavior, maintenance), and many operating costs (costs per operating hour, costs per full load hour, costs per year).The mathematical formulation will only be given very briefly. In most cases, the total annualized costs (TAC) are

minimized, although in some cases minimizing CO_2 emissions is also relevant. So, inspired by [10] the target function is formulated like this:

$$\min_{\dot{V}_{n,t},\dot{V}_{e,t},\dot{V'}_{e,t},\delta_{n,t}} TAC = OPEX + CAPEX$$

$$= \sum_{t\in T}\left(\Delta t_t\left(\sum_{n\in C} f_{n,t}\left(\dot{V}_{n,t}\right) + \sum_{e\in E} c_{e,t}\dot{V}_{e,t} - r_{e,t}\dot{V'}_{e,t}\right)\right) + \sum_{e\in E}\hat{c}_{e,t}\dot{V}_{e,t}^{max} + a_{inv}\sum_{n\in C} f_n^{inv}\left(\dot{V}_n^N\right)$$

$$\sum_{n\in C^e}\dot{V}_{n,e,t} - \sum_{n\in C^e}\dot{V'}_{n,e,t} + \dot{V}_{e,t} - \dot{V'}_{e,t} - \dot{D}_{e,t} = 0 \quad \forall\, e\in E \,\wedge\, \forall\, t\in T \quad (1)\ \text{(energy balance)}$$

$$\dot{V}_{n,t} = f_n^{eff}\left(\dot{V'}_{n,t}\right) \quad \forall\, n\in C \,\wedge\, \forall\, t\in T \quad (2)\ \text{(energy conversion efficiency)}$$

$$\dot{V}_n^N \geq \dot{V}_{n,t} \quad \forall\, n\in C \,\wedge\, \forall\, t\in T \quad (3)\ \text{(nominal power per device)}$$

$$\dot{V}_{e,t}^{max} \geq \dot{V}_{e,t} \quad \forall\, e\in E \,\wedge\, \forall\, t\in T \quad (4)\ \text{(peak power grid connection)}$$

$$0 \leq \dot{V}_{n,t} \leq \delta_{n,t}\dot{V}_n^{max} \quad \forall\, n\in C \,\wedge\, \forall\, t\in T \quad (5)\ \text{(minimum part load)}$$

$$\Delta t_t\dot{V}_{n,e,t} \leq V_{n,e,t} \,\wedge\, \Delta t_t\dot{V'}_{n,e,t} \leq V_{n,e,t}^n - V_{n,e,t} \quad \forall\, n\in C_{st} \,\wedge\, \forall\, t\in T \quad (6)\ \text{(charging and discharging)}$$

$$\Delta t_t\left(\dot{V}_{n,e,t} - \dot{V'}_{n,e,t}\right) = V_{n,e,t} \quad \forall\, n\in C_{st} \,\wedge\, \forall\, t\in T \quad (7)\ \text{(filling level storage)}$$

$$\delta_{n,t}\in[0,1];\ \dot{V}_{n,e,t}\in\mathbb{R}^+;\ \dot{V'}_{n,e,t}\in\mathbb{R}^+;\ V_{n,e,t}\in\mathbb{R}^+;\ \left(\dot{V}_{e,t},\dot{V'}_{e,t}\right)\in SOS1$$

The operating expenditures consist of operating costs for running a certain piece of equipment $n \in C$ at a certain point of time $t \in T$. The operating costs are a function of the amount of energy $\dot{V}$ of a certain energy form $e \in E$ at that point in time. Additional costs for purchasing energy from the grid $c_{e,t}\dot{V}_{e,t}$ and revenues from selling energy to the grid $r_{e,t}\dot{V'}_{e,t}$ as well as peak power costs $\hat{c}_{e,t}\dot{V}_{e,t}^{max}$ are included in the OPEX. The capital expenditures (CAPEX) consist of the investment costs for a device n multiplied by the annuity factor a_{inv}. The investment costs are a function of the nominal power $\dot{V}_n^N$. The target function has to be minimized subject to other constraints, most importantly the energy balance. This implies that the demand of each energy form at a certain point in time $\dot{D}_{e,t}$ has to be met by the sum devices producing that energy form $\sum_{n\in C^e}\dot{V}_{n,e,t}$ plus the supply from the grid minus feed-in and the consumption of that energy form by other devices. The feed-in and grid supply are part of a special ordered set I (SOS1), so both cannot be non-zero at the same time. The energy supplied by a device is a function of other energy forms consumed. This function can be a constant efficiency of a piecewise-linear function. The minimum part load is modeled using a binary variable $\delta_{n,t}$ and a Big-M formulation using $\dot{V}_n^{max}$ as Big-M. Storage components (C_{st}) can only supply the amount of energy represented by their actual filling level $V_{n,e,t}$ and can only be charged up to the maximum filling level $V_{n,e,t}^n$.

2.2. Time-coupling constraints

Typical ESOMs for optimizing the design and operation of energy systems can have different kinds of time-coupling constraints, which can be divided into two different categories: On the one hand, there are couplings that introduce a variable as an upper limit for another variable for every single time step. This is the case for design variables, like the nominal power of devices that limit the power of a device for every single time step, and grid peak power variables that limit the power that can be taken from an energy supply grid for every single step in time. These coupling variables introduce complicating variables into the MILP. On the other hand, there are cumulating variables. Examples for these constraints are storage variables and upper limits to CO_2 emissions of an energy system. These variables introduce complicating constraints into the MILP.

One way to deal with these complicating constraints and variables in an MILP that otherwise has a block diagonal structure is Bender or Dantzig-Wolfe decomposition. Because we deal with all kinds of energy systems with very heterogeneous mathematical formulations and mixtures of complicating constraints and variables, these kinds of mathematical decompositions are not used in this work. There are some approaches to use Bender and Dantzig-Wolfe decomposition in literature ([11–13]), but they are tailored to a subset of use cases that are investigated in this work. Instead, the approach of this paper is a generic use of relaxations and downsampling to simplify the overall MILP model.

2.2.1. Upper limit (power price, capacity)

Complicating variables that represent an upper limit to another variable in every single time step occur, for example, in peak power pricing where a certain price has to be paid for the highest energy amount consumed from the electric grid per 15 minutes ((4) in Section 2.1). Another common example of variables representing an upper limit for every time step is the nominal power of a technical component in a design problem. The nominal power is an upper limit to the energy produced by that component per time step ((3) in Section 2.1).

2.2.2. Daily storage

Storages introduce complicating constraints into the ESOM. The state of charge of the storage couples two consecutive time steps and depends on the charged and discharged energy ((7) in Section 2.1).

Storages can be distinguished on the basis of their main application. Storages are economically most feasible, when they have many charging cycles throughout a year. Therefore, daily storages, which store electricity from photovoltaic, for example, are very common today. ESOMs containing these storages can be decomposed using typical days for calculating the storage operation ([14–19]). This kind of decomposition typically uses a cyclic constraint that couples the filling level of the first hour with the last hour of a typical day thus separating the solution of different typical days from each other.

2.2.3. Seasonal storage

Seasonal storages work exactly as daily storages, and the mathematical formulation of the overall problem looks exactly the same. However, the use case is different. Seasonal storages are designed to store energy for very long periods. They often have only one charging cycle throughout the year. A typical example is an ice storage that freezes water during the winter using the cold side of a heat pump. This ice can be used during the summer to cool buildings and thus be thawed again. Because we focus on models with a time frame of only one year, a cyclic constraint for seasonal storages has to be added to the mathematical formulation above, which couples the state of charge of the first time step with the last time step:

$$V_{n,e,0} = V_{n,e,max} \quad \forall\, n \in C_{st}$$

Due to the long-term storing of energy, decomposed typical days do not work for the design of these kinds of applications. There are approaches to couple typical days by a superimposed state of charge variable for every day of the year ([17,20,21]). These approaches do not perform very well for the design of seasonal storages because the order of the typical days has a very big influence on the design of the storage. Calculations with simplified energy system models resulted in deviations in the size of the storage between the full model and the decomposed model of over 85 %. Typical days are often determined using a clustering algorithm. Grouping of typical days by “charge-days” and “discharge-days” improves the design of the storage but still does not give reliable results.

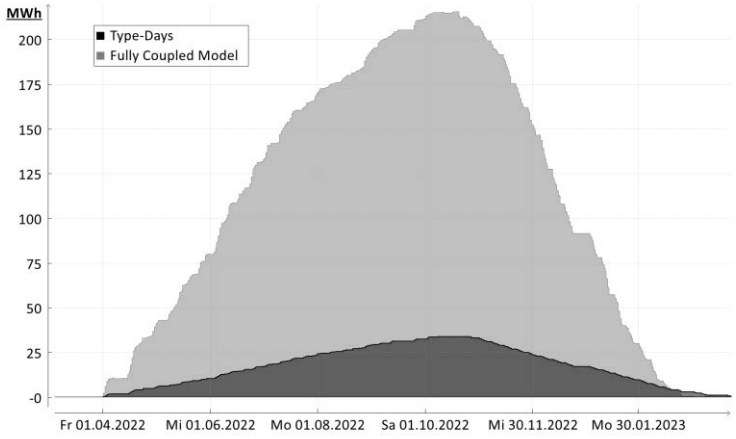

Figure. 1. *State of charge of a seasonal storage designed using typical days compared to the fully coupled original model.*

Figure. 1 shows the resulting state of charge using coupled typical days compared to the result of the original model. The underlying model consists of an oversized photovoltaic plant that produces electricity for hydrogen during the summer in order to produce electricity in a fuel cell during the winter season. The hydrogen is stored in a hydrogen storage of the size which is shown in the figure above. The fully coupled model results in a storage size of 215 MWh, whereas the decomposed model calculates a size of 33 MWh. The design of seasonal storages is one of the main reasons a method is developed that maintains the order of time steps in the reduced model in this paper.

2.2.4. Integral values

Another reason to have complicating constraints from cumulating variables in an ESOM are integral values. Typical examples are upper limits for CO_2 emissions of an energy system or performance indicators that should be met throughout the year. These constraints often come from corporate ecological goals or government regulations [22]. Equations of integral values are not included in Section 2.1. A typical formulation might look like this:

$$\sum_{e\in E}\sum_{t\in T}\theta_{e,t}\left(\dot{V}_{e,t}-\dot{V}'_{e,t}\right)\leq\theta_e^{max}\qquad\forall\, e\in E\qquad(8)\quad(CO_2\text{ emission limit})$$

$$\frac{\sum_{e\in n}\sum_{t\in T}\dot{V}_{e,t}}{\sum_{e\in n}\sum_{t\in T}\dot{V}'_{e,t}}\geq\hat{\eta}_c\qquad\forall\, n\in C\qquad(9)\quad(\text{Overall efficiency constraint})$$

In formulation (8), θ_e^{max} is an upper limit of an integral value: in this case, the CO_2 footprint of all energy forms bought from the grid minus the ones fed into the grid. In (9) the quotient of produced energy and consumed energy throughout the year of one component (overall efficiency) should be higher than a target efficiency $\hat{\eta}_c$. These formulations exist in cogeneration subsidies in Germany, for example.

2.3. Binary variables and their relaxations

The main idea of this paper is to use LP relaxations combined with the downsampling of time steps in order to reduce the complexity of the ESOM, while maintaining the chronological order of the time steps. Therefore, different typical applications of binary variables in ESOMs will be discussed in the following Section.

2.3.1. Part load characteristics and cost functions

Some variable relations in ESOMs are non-linear and have to be linearized in order to use them in MILP models. Typical examples are part load characteristics of technical equipment, which represent energy conversion efficiencies in part load ((2) in Section 2.1). Another common example are cost functions of technical components that usually have an economy of scale effect, which means the specific price of a technology is lower, when the plant size is bigger (f_n^{inv} in Section 2.1). The relation between variables is mostly described using piecewise linear functions (PWL) that are characterized by supporting points and interpolation in between those points. These PWLs can be modeled using special ordered sets (SOS) using the following formulation:

$$\sum_{i=1}^{n}\lambda_i x_i=x;\ \sum_{i=1}^{n}\lambda_i y_i=y\ ;\sum_{i=1}^{n}\lambda_i=1$$

$$\lambda_i\geq 0;\ \lambda_i\in \text{SOS2};\ i=1,\dots,n$$

in which the PWL is defined by the supporting points $(x_1,y_1),(x_2,y_2),\dots,(x_n,y_n)$. In a SOS constraint of type 2 (SOS2), not more than two variables are allowed to take a non-zero value, and these non-zero variables must be consecutive in the list. SOS constraints are often reformulated using binary variables.

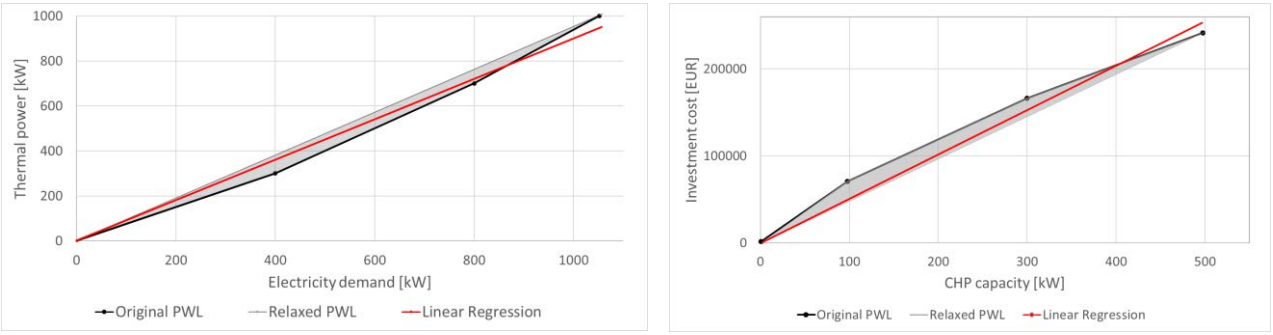

Figure. 2. *Typical structure of part load curves and investment cost function.*

The figure above shows two piecewise linear functions (black) and the space of possible solutions with relaxed binaries (grey). In this paper, we use a linear regression of the PWL function instead of an LP relaxation. This way, the deviation between the LP formulation and the PWL is smaller. The linear regression is also shown in Figure. 2 (red).

Typical part load curves have a convex structure due to inefficiencies in part load. Cost functions are usually concave due to economy of scale effects. However, in relation to the objective function, the PWLs are typically concave. In case of the part load curve, the objective function favors higher output power; in case of the cost function, the objective function favors lower investment costs. Therefore, binaries are needed for the formulation of the PWLs, and regression functions are used as replacement formulation in this work.

2.3.2. Semi-continuous variables for minimum part load and start/stop restrictions

Many energy conversion devices cannot be operated continuously between 0 % and 100 % of power output. In most cases, the part load behavior is continuous down to a point called minimum part load below which the device has to be turned off ((5) in Section 2.1). Therefore, the use of semi-continuous variables is very common in order to model this kind of behavior. Semi-continuous variables can either be 0 or in a range between a lower (ℓ) and an upper bound (u). They are reformulated using a binary variable (δ) by MILP solvers:

$$\ell \cdot \delta \leq x \leq u \cdot \delta$$
$$\delta \in \{0,1\}$$

Relaxing these kinds of variables leads to a continuous solution space between 0 and u for the variable x. So, in the LP relaxation, the minimum load of the component is not taken into account.

Because the binary variable δ is also the indicator for whether a component is on or off, this also cannot be distinguished in the LP relaxation leading to other constraints not being considered. Start and Stop constraints, for example, are often modeled in a way that a component cannot be switched on and off very frequently. If the on/off state cannot be determined anymore, start/stop constraints can also not be included.

2.3.3. Binary variables for buying and selling energy

Another typical application for special ordered sets represented by binaries are prices for buying electricity from the grid and the respective revenues for selling electricity to the grid. This can be represented by an SOS1 constraint, which means electricity can either be bought or sold, but not both at the same time. The amount of electricity bought and sold is represented by a variable that is part of an SOS1 in each case. So only one of them can be different from 0 at the same time step. These variables are then multiplied with the purchase or feed-in price and added to the target function.

In the LP relaxation, the variables in the SOS1 can both be different from 0 at the same time, which means buying and selling electricity at the same time step is allowed. As prices for buying electricity are usually much higher than the revenues for selling electricity to the grid, this is not a problem in most cases. Because the use cases discussed here are very heterogeneous, there might be situations where the price for buying electricity is very low. This can happen, when the selling price is determined by a subsidy (e.g., PV) and the buying price by a spot market (e.g., EPEX intraday). In these cases, the LP relaxation will buy cheap electricity from the grid and feed it back for a higher price, leading to an unbound MILP. This issue can be resolved by setting the same price for buying and selling electricity in the LP relaxation in these rare cases.

In cases in which the target function is not operating costs or annualized costs but rather CO_2 emissions or primary energy, simultaneous supply from the grid and feeding into the grid is possible. In these cases, the MILP will not become unbound, but the cost results of the model will be wrong.

2.3.4. Indicator constraints for if-then relations in control statements

Sometimes in ESOMs a constraint is only active if another condition is met. This can be modeled using indicator constraints, which themselves are represented using a binary variable with a Big-M formulation. An example is a heat pump that can only produce a certain amount of heat, when the heat source has a temperature above a certain value. The temperature of the heat source may be determined by another component (e.g., geothermal) that determines whether the source temperature can be reached. In this case, the heat pump can produce only a certain amount of heat, when the geothermal system is running. The on/off variable of the geothermal indicates the maximum power of the heat pump in this case. Using an LP relaxation of the original model, these indicator constraints cannot be modeled anymore, and the relation between the binary and the indicator constraint is lost.

3. Methodology

The methodology of this paper is based on a multi-stage approach using an LP relaxation and a downsampling in the first couple of stages to calculate the complicating variables and a rolling horizon approach in the last stage to calculate the complicating constraints and all other results. Using 5 different energy system models, times for solving LP relaxations were determined [23]. The measure to compare solving times are gurobi [24] work units, because they are independent of other processes running on the same machine and thus reproducible. A gurobi work unit is almost the same as a second on a single core processor. The measurements show a significant reduction in the LP relaxation. LP relaxations of MILP Models that do not solve in hours can be calculated in less than an hour.

The LP relaxations used in this paper are not only relaxations of the original model but in fact reformulations of characteristic curves and some energy prices in order to generate a formulation that is closer to the original model than the LP relaxation without using any binaries. These reformulations are described in Section 2.

An additional downsampling of the LP leads to another significant reduction of the solving time typically to less than a minute. We experimented with other time series reduction algorithms as described in [17]. Especially feature-based segmentation methods [25] that do not produce typical days but keep the order of the time steps intact were tested without significant improvements in the solution quality. Nevertheless, further investigations of these methods should be done in the future.

3.1. Substitute formulation of binary variables

In order to get as close as possible to the original unrelaxed formulation with the new LP formulation, some constraints can be reformulated in a way that does not require any binary variables. This has been done for piecewise linear functions using a linear regression with an axial intercept at 0/0. The advantages of this formulation were tested in [23]. It could be shown that a regression is faster. It is also more accurate in most

cases, but depending on the convexity of the PWL, it might also be worse than a relaxation. Nevertheless, we favor the regression because we do not want to exploit the convexity of PWL functions.

In the case of grid connections that have different purchase and feed-in prices, we use a different approach. In [23] we investigated different reformulations of the SOS1 constraint for feeding and purchasing electricity. Relaxing the SOS1 constraints led to high shifts in the target function value in time steps where the feed-in price is higher than the purchase price. Setting a medium price for buying and selling electricity would be a solution but also leads to high errors. So in this work, we propose for time steps in which electricity is bought and sold at the same time to add binary steps in later stages.

3.2. Fixing complicating variables (first stages)

Results of the LP relaxation are used to determine and fix complicating variables in the first stage of the optimization process. Because the LP relaxation violates a lot of binary constraints, the results of the complicating variables can be improved by re-adding some binary constraints that are violated in stage one back into the model. A solution of this partially relaxed model is stage two.

Further studies on two different ESOMs (see **Figure. 3** and **Figure. 5**) show the work units of models with different numbers of unrelaxed time steps (**Figure. 4** and **Figure. 6**). The figures show a significant increase in work units above 100 unrelaxed time steps. Another significant increase happens above 1000 unrelaxed time steps.

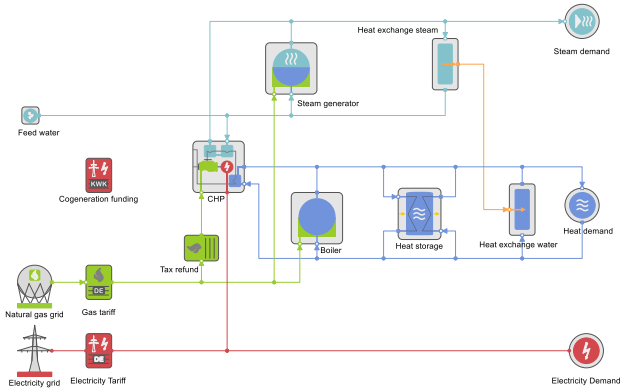

Figure. 3. *Heat and steam supply with efficiency constraint (Model A).*

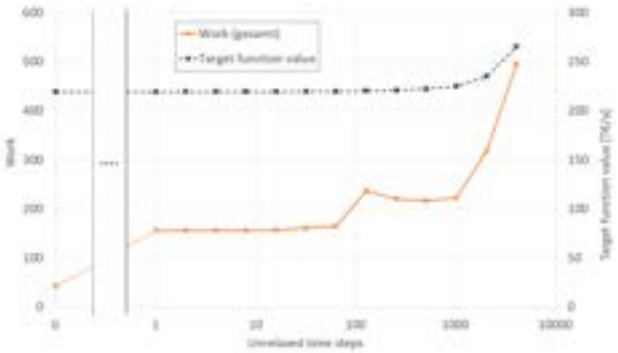

Figure. 4. *Work units and target function value over the number of unrelaxed steps (Model A).*

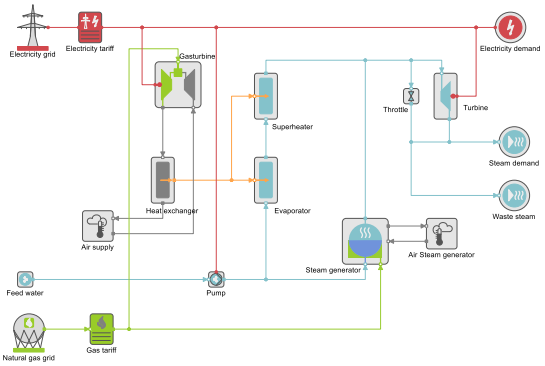

Figure. 5. *Steam supply with gas turbine and peak power price (Model B).*

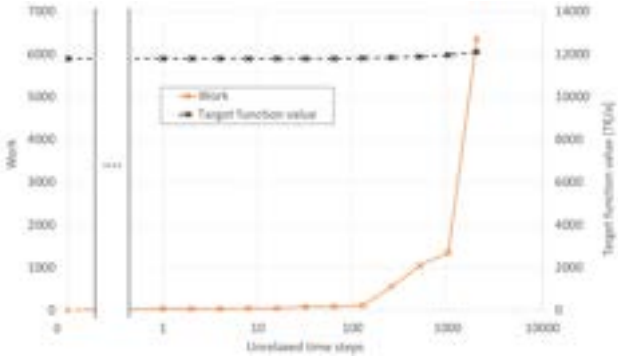

Figure. 6. *Work units and target function value over the number of unrelaxed steps (Model B).*

Model A consists of 259 continuous and 31 binary variables per time step of which presolve of gurobi removes about 90 %. Model B has 566 continuous and 70 binary variables per time step of which 96 % are removed during presolve.

The idea of the algorithm is to add binary variables back into the relaxed model and solve it until the violation of binary constraints is acceptable or calculation time are getting unacceptable. When this algorithm terminates, the complicating variables are fixed. These are nominal powers of technical components and peak power of the electric grid.

3.3. Calculating unrelaxed results using a rolling horizon

With the complicating variables fixed, the other results are calculated using a rolling horizon approach. The rolling horizon is designed in a way that results are calculated using unrelaxed time steps that are not

downsampled. The rest of the year is taken into account using a downsampled a relaxed time frame. This way, the development of complicating constraints by cumulating variables can be considered in the decision for the unrelaxed time frame. The advantage of this approach over a relaxed calculation is that the results do not violate any binary constraints and are not downsampled. The result is a solution of the original model, which is a requirement by most users. Analog to [26] the solution could be used to warm-start the original model. This has not been implemented in this work, but is subject to further investigation.

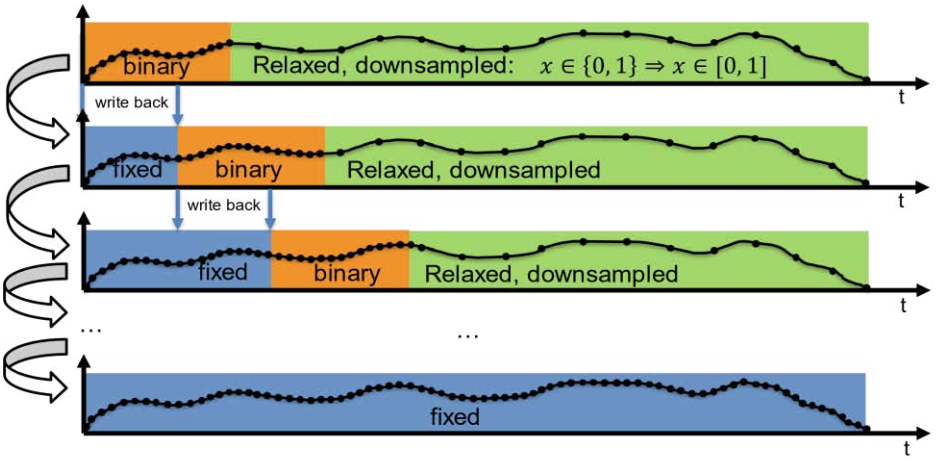

Figure. 7. *Illustration of binary rolling horizon, writing back, fixed past, and relaxed future.*

4. Runtime experiments

Whereas preliminary studies used many different models (Section 3.1) final experiments used a model with an oversized photovoltaic system and a power-to-gas unit to produce hydrogen out of a surplus of electricity. The hydrogen can later be used to produce electricity in a fuel cell. Both fuel cell and power-to-gas produce low temperature heat as a by-product. This heat can either be dumped in an emergency cooler or upgraded in a heat pump to high temperature heat. The high temperature heat from the heat pump is used to supply the high temperature heat demand. Heat that cannot be produced by the heat pump has to be generated using a common boiler. The ESOM was modeled using the modeling framework TOP-Energy. Most of the runtime measurements have been done using a python reimplementation of the same model. The model was chosen, because the full unrelaxed solution to a of gap 0.1 percent with 8760 time steps can be obtained in a reasonable time (about 30 minutes). Other example models did not solve in hours, which made it hard to do lots of evaluations with them. The prove of optimality for this model would take more than 24 h and has therefore not been carried out. A scheme of the ESOM is shown in Figure. 8.

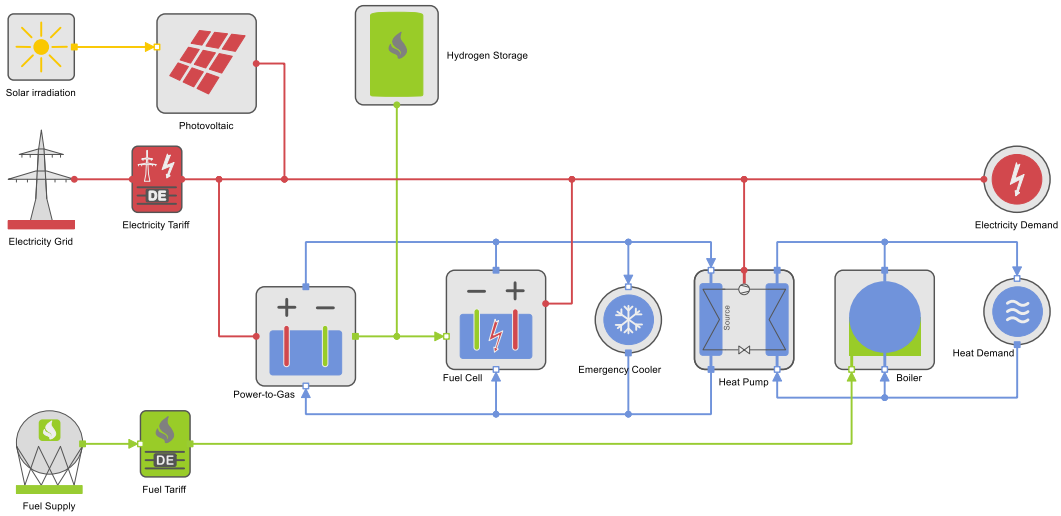

Figure. 8. *ESOM with photovoltaic and hydrogen storage for electricity and heat supply (Model C).*

The model contains two complicating constraints. One is the size of the hydrogen storage, and the other one is the peak power taken from the electric grid. The fuel cell has a minimum part load of 20 % and a nominal power of 600 kW. The heat pump has a characteristic curve that describes the part load behavior. The hydrogen storage has a characteristic curve that describes the investment cost function with an economy of

scale effect. Both characteristic curves have three supporting points which result in three variables in the SOS2 formulation.

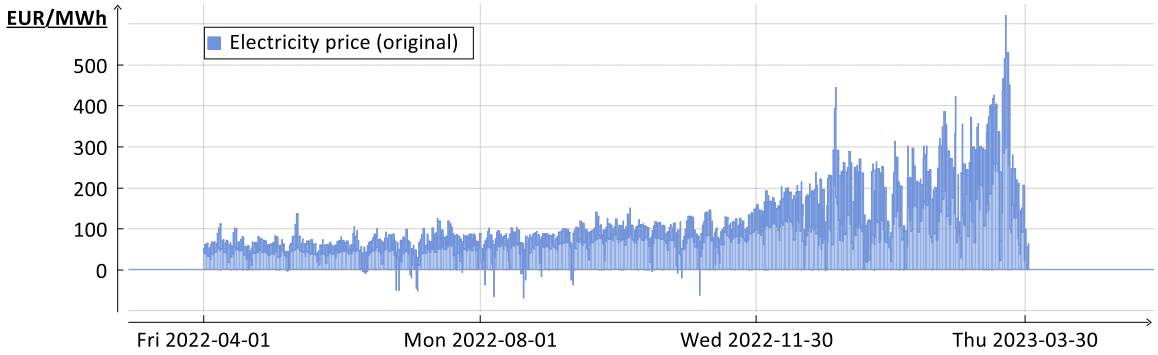

Figure. 9. *Electricity prices based on EPEX spot prices from 2021.*

The electricity price was taken from the EPEX day-ahead auction in Germany in 2021 [27] and moved 8 months back to cover the time frame of the model which is from April 2020 until the end of march 2021 (to get a better charging and discharging regime of the seasonal storage).

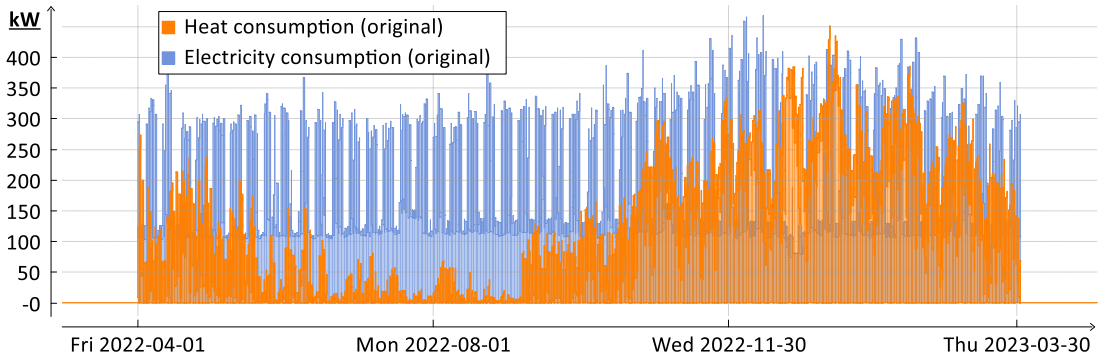

Figure. 10. *Heat and electricity demand.*

The electricity demand was measured at an office building and scaled up by a factor of 10. The heat demand was generated from a temperature profile of Berlin. The electricity production of the photovoltaic system is calculated using solar irradiation data of Berlin for a typical year. These data are provided by the German Meteorological Service DWD. A study from 2020 [28] states a price of 0.6 €/kWh for a very big cavern storage of 26 GWh. To make the storage economical for the sake of the study, these prices were further reduced. The specific costs of the hydrogen storage were set to 0.3 €/kWh for small storages (up to 300 MWh) and 0.255 €/kWh for bigger storages.

4.1. Runtime for stage one

The best available result for the complicating variables in stage 1 of model C was achieved by running the whole time frame (8760 steps) with binary variables and a gap of 0.1 %. This calculation took 1661 work units. Lower gap values took too long to calculate. This calculation results in 288 kW peak power for the grid connection and 569 MWh capacity of the hydrogen storage.

Table. 1. *Work units and errors of downsampled solutions in stage 1.*

Timesteps	Work units	Peak power	Error	Hydrogen storage	Error
1095	0.608	318 kW	10.4 %	554.92 MWh	2.5 %
1460	0.844	261 kW	9.4 %	475.36 MWh	16.5 %
2190	1.932	267 kW	7.3 %	492.49 MWh	13.5 %
4380	7.664	272 kW	5.6 %	494.53 MWh	13.1 %
8760	30.942	273 kW	5.2 %	490.47 MWh	13.8 %

The table above shows the work units of certain levels of downsampling and the respective results for hydrogen storage size and peak power. The downsampled models do not contain any binary variables. All binaries are replaced by substitute formulations or relaxed. While the peak power is getting better with a higher number of time steps, the storage size gets worse. This is not reproducible for different setups, so we assume it is a random behavior. The target function value of the overall problem is 211,126 Euro, so the error of the peak power as well as the error of the hydrogen storage size led to errors in the peak power price and the hydrogen storage price close to 0.1 % of the target function value in a solution with gap 0.1 %.

In this study, a downsampling rate of 4 was chosen for this example. Because the results from **Table. 1** are not known beforehand, we start the investigation with a downsampling to 4-hour intervals. This seems to be a reasonable resolution to account for fluctuating renewable energies, and it led to acceptable calculation times in the other models as well.

4.2. Adding binary steps in stage 2-5

In the next stages, the violation of binary constraints is fixed by adding binary steps to the relaxed model. The results of the stages are shown in the table below. Although the solution time other than the work units may depend on other tasks on the same processor, solution times are given next to work units for reference.

Table. 2. *Complicating variable results of the first 7 stages of optimization.*

Stage	Binary Steps	Work	Time	Peak Power	Error	Hydrogen Storage	Error
1	0	1.93	1.51 s	267 kW	7.3 %	492.49 MWh	13.5 %
2	137	5.12	4.37 s	265 kW	8.0 %	497.97 MWh	12.5 %
3	204	5.86	4.82 s	261 kW	9.4 %	511.89 MWh	10.0 %
4	220	4.13	3.90 s	259 kW	10.1 %	513.32 MWh	9.8 %
5	239	4.54	4.99 s	267 kW	7.3 %	518.92 MWh	8.8 %
6	250	3.66	4.22 s	267 kW	7.3 %	521.42 MWh	8.4 %
7	250			Stage 7 not carried out (no change)			
	Result 2-6:	25.26	23.80 s	267 kW	7.3 %	521.42 MWh	8.4 %

A peak power of 267 kW and a hydrogen storage size of 521,427 kWh is used for the last stage.

4.3. Rolling horizon stage

In the last stage, a rolling horizon of 84 time steps is used. Each frame is calculated using 96 unrelaxed time steps that are not downsampled and the rest of the year with a relaxed downsampling of 4. The first 84 time steps of each calculation are stored as results and fixed for the next frames. 103 calculations are needed to calculate the whole year. These 103 calculations take another 70 work units and 105 seconds. The sum of all stages took 95 work units and 129 seconds compared to 1661 work units and 1956 seconds for the full model.

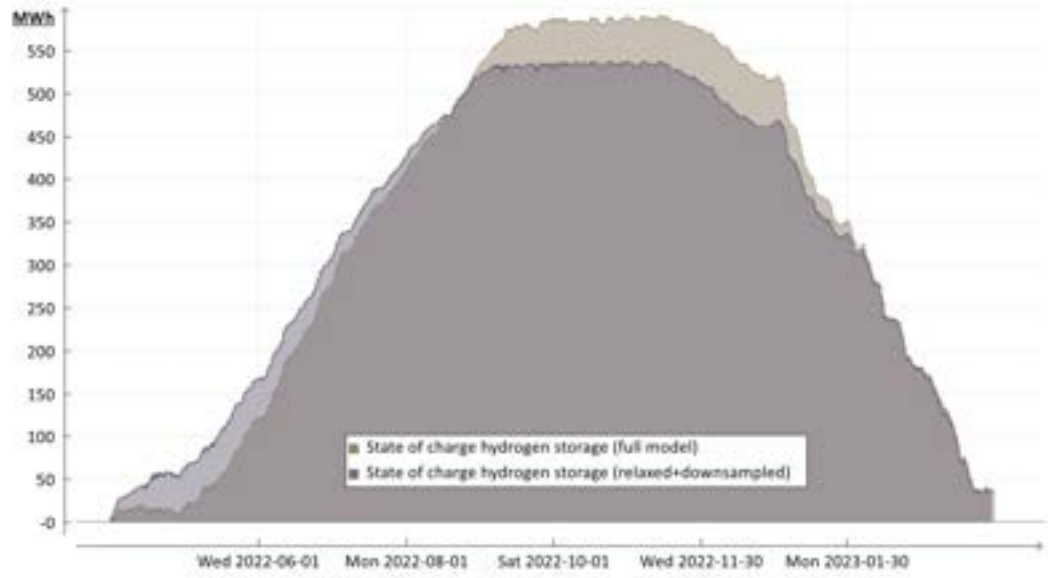

Figure. 11. *State of charge of the full model compared to the result acquired by the methodology.*

The patterns of charging and discharging the hydrogen storage are similar between the unrelaxed solution based on 8760 time steps and the relaxed and downsampled solution. The grid consumption of electricity (which is not shown here) is also very similar. For this example, the methodology delivers a reasonable result, which fulfils the requirements.

4.4 Sensitivity analysis

One requirement for the methodology was the traceability of results. Therefore, we carry out a sensitivity analysis for the original solution and the relaxed and downsampled solution to see whether the dependency on peak power pricing and hydrogen storage price are similar.

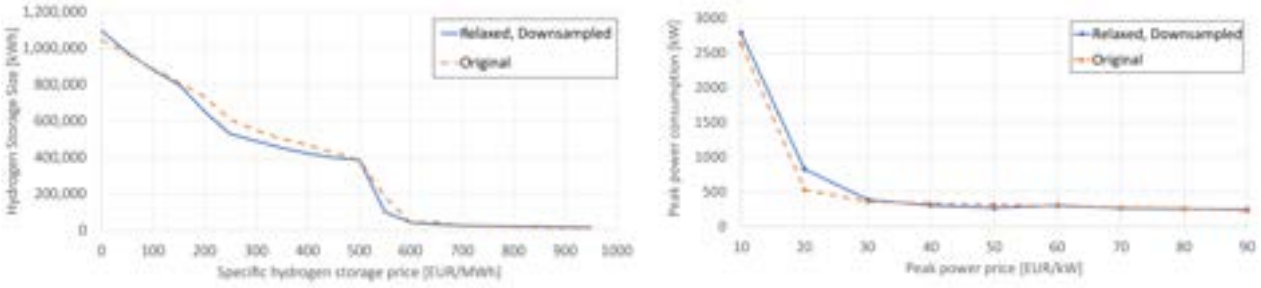

Figure. 12. *Dependency of prices and peak power (r) and storage size (l).*

The figure above shows the dependency of the consumed peak power on the peak power price and the dependency of the hydrogen storage size on the specific price of the hydrogen storage. The figure shows that the general behavior of the correlation is the same, and the methodology represents the values quite good.

5 Conclusions and future work

The examples above show that a relaxation of binary variables combined with a reformulation of some constraints together with a downsampling of time steps is capable of replacing the original more complex formulation and producing good results for design variables and peak power prices. In a multi-stage approach adding binary steps back into the problem in later stages and then calculating a feasible solution using a relaxed rolling horizon approach, reasonable results for problems with all kinds of time-coupling could be calculated.

The statements made here are tested against a small set of energy system models and should be investigated further. The fact that for some of the tested ESOMs the original solution is not known makes this evaluation a hard task.

In future work it should be tested whether the solution can be improved even further when the final solution of the rolling horizon approach (which is feasible for the original problem) is used to warm start the solution of the original problem. Having this lower bound of the original problem has proven to have big advantages [26].

Another way to improve the solution is to use a multivariate feature based segmentation [29] to reduce the number of time steps. This means removing steps from the input time series that change the time series as little as possible. An implementation based on the bottom-up approach from [25] was tried by the authors, but did not have a significant effect yet.

Metaheuristic vs. mathematical optimization: A comparison of methods for the design optimization of residential building energy systems

Pierre Krisam[a], Lena Rosin[a], Sebastian Glombik[a] and Eva Schischke[a]

[a] *Fraunhofer Institute for Environmental, Safety, and Energy Technology, Oberhausen, Germany*

Abstract:
The energy system of residential buildings and their impact on the transition towards an emission-free energy supply has been a focus in a wide range of studies over recent years. For the design of energy systems, a variety of methods are used, most commonly heuristic, mathematical optimization and metaheuristic approaches. While the strengths and weaknesses of these methods are well known, knowledge about the discrepancy in results produced for the design of energy systems is limited. Moreover, metaheuristics have rarely been utilized in the field of household energy system planning. This leads to problems whenever findings from different studies are compared and raises the question about the optimal choice of methodology under given circumstances. To approach this question, we examine the energy system of a residential building with two different methods - a mathematical optimization and a metaheuristic optimization applied to the same MILP model. The energy system model considers a PV system, a heat pump, a heat and a battery storage system as well as a gas boiler. The layout and size of these components along with their operation are optimized. We compare the results regarding the difference in layout and size of individual components, investment costs, operational costs, CO_2 emissions and computational performance of the methods. In this case study, the mathematical optimization resulted in the best Pareto front. Using the metaheuristic approaches, it is possible to compute a Pareto front in a considerably shorter time. However, the quality of the Pareto front is significantly worse.

1. Introduction

The design and operational optimization of energy systems, considering renewable energies and the resulting temporal resolution, is a complex mathematical problem. The complexity of such optimization problems increases strongly with an increasing number of variables, local optima, and non-linearities, which also leads to increasing computational effort [1]. In general, global optimization algorithms can be divided into two methods: Deterministic methods also called mathematical optimization and probability-based methods referred to as metaheuristic optimization. In the past energy systems and especially unit commitment problems were mostly modeled as Linear Programming (LP) or Mixed Integer Linear Programming (MILP) optimization models [2] and solved using mathematical optimization techniques such as the branch and cut algorithm. Today, various metaheuristics are widely used to solve unit commitment problems [3] and are even predicted to become the standard for design optimization problems in the near future [4, 5].
While mathematical optimization is guaranteed to find the global optimum of a feasible problem, the complexity of global optimization problems can become so large that the global optimum cannot be found within a reasonable time. [6, 7] Metaheuristic methods, on the other hand, can solve complicated models in a shorter time frame, but do not guarantee the optimality of the results [8].
Since both solution techniques have their advantages, it is important to have a decision guide when to use which technique. Nevertheless, there is little research on how metaheuristics compare to other solution techniques such as mathematical optimization and heuristics in the field of energy system optimization. This paper aims to make a start in filling this research gap by comparing the performance of two popular metaheuristics, the Speed-constrained Multi-objective Particle Swarm Optimization (SMPSO) [9] and the Non-dominated Sorting Genetic Algorithm II (NSGA II) [10], with the performance of classical mathematical optimization on a MILP model for the design optimization of an energy system. The two selected metaheuristics are based on two different approaches.The NSGA-II is based on the principle of survival of the fittest, i.e. inheritance, mutation and selection of the best genes or, in this case, the decision variables. The SMPSO, on the other hand, is based on the flocking behavior of birds and schools of fish, and takes into account the speed of the neighbor

as well as a random change in the speed parameter.

There is a significant amount of papers comparing different metaheuristic algorithms [11, 12, 13, 14] but only a little research on how different solving techniques like metaheuristics, heuristics and classical mathematical optimization perform compared to each other, especially regarding the differences in results.
In Suh et al. [15] it is shown that metaheuristics outperform the heuristic layout of professionals by far in terms of finding the global optimum for this case study. Here, the layout refers to building decisions such as window area, insulation thickness and light bulbs.
In Silveira et al. [16] five different metaheuristics are compared to MILP, MINLP and MISOCP with classical optimization. As a case study, three different configurations of distribution systems are considered. The computational time of the metaheuristic optimization was significantly shorter than that of the mathematical optimization. For large problems, metaheuristics even found a better solution with regard to the objective function than classical mathematical optimization.
Stojiljković et al. [6] and Schmeling et al. [17] use a combined approach where the optimization problem is decomposed into two new problems. The main problem is the design optimization including synthesis, which is solved by a metaheuristic. The subproblem is the operational optimization, which is formulated as a MILP and solved by the brunch-and-cut method. The authors did not compare the results with solving the original problem using the branch-and-cut algorithm directly on the design optimization problem. However, it is noteworthy that the proposed approach has the potential for a comparison between metaheuristic algorithms and mathematical optimization, since the same constraints can be used to model the individual components of the power system.
In the following, we will compare the decomposed metaheuristic design optimization with a mathematical design optimization also referred to as structural optimization approach using MILP only.

The remaining sections of this paper are structured as follows: Section 2. provides an overview of the case study used to compare the methods. Section 3. introduces the unit commitment model used for design optimization and the corresponding metaheuristic approach. Section 4. presents and compares the results of the case study. Finally, section 5. discusses the results and draws relevant conclusions.

2. Case Study: Residential building energy system

Decarbonizing the building stock is a major challenge. As most of the existing building heat demand is met by fossil fuel-fired boilers, there is a high demand to find optimal solutions considering alternative technologies that reduce local emissions at minimal cost. Therefore, in this study, a residential building is chosen to test different approaches for designing energy systems as a problem with high practical relevance. A key strategy for decarbonizing building energy systems is to switch from combustion-based towards electricity-based heat supply combined with local electricity generation. Therefore, the design optimization of the energy system in this study considers a gas boiler, an electric heat pump for heat generation combined with heat storage. Local electricity can be provided by a photovoltaic system combined with battery storage. All components can be considered as options for the optimization algorithm. Thus, not all components have to be part of the final solution of the corresponding optimization problem. The full set of technology options and the possible energy flows in the system are given in Figure 1.

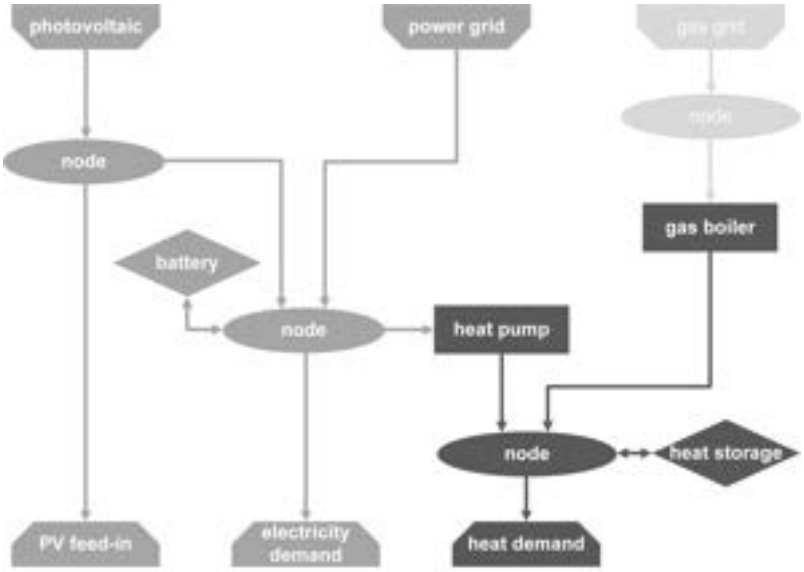

Figure 1: Schematic representation of the residential building energy system

The energy prices used in the model are form 2021. The emission data and the energy prices are listed in Table 1.

Table 1: Energy prices and CO_2 emissions

Data type	Costs	CO_2 Emissions
Electricity	0.337[€/kWh] [18, 19]	478 [g/kWh][20]
Gas	0.083 [€/kWh] [21, 22]	247 [g/kWh] [23]
PV feed-in tariff	0.073 [€/kWh] [24]	-

The investment costs for the various components are listed in Table 2.

Table 2: Investment costs of the components

Component	C_{var}	C_{fix}
Photovoltaics [25]	1260[€/kWp]	258 [€]
Heat pump [20]	426 [€/kW]	7072 [€]
Gasboiler[20]	445 [€/kW]	724 [€]
Heatstorage[26]	1000[€/kWh]	600 [€]
Battery (capacity)[27]	432 [€/kWh]	2130 [€]
Battery (inverter)[28]	150[€/kW]	-

The demands are modeled by using the open source tool *districtgenerator* [29] released by E.ON Energy Research Center, RWTH Aachen which is based on validated models from other research projects. It offers the possibility to define residential districts by specifying archetype buildings and generating building-specific energy demand profiles. The occupancy and corresponding electricity profiles are generated by a stochastic model based on [30]. The occupancy data is used to model the heating demand by modeling the domestic hot water consumption based on [31]. The space heating demand calculations are based on a 5R1C model according to EN ISO 13790 [32], where the corresponding building parameters are given by TABULA archetype buildings [33]. For this study a single building is defined. The *building type* is defined as a multi family house. The *construction year* is set to 1990 and the *retrofit state* according to TABULA [33] is a assumed to be in an usual refurbishment state. The *reference floor area* is defined as 778 m^2. The location is set to Potsdam (Germany) and the corresponding TRY dataset is used for the weather profiles.

3. Optimization models

In this section, the energy system model is described, starting with the unit commitment model for energy system operation, which forms the basis for both mathematical optimization and metaheuristic approaches. Next, the extensions to the unit commitment model necessary for design optimization are presented. Then, the modifications made to the unit commitment model in order to use the model with the metaheuristic algorithms are summarized. Finally, the metaheuristic method and the optimization setup are described.

3.1. Model for energy system operation

A mixed-integer linear unit commitment model is used as the base model for both the mathematical design optimization and the metaheuristic optimization. The model is implemented using the energy system optimization framework oemof. The household demand for electricity, heat, and hot water are modeled as sinks. The gas and electricity grids are represented as sources. The PV generation profile is simulated using a PVLib [34] model. For all other energy system components, we used the base class Transformer to write our own models. These models are briefly described below:

Let T be the set of all time steps that are considered in the optimization.

All components are limited by a maximum power rating $P_{el/th,max}$, either electric power or heat. Except for the heat pump and the gas boiler, all components are allowed to operate between 0 and this maximum power rating.

$$0 \leq P_{el/th}(t) \leq P_{el/th,max} \text{ for all } t \in T \tag{1}$$

For the heat pump and the gas boiler a minimum part load MPL is set as a percentage of the maximum power rating. To allow the output power to be zero, the binary variable Y_{op} is introduced.

$$Y_{op}(t) \cdot MPL \cdot P_{el/th,max} \leq P_{el/th}(t) \leq P_{el/th,max} \text{ for all } t \in T \tag{2}$$

The COP of the heat pump is modeled as ambient temperature dependent:

$$P_{th}(t) = P_{el}(t) \cdot cop(T(t)) \text{ for all } t \in T. \tag{3}$$

The efficiencies of the boiler and the battery storage are modeled as constant. The storage level is limited by a maximum storage capacity for both the battery and the thermal storage. The battery has no self-discharge, while the thermal storage has both temperature-dependent and level-dependent losses, which are calculated using the volume, the volumetric thermal transmittance and the density of the storage medium. The objective function of the model is to minimize the operating costs of the energy system, consisting of fuel and electricity costs for purchasing gas and electricity from the respective grid. Electricity produced by the PV system that is not consumed but fed back into the grid is compensated by the respective feed-in tariff. CO_2 emissions are calculated using constant emission factors assigned to the consumption of gas and electricity from the grid.

3.2. Design optimization model for the mathematical optimization

To transform the unit commitment model into a design optimization model constraints regarding the sizing of the components are added to the optimization problem. Additionally, the maximum power rating parameter $P_{el/th,max}$ of the unit commitment problem becomes a variable in the design optimization problem. To limit the solution space the maximum power rating is limited by P_{MAX}.

$$0 \leq P_{el/th,max} \leq P_{MAX} \tag{4}$$

In order to limit the solution space and thus the computation time, lower and upper bounds for the parameter P_{MAX} are introduced. The lower bound is set to zero and the upper bounds are determined by analyzing the energy demand, such as the maximum required heat output. For the PV system, the available roof area is used as the limit. When $P_{el/th,max}$ is zero the component is not built.
In both storage models, not only the capacity but also the maximum electrical/thermal power is optimized. For the battery, a power-to-energy ratio is implemented, to ensure a realistic battery layout. Furthermore, the total charged energy is limited according to cycle and calendar lifetimes.

$$\sum_{t \in T} P_{in}(t) \leq Capacity \cdot \frac{Lifetime_{cycle}}{Lifetime_{calender}} \tag{5}$$

We perform a multi-objective optimization with two objectives, the total annual cost of the system and the annual CO_2 emissions, to compute a Pareto front. For this purpose, the energy system is first optimized with respect to costs only. Here the objective function is the systems total annual costs (*TOTEX*).

$$TOTEX_{annual} = CAPEX_{annual} + OPEX_{annual}. \tag{6}$$

with $OPEX_{annual}$ the grid energy costs and maintenance costs for one year and $CAPEX_{annual}$ the investment costs annualized over the lifetime of the technology. Since the relation between the size of a component and its price is not linear, the *CAPEX* is calculated using a fixed C_{fix} and a variable C_{var} price component.

$$CAPEX = C_{fix} + P_{el/th,max} \cdot C_{var} \tag{7}$$

To build the Pareto front, an epsilon constraint is added to the optimization problem. This constraint limits the total annual CO_2 emissions of the system to x percent of the CO_2 emitted in the cost optimal case.

$$CO_{2_{total,annual}} \leq CO_{2_{total,annual,costoptimal}} \cdot \frac{x}{100} \tag{8}$$

In our case, x is decreased in steps of 2.5 starting at 100 (the cost optimal case) and stopping at 50 (a near CO_2 optimal case). No exclusively CO_2 optimization is carried out.

3.3. Metaheuristic optimization

The optimization problem has been decomposed into two subproblems, as proposed in [17]. The selection and sizing of the technologies here referred to as metaheuristic design optimization and the operational optimization of the resulting energy system (cf. Figure 2). The design optimization passes a set of variables to the operational optimization which returns the annual costs and emissions for each set of variables. Afterwards, the metaheuristic design optimization selects a new set of variables according to the KPIs, here CO_2 emissions and TOTEX, and passes it back to the operation optimization. The process ends when the termination criterion, here the computation time limit, is reached.

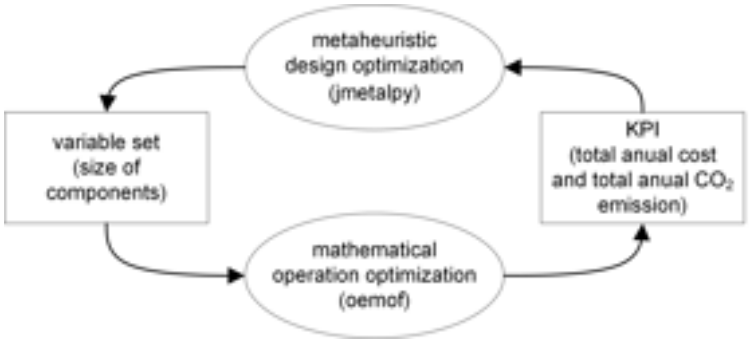

Figure 2: Two-level design optimization

The operation optimization is performed with the same unit commitment model described in 3.1.. The MILP is solved with Gurobi using a branch-and-cut algorithm. The emissions during the operation are limited by an emission factor to achieve comparable results to the MILP design optimization, which indirectly optimizes the operation to meet the global emission limit.
The main problem of design optimization is solved by a metaheuristic algorithm. The algorithm can determine the dimensions and capacity of the technologies and limit the emissions of the operation by an emission factor. The upper and lower bounds are set exactly as described in 3.2.
Analogous to mathematical optimization, two objective functions are used for metaheuristic optimization: The total annual costs and the total annual CO_2 emissions.
The metaheuristic optimization is done with the python package jmetalpy which uses the java-based framework jmetal.

3.4. Optimization Setup

In this section we give some insight into our setup and the software and settings we used. The calculations were performed on a computer with an Intel(R) Xeon(R) W-1390P @ 3.50Ghz and 128 GB RAM.
The design optimization MILP is solved with Gurobi Optimizer version 9.1.1 using up to 16 threads. A mipgap of 0.01 and a time limit of 6 hours per optimization is used. If the time limit is exceeded, the best solution and

the resulting mipgap are saved and the epsilon constraint method is continued.
The operation optimization MILP is solved with the same solver and solver settings except for the time limit, which is set to 5 minutes. The metaheuristic design optimization uses the default settings of the respective algorithms as presented in jmetalpy. In contrast to mathematical optimization, in metaheuristic optimization, it is not clear whether the global optimum has been found. Therefore, a termination criterion is needed. In order to be able to compare the results of the two methods, a time limit is set as the termination criterion. To make the results of the metaheuristic optimization reproducible, the same random seed is used for all algorithms and runs. All optimizations are computed for a whole year with a time resolution of one hour, i.e. 8760 time steps.

4. Results and Comparison

In this section, we analyze the results of the case study. We begin by examining the metadata of the algorithms used, followed by a comparison of the Pareto fronts. We then take a closer look at the actual energy systems built for the Pareto solutions.

Table 3 summarizes metadata such as the number of non-dominated solutions and the total computation time. A time limit of 20.15 hours and 5 hours was implemented for the metaheuristic methods, as well as a variation of the population or swarm size of 10 and 100. It can be seen that the termination criterion was not exactly met. Both NSGA-II and SMPSO exceeded the time limit. The population and swarm size appear to have a direct influence on the time limit violation. It seems that the termination criterion is applied only after the total generation has been computed. Mathematical optimization using the epsilon constraint produced 19 non-dominated solutions and two dominated solutions. The observed phenomenon is a direct consequence of the results reported in the recent research [35], which concluded that the epsilon constraint approach fails to accurately compute the true Pareto front. As a result, the use of lexicographic optimization is proposed to compute the true Pareto front. The metaheuristic methods found significantly more non-dominated solutions and total feasible solutions than mathematical optimization with the 20-hour time limit. Reducing the population/swarm size resulted in more optimizations and feasible solutions for both algorithms. For NSGA-II, the number of non-dominated solutions also increased significantly. For SMPSO, the number of non-dominated solutions decreased from 48 to 46.

Table 3: Meta data of the optimization

Method	MILP	NSGA-II	NSGA-II	NSGA-II	SMPSO	SMPSO	SMPSO
time limit [h]	N/A	20.15	5	20.15	20.15	5	20.15
total time [h]	20.15	21.40	5.40	20.19	21.66	5.55	20.18
population/swarm size [-]	N/A	100	100	10	100	100	10
generations [n]	N/A	12	3	140	10	3	121
total optimizations [n]	22	1200	300	1400	1000	300	1210
time limit reached [n]	0	11	5	1	11	5	10
infeasible [n]	1	259	91	226	279	94	470
feasible [n]	21	930	204	1173	710	201	730
non-dominated solutions [n]	19	38	14	85	48	22	46

Figure 3 shows the Pareto front of the different design optimization methods. The mathematical optimization Pareto front, hereafter referred to as the MILP Pareto front, is used as a reference in all subsequent figures. The computation time of the methods in this figure is about 20.15 hours (see Table 3) and the population and swarm size is set to 100. The solutions of the mathematical optimization for the case study lead to the best Pareto front in both dimensions. This implies that the Pareto front contains the most cost-optimal and CO_2 efficient Pareto points, in terms of all three algorithms. In this example, we observe that the SMPSO algorithm outperforms the NSGA-II algorithm in terms of finding the cost-optimal solution. However, we found that the NSGA-II algorithm was closer to the MILP front at the bending point of the Pareto curve. In other words, NSGA-II comes closer to the ideal point in Figure 3 than SMPSO. On the other hand, the emission-optimal point found by the SMPSO algorithm is more cost-optimal and has lower emissions than the one found by the NSGA-II algorithm. The emission-optimal solutions found by the metaheuristic methods are much more expensive than the emission-optimal solution of the MILP solution. In addition, the metaheuristic Pareto fronts continue to separate from the MILP Pareto front as emissions decrease.

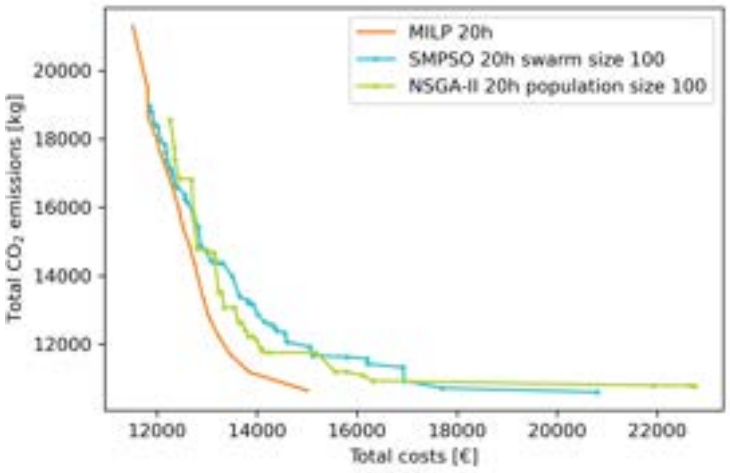

Figure 3: Pareto MILP, NSGA-II and SMPSO (20h time limit and population/swarm size of 100)

In Figure 4, the Pareto front of the MILP mathematical optimization from Figure 3 with a computation time of 20 hours is compared to the metaheuristic methods with a computation time of about 5 hours. The metaheuristic solutions are now much further away from the MILP Pareto front. For the same CO_2 emissions, the metaheuristics incur significantly higher total annual costs than the MILP Pareto solutions. This effect increases significantly with decreasing CO_2 emissions. The SMPSO, in contrast to the NSGA-II, found a point particularly close to the MILP Pareto front. Compared to the NSGA-II, the SMPSO found the solution with the lowest emissions and the solution with the lowest total annual cost.

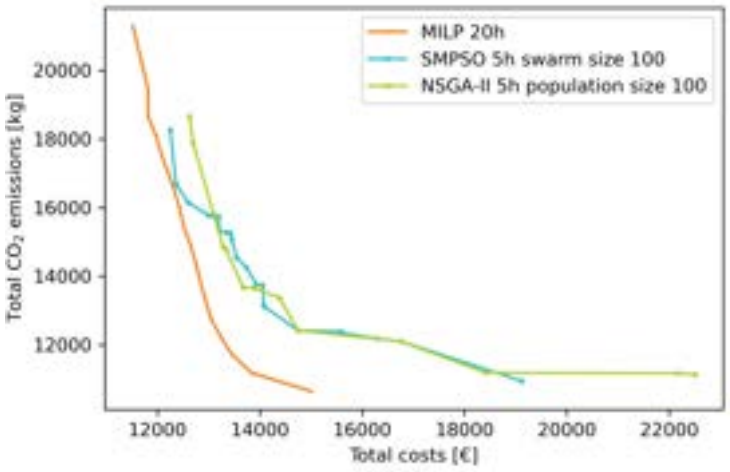

Figure 4: Pareto MILP, NSGA-II and SMPSO (5h time limit and and population/swarm size of 100)

In Figure 5 the population/swarm parameter was set to 10. The time limit here is 20.15 hours, as in Figure 3. The Pareto fronts of the NSGA-II and the SMPSO are close. The Pareto front of NSGA-II covers a smaller solution space than that of SMPSO. Compared to Figure 4, the Pareto front of the metaheuristics is much smoother. The NSGA-II and SMPSO perform slightly better with a swarm/population size of 10 in the emission optimal range. This could be due to the significantly higher number of generations. Compared to Figure 3, the algorithms perform better in some parts of the Pareto front and worse in others.

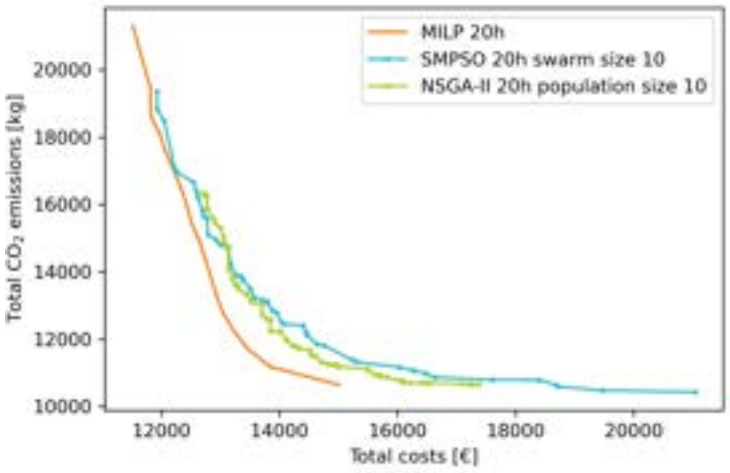

Figure 5: Pareto MILP, NSGA-II and SMPSO (20h time limit and population/swarm size of 10)

Closer examination of the energy systems built for the Pareto optimal solutions for the 20h mathematical optimization and the 20h metaheuristics with a population/swarm size of 100 reveals significant differences between the mathematical optimization and the metaheuristics. Figure 6 show the components and their sizes for all Pareto optimal results. The plots are sorted from cost optimality on the left to CO_2 optimality on the right .

Regarding the mathematical optimization, the capacity of the heat producers increases moderately across all solutions, as shown in 6a. It is noteworthy that only in the cost-optimal case no heat pump is built. For the next Pareto point, the gas boiler capacity decreases slightly and a heat pump is installed. Interestingly, the boiler and heat pump capacities remain almost constant for ten Pareto points until a tipping point is reached where no gas boiler is installed and the heat pump provides the whole heat demand.

Conversely, for both metaheuristics, a gas boiler is built for all Pareto optimal solutions.

For the NSGA-II algorithm, the gas boiler capacity initially decreases as emissions decrease, but then increases significantly for the last eight CO_2 optimal solutions, so that the gas boiler capacity for the cost-optimal and emission-optimal cases are nearly equal.

On the other hand, for the SMPSO algorithm, the gas boiler size remains nearly constant for the more cost-optimal Pareto points until a tipping point where only a very small gas boiler is built. But similar to the NSGA-II algorithm, the gas boiler size increases again for more emission-optimal solutions.

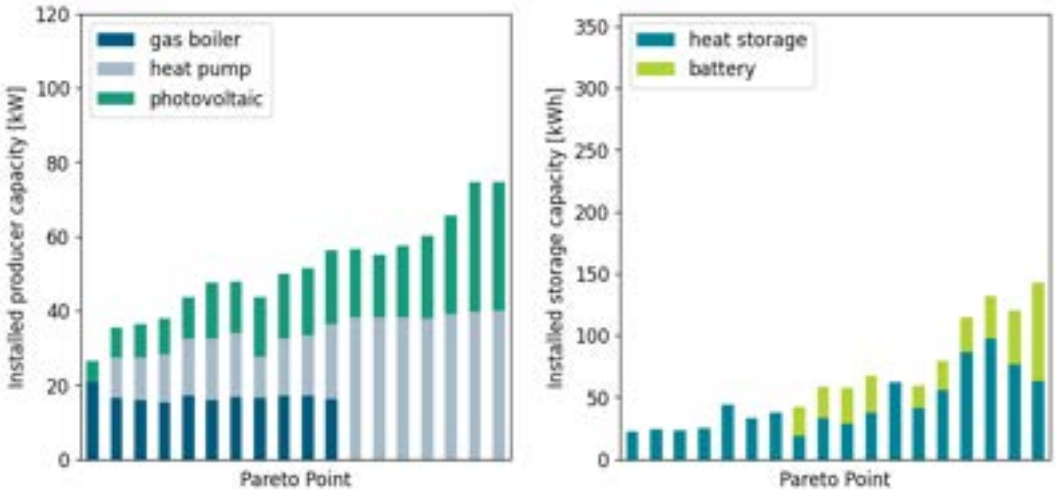
When analyzing the operation of the boiler over the course of a year for the SMPSO and NSGA-II algorithms for the emission-optimal solution, it can be observed that the boiler was rarely used, running only 54 hours and 249 hours, respectively, throughout the year. The installation of the boiler despite its limited use can be attributed to the absence of indirect emissions which are not included in this anaylsis. In fact, there are no "investment emissions" for the components. Similar to the mathematical optimization, figures 6b and 6c show that the heat pump size increases towards the CO_2 optimal solutions. However, in contrast to the mathematical optimization, the overall installed capacity of heat producers is higher for the metaheuristic algorithms.

Regarding the installed photovoltaic capacity, a constant growth along the Pareto front towards the CO_2 optimal solution is observed for both the mathematical optimization and the metaheuristics.

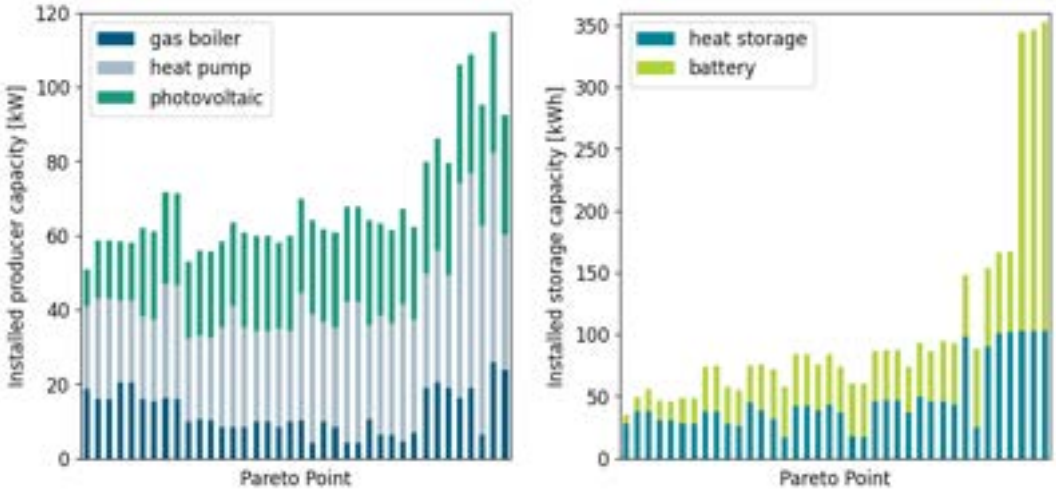
Despite an overall increase in storage capacity towards the CO_2 optimal solution for all three algorithms, significant differences in storage capacity are observed between the mathematical optimization and the metaheuristics.

The most notable difference is the approximately twofold increase in total storage capacity for the metaheuristics compared to the mathematical optimization. In the mathematical optimization, only the thermal storage is built in the cost-optimal case, and its size increases along the Pareto front until an additional battery is installed. At this juncture, the size of the heat storage drops before increasing again. Furthermore, the size of the battery increases steadily until the point where no gas boiler is installed. At this point, the size of the battery decreases to zero before increasing again toward the emission-optimal solution.

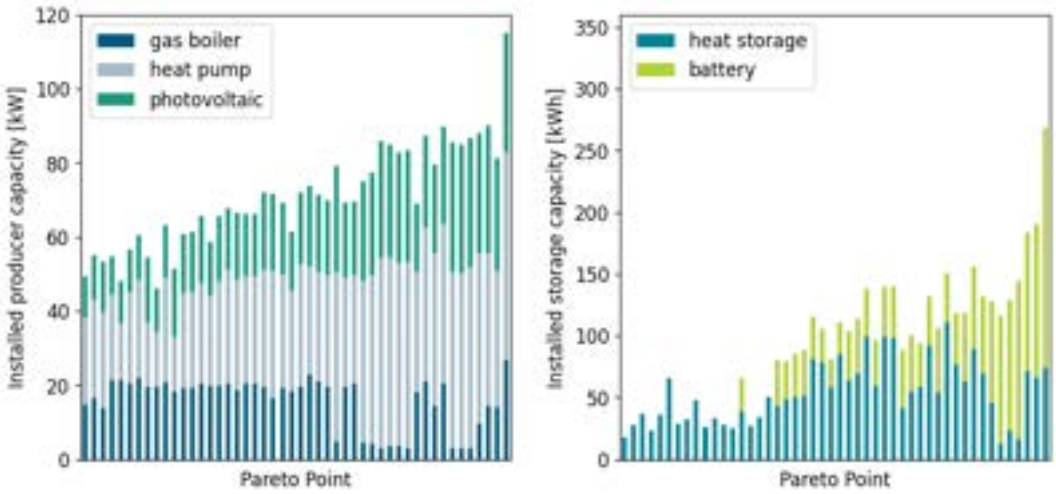
Similarly, both metaheuristics build thermal storage for all Pareto points. The NSGA II algorithm maintains a relatively constant heat storage capacity for most of the Pareto front. However, for more CO_2 optimal cases, the heat storage doubles in size. The battery size increases moderately toward the CO_2 optimal solution until a tipping point where the battery capacity increases dramatically to over 230 kWh.



(a) mathematical optimization (MILP)



(b) metaheuristic optimization (NSGA-II)



(c) metaheuristic optimization (SMPSO)

Figure 6: Energy systems from the pareto optimal results for different algorithms

In contrast to the NSGA-II algorithm, the heat storage capacity fluctuates significantly throughout the Pareto front of the SMPSO algorithm, peaking in the middle. In addition, the SMPSO algorithm does not install a battery until almost the middle of the Pareto front. Then the battery capacity increases steadily.

The higher costs associated with the emission-optimal solutions generated by the metaheuristics, as observed in Figures 3-5, can be attributed to the substantially higher storage and producer capacities employed by these algorithms. The reason for this could be that metaheuristics are severely penalized for choosing infeasible solutions or reaching the time limit in operations optimization. Therefore, the trained behavior of these metaheuristics is biased toward quickly producing feasible solutions, which results in larger capacities. This is probably the cause of the unexpected behavior of the metaheuristics in constructing a boiler for all solutions. This behavior can be reduced by allowing a higher time limit for operations optimization and more time overall for the computations, so that the metaheuristics can compute more generations.

Another notable characteristic of metaheuristics is the greater fluctuation in capacity sizing, as opposed to the smoother trend observed in mathematical optimization. This fluctuation can be explained by the random nature of the metaheuristics. This effect should be further investigated in future studies.

5. Conclusion

This paper compares two methods and their results for the design optimization of a residential building. A multiobjective mathematical design optimization approach and a two-stage metaheuristic design optimization approach using the metaheuristics SMPSO and NSGA-II were described, and the Pareto fronts and energy system designs of the Pareto solutions generated by each algorithm were analyzed.

In our case study, the mathematical optimization resulted in the best Pareto front. However, it should be noted that the calculation time was quite extensive at 20 hours. To reduce the computation time of the mathematical design optimization, a larger step size of the epsilon constraint could be applied. This would reduce the number of optimizations but at the same time the resolution of the Parteo front. Additionally, a lexicographic optimization approach can be used to compute the real Pareto front, which could lead to more accurate and efficient results and avoids caluating dominated solutions. Further research is needed to fully explore these possibilities and improve the efficiency of the optimization process.

Furthermore, our study has shown that the choice of parameters such as swarm/population size has a strong influence on the optimality of the results. Depending on the choice of metaheuristic parameters, either the NSGA-II or the SMPSO performed better. Therefore our optimization results do not allow a conclusion which of the two metaheuristic algorithms is better suited for the design optimization of residential buildings. In addition, it was shown that it is possible to compute a Pareto front with the metaheuristic approaches in shorter time frames, but this results in a significantly worse Pareto front compared to the MILP and 20 h metaheuristic solutions. For this reasons, further studies are necessary.

As mentioned above, the parameter settings of metaheuristic algorithms have a large influence on the quality of the results. For this reason, guidelines for the parameterization of metaheuristic design optimizations for energy systems would be beneficial. In order to ensure the comparability of the results of the different methods, a time limit was used as a stopping criterion in this study. However, when metaheruistic methods are used to obtain results in practice, a termination criterion is needed that allows a statement to be made about the quality of the solution or the convergence of the algorithm. Since one of the main advantages of metaheuristics is their computational efficiency compared to mathematical optimization, it would be worthwhile to investigate how solution-quality-oriented termination criteria such as the hypervolume could enhance performance. In addition, a warm start, i.e. the implementation of coherent start variables such as a standard desgin according to DIN norms, could make the solution process more efficient and robust. The factor that metaheuristics are not limited to MILP problems, like mathematical optimization, but can also be used with Non Linear Programming or simulation was not considered in this study. Hence it would be interesting to investigate a single-stage metaheuristic optimization instead of the two-stage approach used in this paper.

Lastly, additional case studies involving more complex energy systems and a wider range of scenarios are required to develop a reliable guideline for selecting an appropriate design optimization method.

Abstract:

The renovation of buildings in urban areas has become an urgent need for public authorities to reduce energy consumption and comply with the Paris Agreement's objectives. The potential for energy consumption reduction through renovation is especially high in old European cities considering that in average 70% of the buildings were built before 1981. This paper presents the work realised within the Charl-e-district project, which addresses the renovation of public buildings through a new approach combining numerical simulations and optimisations. The objective is to develop a tool to help public authorities in decision-making regarding refurbishment of public buildings (measure, intensity, building selection, expected benefits). Firstly, a numerical building model is constructed using OpenStudio/EnergyPlus and calibrated using monitored data. Secondly, renovation scenarios are defined depending on the complexity and costs of implementation. A set of optimizations is then run to determine the values of parameters that will allow the maximum reduction in energy consumption. The novelty of this methodology is the top-down approach, indeed the sets of renovation measures to be investigated are known, the values of the parameters of interest are to be determined. The results are visualised in the METRON platform, with comprehensive modules and user-friendly dashboards that allow dynamic comparisons with monitored data and KPIs for renovation scenarios.

Keywords:

Building Energy Model; Optimisation; Renovation scenarios, Energy monitoring platform.

1. Introduction

The importance of the building stock in the global energy consumption is well-known internationally and the urge to reduce the energy consumption of buildings is commonly shared. To do so, several ways are available: build energy performant buildings, ensure an appropriate maintenance of buildings energy production and distribution systems and renovate existing buildings [1]. On the one hand considering that most of the buildings that will be in use by 2050 are already built and on the other hand considering that in old European cities in average 70% of the buildings were built before 1981 [2], the renovation of existing non-performant building is capital to reach the objectives of energy consumption reduction and CO2 emissions reductions in the building sector [3-5]. The Charl-e-district project consists in evaluating various renovation strategies of public buildings of the city of Charleroi, Belgium, to raise awareness of public authorities regarding their building assets and help in the decision-making process by providing insights regarding the potential and the impact of renovation measures (to improve their energy performance and indoor comfort, to reduce their carbon footprint and operation costs). This paper presents the work carried out within the framework of the Charl-e-district project for the evaluation of renovation scenarios of one public building.

As thermal renovation of buildings is not a new area of research, several methodologies and tools are available to evaluate the renovation potential of buildings. These tools are usually made for a quick estimation of renovation possibilities based on a few characteristics of the energy demand [6-8]. In such tools, the lack of details in the demand evaluation and building thermal characteristics lead to generic solutions. In [9] the authors developed a methodology based on Life Cycle Analysis to find optimal retrofitting solutions to introduce sustainability criteria in the evaluation and provide more insights. Several literature reviews on methodologies for building refurbishment have been carried out, considering different approaches

of classification. Today the common statement highlighted in all the literature reviews is the lack of a common evaluation framework, leading to the assessment of common renovation packages, but various results, interpretation, and considerations. In [10] the authors present a literature review of methodologies to evaluate renovation measures, categorized by building type and renovation packages, showing the difficulties in the decision-making process to pick the appropriate tool or evaluation method. In [11] the authors make a scientific and 'grey' literature review of challenges of the built environment and building renovations and conclude on the wide variety of tools, approaches and methodologies, but underline that there is no holistic or systematic approach to evaluate renovation potentials. Additionally, methodologies for assessment of building renovation measures are usually applied to residential buildings, and by consequence are not directly transferable to tertiary public buildings, because of their different energy behaviours (in terms of energy demand, building usage and potential for energy production). Based on these considerations, a new methodology using a detailed building numerical model and advanced optimisation methods, is developed for public buildings, providing very specific results to help the public authorities in developing their renovation plan at building scale. This methodology using a top-down approach, is developed and applied to a detailed multi-zone numerical building model after it is calibrated with real measured data. Packages of renovation measures are defined in 3 scenarios and the building model parameters related to the renovation measures are optimised with the objective to minimize the gas consumption. The results of the optimisations give the values of parameters of interest that will allow to reach the lowest gas consumption taking into account electricity consumption and thermal comfort constraints, to ensure the satisfaction of occupants needs. Through this top-down methodology, the renovation measures are sized to the studied building in terms of type and intensity of renovation.

2. Building case description

The building studied in this paper is a public school located in Charleroi, Belgium which host 1200 students. This building of 3 130m2 has 3 floors above ground and 2 underground floors. A gas boiler of 240kW supplies heat to the building, which has an annual consumption of approximately 560 633.76kWh of gas and 41 414.99kWh of electricity. As it is a public school and no domestic hot water (DHW) measured data are available, the DHW is not included in the study. The building was built in 1963 and no data were available regarding possible renovations.

3. Methodology for development and calibration of building model

The building iss modelled in two steps, first the 3D geometry along with the neighbouring shading surfaces are created from scratch in SketchUp, as illustrated in Figure 1, based on 2D architect plans and visual checks on the building. Then the building energy model is developed with 31 thermal zones, using the OpenStudio software, and thermal characteristics are added based on technical data, typical values, etc. The EnergyPlus calculation engine is used through the OpenStudio interface to simulate the energy behaviour of the building.

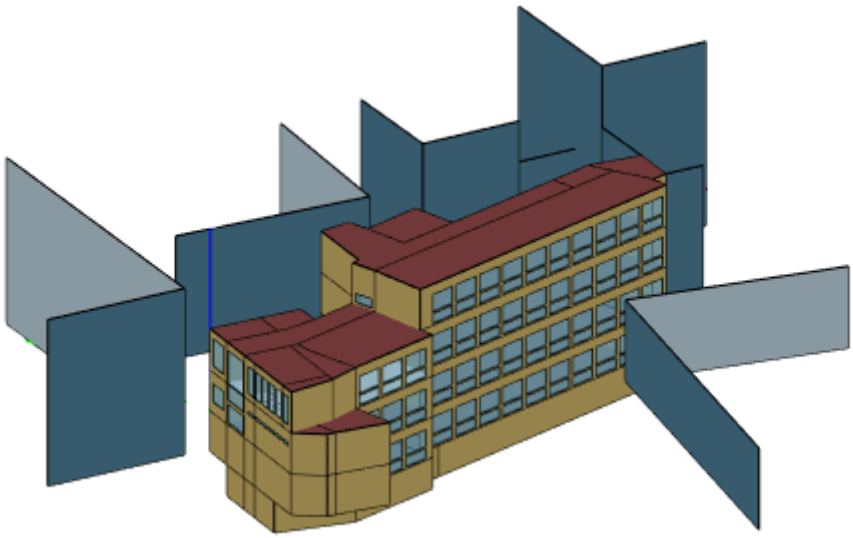

Figure. 1. 3D sketch of the studied building.

In this paper the objective of the study at building scale is to evaluate different renovation scenarios using dynamic Building Energy Simulation (BES). Therefore, the building model must be calibrated to provide relevant results. The building model is manually calibrated based on monitoring data, typically the gas

consumption measured by the gas meter and available through the METRON energy monitoring platform used by the city of Charleroi [12]. Based on previous experience [13] and literature review [14-16], key parameters are chosen, see Table 1, to be adjusted until the model is able to reproduce well enough the energy behaviour of the real building.

Table 1. Building's parameters to be adjusted to calibrate the model.

Type of parameter	Parameters
Building use	Building equipment schedule
	Building occupancy schedule
	Electrical loads
Heat production/distribution	Boiler capacity
	Boiler efficiency
	Heating setpoint temperature
	Pump motor efficiency
	Rated pump head
	Operating temperatures

The quality of the calibrated model is then evaluated by two statistical indices, often used as a pair to analyse the goodness-to-fit of Building Energy Model (BEM) i.e., NMBE (Normalized Mean Bias Error) and Cv(RMSE) (Coefficient of variation of the Root Mean Square Error). The definition of these statistical indices is given by the equations Eq. (1), Eq. (2) and Eq. (3). The NMBE measures the distance between simulated and monitored data, the closer it is to zero, the better the model represents the behaviour of the real building. For a monthly calibration of BEMs, the ASHRAE Guidelines 14-2002 [17] recommend: NMBE < 5% and Cv(RMSE) < 15%.

$$\mathrm{NMBE} = \frac{\frac{1}{N}\sum_i^N (S_i - M_i)}{\bar{M}} \quad (1)$$

$$\bar{M} = \frac{\sum_{i=1}^N M_i}{N} \quad (2)$$

Where:

- M_i is the measured value of i^{th} point
- S_i is simulated value corresponding to the ith point.
- N is the number of measured points

$$\mathrm{Cv}(RMSE) = \frac{1}{\bar{M}}\sqrt{\frac{\sum_i^N (S_i - M_i)^2}{\mathrm{N}}} \quad (3)$$

The results of the calibration evaluations are shown in Table 2, and the model results are illustrated in Figure 2 for the gas consumption and Figure 3 for the electricity consumption. Considering that the energy consumption presents both missing data and important variations from one year to the next one, especially during the covid years, several years of monthly gas and electricity consumption data are used to adjust the model parameters values and evaluate the precision of the model's responses (gas and electricity consumption). The so-called Reference year ("Ref" in this paper) is a virtual monthly profile generated based on the average monthly data available. Both indicators are calculated for 3 years and a reference year. Considering the values of NMBE and Cv(RMSE) correspond to the Guidelines criteria, (values highlighted in Table 2), the model is considered as calibrated.

Table 2. Values of NMBE et Cv(RMSE) indices after calibration using several years of monthly gas and electricity consumption data.

		2019	2020	2021	Ref
Elec	NMBE (%)	**6.77**	23.35	**-16.49**	**-2.41**
	RMSE	569.78	1062.40	810.32	334.40
	CV(RMSE)	16.51	30.78	23.48	**9.69**
Gas	NMBE (%)	**-0.56**	**11.10**	**-10.83**	**-3.71**
	RMSE	5822.09	12056.96	8164.90	3587.85
	CV(RMSE)	**12.46**	25.81	17.48	**7.68**

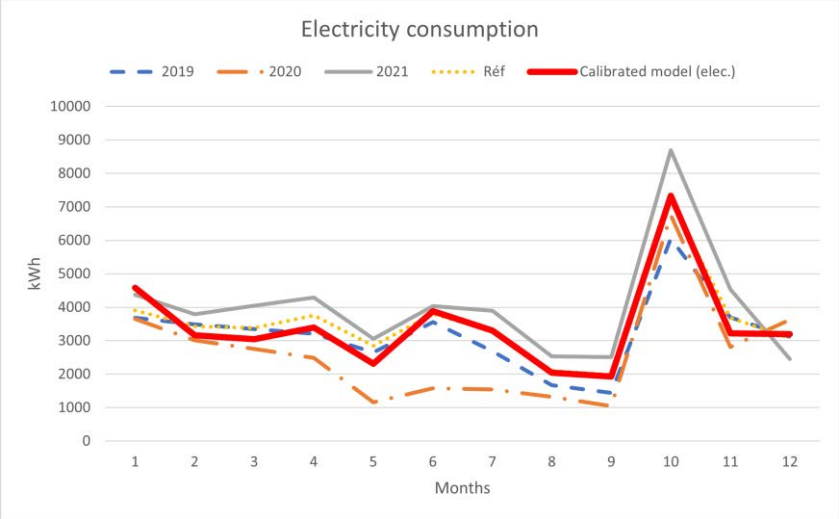

Figure. 3. Comparison between measured data and model results for electricity consumption after calibration.

3. Methodology for renovation scenarios study

The objective of the model calibration is to have a model detailed and reliable to perform renovation scenarios and evaluate the impact of the proposed renovation measures on the model responses (gas and electricity consumption). Different renovation measures are proposed within 3 scenarios, as presented in Table 3, depending on the complexity and costs of implementation. Indeed Scenario 1 (SC1) does not require any renovation works, only an improvement in the regulation of systems, while Scenario 2 (SC2) implies an adjustment of the regulation and deep renovation works, such as adding new material as insulation into walls, roofs and floors of the building. Scenario 3 (SC3) proposes to add the replacement of the gas boiler and pumps to all the previous measures. The model parameters corresponding to the renovation measures are identified with their variation ranges and a set of optimizations is run to optimise the values of these parameters and by doing so, allow the maximum reduction in energy consumption. In SC3, the measures of SC1 are applied except the “Improved boiler regulation measures”, because these regulations are linearly linked to the “Replacement of boiler” measures. To avoid losing in thermal comfort, the ranges of variation of the relative humidity and the temperature in the constraints used in the optimizations are the same as the initial ranges calculated as simulation results in the Base Scenario (Base SC).

Table 3. Description of renovations scenarios.

	Measures	Building parameters in EnergyPlus	Min value	Max value	ref value (Base SC)	Unit
SC1	Setpoint temperatures reduction	Setpoint temperatures	20	24	24	°C
	Improved boiler regulation	Boiler operating temperatures	85	120	110	°C
		Distribution system temperatures (at heat exchangers and radiants)	85	115	110	°C
SC2	SC1 Measures					
	Renovation of insulation	Wall Insulation : Thickness	0.0566	0.25	0.0566	m
		Wall Insulation : Conductivity	0.035	0.05	0.0432	W/(m.K)
		Roof Insulation : Thickness	0.05	0.3	0.05	m
		Roof Insulation : Conductivity	0.035	0.05	0.049	W/(m.K)
		Floor Insulation : Thickness	0.00001	0.3	0.00001	m
		Floor Insulation : Conductivity	0.022	0.04	0.035	W/(m.K)
	Replacement of windows	Thickness	0.003	0.24	0.003	m
		Conductivity	0.0195	0.672	0.0195	W/(m.K)
SC3	SC1 Measures SC2 Measures					
	Replacement of boiler	Nominal Thermal Efficiency	0.55	1	0.55	-
		Water Outlet Upper Temperature Limit	55	120	120	°C
	Replacement of pumps	Rated pump head	7000	17000	7000	Pa

The objective function for all the sets of optimisations is as in Eq. (4)

$$\mathrm{f} = \sum_{i=1}^{N} C_i^{gas} \quad (4)$$

Where C_i^{gas} is the gas consumption of *i*th day over a total number of N days. The constraints considered in all Scenarios are described in equations Eq. (5), Eq. (6) and Eq. (7). These constraints are related to electricity consumption (to avoid that the model compensates the reduction of heat gains by extra electricity consumption of appliances) and to thermal comfort of occupants (in terms of humidity and temperature).

$$C_{SC}^{Elec} \leq C_{Base\ SC}^{Elec} \times a \quad (5)$$

$$15\% < RH < 85\% \quad (6)$$

$$24 < T < 31 \quad (7)$$

Where $C_{Base\ SC}^{Elec}$ and C_{SC}^{Elec} are respectively the annual electricity consumption of the Base Scenario and the current Scenario, a is a coefficient equal to 1.015 (to simulate a slight increase of 1.5%) for Opti and 0.845 for Opti_2 et Opti_3 (to simulate a decrease of 15.5%). RH and T are the relative humidity and the temperature in each thermal zone at each time step. The different sets of optimisations and their related constraints are summarized in Table 4.

To optimise the parameters values in Scenario 3, only one set of optimisations that consider all constraints, is run. Indeed, Scenario 3 considers the same parameters as Scenario 2 plus extra parameters to be optimised. As the optimisation results of Scenario 2 show the importance of all the constraints (including the thermal comfort constraints) to optimise the parameters, it was chosen to run the optimisation for Scenario 3, using only one set of optimisations that consider all constraints.

The optimisations are performed using Cenaero's in-house multi-disciplinary optimization tool, Minamo, which uses a Surrogate Based Optimization (SBO) approach and relies on a genetic algorithm. A brief explanation is given in the following, but for further details about the Minamo tool and the use of SBO optimisation see [18]. The surrogate model used by Minamo for this study is the Tuned RBF model (Tuned Radial Basis Function), for more details about Minamo's surrogate models, see [19-20].

For each scenario, the first step while using the Minamo tool is to generate and evaluate a Design of Experiments (DoE). The DoE is a randomly generating set of points (each point (or individual) represents a set of optimization parameters or variables) sufficiently well distributed in the design space, illustrated by the blue circles on the Figure 4, Figure 5 and Figure7. Based on the evaluation of output results of the DoE, a surrogate model is built, it will allow to evaluate the objective function and constraints at low computational cost. Then the optimisations are run using the surrogate model to determine the optimum values of parameters that minimize the gas consumption (objective function).

Table 4. Constraints for the sets of optimisations of all Scenarios.

	Optimisation set 1		Optimisation set 2		Optimisation set 3	
	ID	Constraints	ID	Constraints	ID	Constraints
SC 1	Opti	$C_{SC}^{Elec} \leq C_{Base\ SC}^{Elec} \times 1.015$	Opti_2	$C_{SC}^{Elec} \leq C_{Base\ SC}^{Elec} \times 0.845$	Opti_cont.	$C_{SC}^{Elec} \leq C_{Base\ SC}^{Elec} \times 0.845$ $15\% < RH < 85\%$ $24 < T < 31$
SC 2	Opti	$C_{SC}^{Elec} \leq C_{Base\ SC}^{Elec} \times 1.015$	Opti_2	$C_{SC}^{Elec} \leq C_{Base\ SC}^{Elec} \times 0.845$	Opti_3	$C_{SC}^{Elec} \leq C_{Base\ SC}^{Elec} \times 0.845$ $15\% < RH < 85\%$ $24 < T < 31$
SC 3	-		-		Opti	$C_{SC}^{Elec} \leq C_{Base\ SC}^{Elec} \times 0.845$ $15\% < RH < 85\%$ $24 < T < 31$

3. Results analysis

Figure 4, Figure 5 and Figure 7 illustrate the set of values for the annual gas consumption after the DoE and different optimisations. Each dot of the graphs represents an experiment, in other words a set of parameters values from which the model responses are calculated. For each set of optimisations, various graphs are generated to interpretate the results, typically the responses and parameters vs the experiments. In the following, only the most relevant graphs are shown.

For Scenario 1, the first set of optimisations (Opti) gives better results than the later ones, in terms of annual gas consumption and at the same time these first optimisations respect the thermal comfort conditions (without imposing them as constraints). When the electricity constraint become stricter (Opti_2) and when comfort constraints are added (Opti_cont.), the gas consumption results from Opti to Opti_cont. increase of around 72% (from 325MWh to 560MWh). That is why the optimum parameters values belong to the first set of optimisations (Opti, orange dots on Figure 4). For Scenario 2, the first and second sets of optimisations give a lower gas consumption than the third set of optimisations, as illustrated by Figure 5, but for these two first sets the maximum comfort temperature constraint is not respected (between 40°C and 47°C) as illustrated by Figure 6, while for the third set of optimisations, the maximum temperature is between 30°C and 32.5°C, which is an acceptable range. For this scenario, the optimum parameters values belong to the Opti_3 set of optimisations. The DoE and optimisation results of Scenario 3 are illustrated by Figure 7. For this scenario, the results from the different runs of experiments converge rapidly to the optimum parameters values (the orange dots reach a value close to 100 000kWh from the 5th experiment).

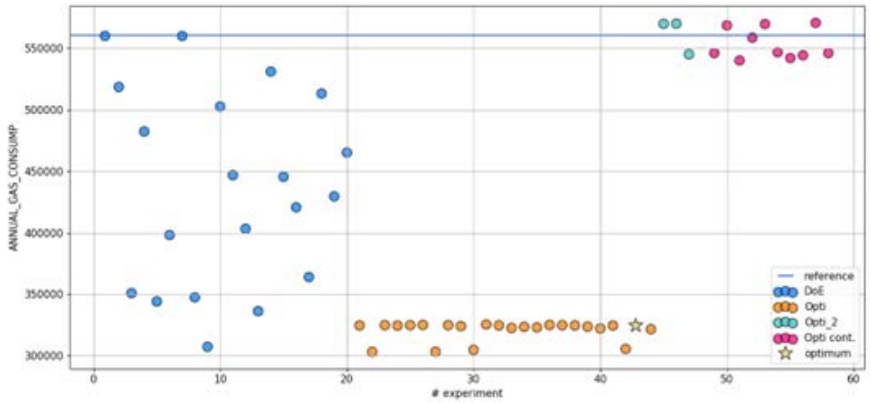

Figure. 4. DoE and optimisations results for Scenario 1.

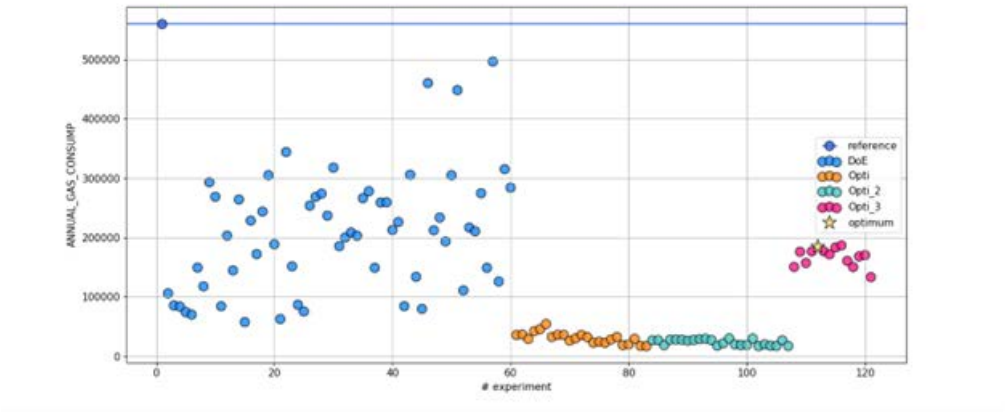

Figure. 5. DoE and optimisations results for Scenario 2.

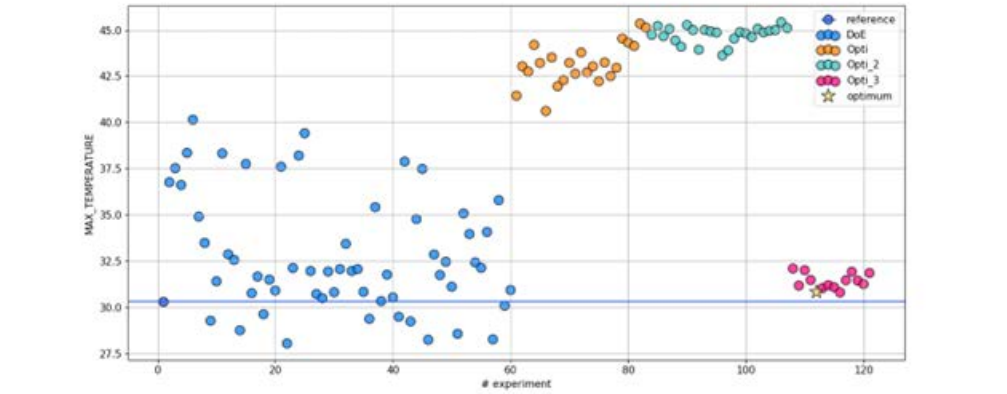

Figure. 6. Evolution of maximum temperature in the building for the DoE and different sets of optimisations for Scenario 2.

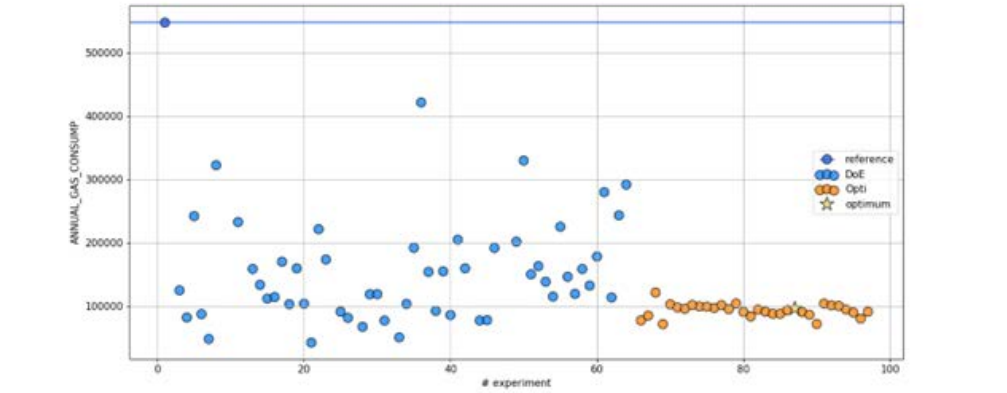

Figure. 7. DoE and optimisations results for Scenario 3.

The optimum values of the evaluated building parameters and the model responses are presented in Table 5 and illustrated by Figure 8. The optimum parameters values for SC1 indicate a reduction of all temperatures except the radiant temperature, while in the other scenarios all temperatures are reduced. For all scenarios, the optimum value of heating setpoint temperature is (or is close to) the lower boundary of the variation range of that parameter (20°C). A variance analysis (ANOVA), based on the decomposition of the variance of a function, [21-22], is carried out after the optimisations and shows that the setpoint temperature is by far (more than 50%) the most influencing parameter for the gas consumption. The results of this ANOVA are not shown in this paper because of the limited number of pages. The optimum values of thickness parameters for SC2 and SC3 are close to the upper boundaries of the variation ranges while the conductivity parameters are chosen by the optimizer around the mid-value of their variation ranges.

Table 5. Optimum values of parameters and model responses for all scenarios.

Parameters	Base SC	SC1	SC2	SC3
SETPOINT_REDUCTION	24	20	20.3	20
SETPOINT_SUPPLY_BOILER	110	104.2	102.7	-

MAXIMUM_TEMPERATURE (°C)	31.00	29.65	30.87	30.91

SC3 which proposes a replacement of the boiler, gives an optimum efficiency value of 1, which is relevant for the installation of a condensing boiler (this type of boilers generally presents efficiencies around 110%). The optimum values for rated pumps heads are surprisingly low considering the initial variation range, which would basically mean that there is no need to replace the pumps because the other measures are sufficient to decrease the total heat demand and the operating boiler temperatures, and consequently the gas consumption (objective function).

When analysing the simulation results for the optimum parameter values, one can clearly notice the decrease in gas consumption from one scenario to another. Indeed, in SC1 the annual gas consumption decreases of 42% compared to the Base SC, while this decrease is steeper in SC2 (-67%) and SC3 (-83%). As the electricity consumption is not part of the objective function for the optimisation, but part of a constraint, the reduction of electricity consumption is noticeable but not very different between the scenarios, it ranges between -17% for SC3 to -19% for SC2 compared to the Base SC. From SC1 to SC3, the maximum and minimum relative humidities are closer to the constraints limits, but tend to get respectively lower and higher than their maximum and minimum limits. The maximum and minimum temperatures are respectively around 4°C lower and 0.5°C lower than Base SC. The results from the simulations of the building model with the optimum values give maximum and minimum temperatures very close between all the scenarios (around 30°C and 20°C).

The results from the simulation runs with the optimum parameters values are pushed into the METRON energy platform database and visible through various comprehensive modules, named widgets, and user-friendly dashboards developed in the platform itself. The objective is to allow users, here public authorities, to visualize quickly the indicators calculated for each scenario and compare the KPIs of the different scenarios with monitored data, in order to understand better the current situation and the renovation potential and possibilities. The simplicity of the visualisation that allows dynamic comparisons together with the corresponding database if further analyses are required, give to this approach a powerful weight in decision-making processes. Examples of widgets are given by Figure 9 and Figure 10 to compare the scenarios in terms of monthly gas consumption, CO2 emission reductions and evolution of temperature throughout the year in one typical thermal zone (classroom) of the building. Other widgets are available on the platform, to visualise KPIs such as savings in gas consumption (economic indicator) or humidity heatmaps (thermal comfort indicator).

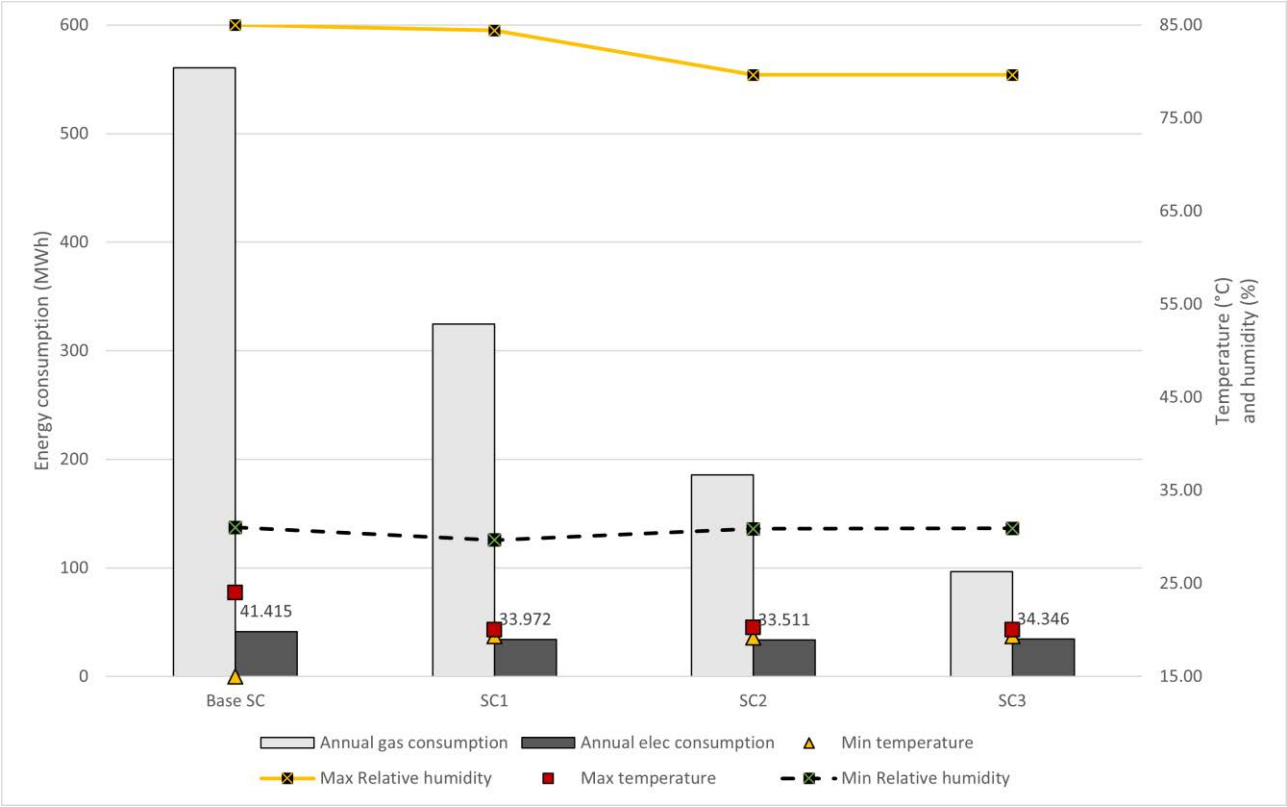

Figure. 8. Simulation results from optimum values of parameters for all Scenarios.

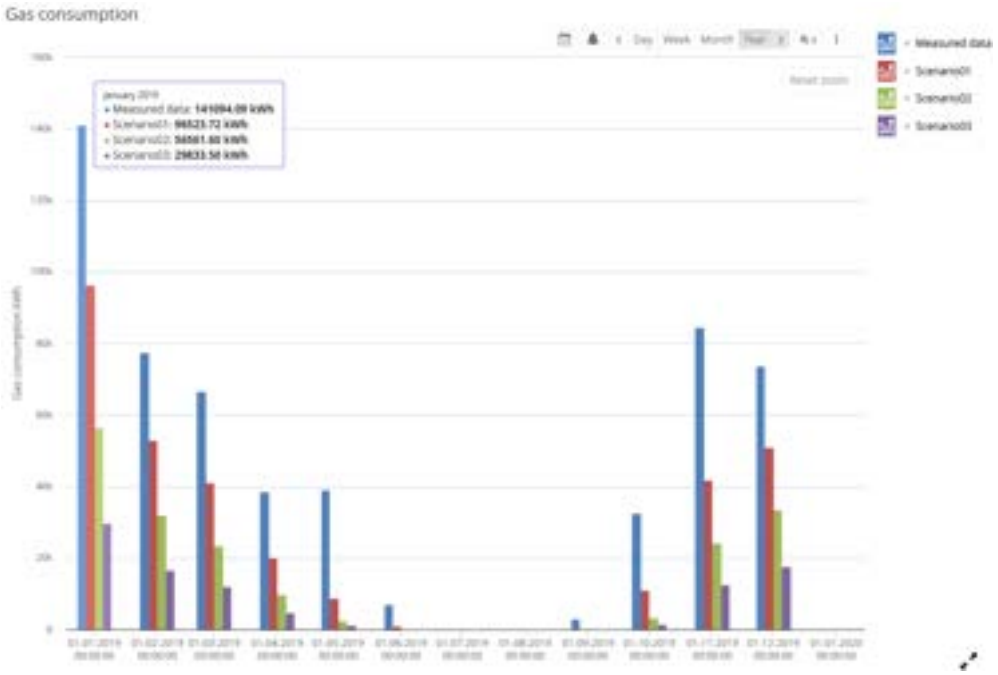

Figure. 9. Histogram widget in the METRON energy platform. Comparison of gas consumption between the measured data and the different results from optimum scenarios.

Figure. 10. Gauges widgets in the METRON energy platform. Comparison of CO2 emission reductions and temperature heatmaps in one typical thermal zone (classroom) between the different results from optimum scenarios.

3. Discussions and perspectives

To be useful and relevant, the results of the optimisations must be taken with hindsight. The optimum parameters are identified through advanced calculations and correspond to perfectly optimised systems. SC1 proposes the easiest measures to implement, because they do not require any work, only a new setup of the building setpoint temperature and a new setup of the regulation. Considering the uncertainties due to the assumptions made in the modelling (geometrical and technical assumptions) and the calibration steps (interpolation of measurements), one should expect some differences between the model results and the real gas consumption if the new setups are tested, however this scenario is in any case recommended for implementation insofar as it results in more than one third of gas consumption reduction compared to the Base SC. It is important to note that the renovation measures resulting from SC2 and SC3, correspond to deep renovation in real-life implementation (improvement of insulation, replacement of windows, boiler and pumps, etc.) and are implemented at building scale (all the walls are renovated, all the windows are replaced, etc.), which explains why the reduction of gas consumption decreases drastically for each scenario, to reach -83% with SC3 compared to the Base SC. In real-life implementation, such deep renovation is extremely costly and it is most probable that the renovation measures regarding the improvement of insulation would not be made for all building's walls, but only on the less exposed façades and the walls that present the most heat losses. For a more complete renovation study, it would be interesting to precise the renovation scenarios with measures that would consider partial building envelop renovation and evaluate the potential and interest of implementation of greener solutions, such as air-sourced heat pumps or the connection to the local district heating network. Further exploitation of results through economic analyses would also be an added value to help public authorities in the decision-making process.

4. Conclusions

This paper presents a new top-down approach to evaluate various renovation strategy, in terms of type and intensity of renovation measures, for a public building of the city of Charleroi, Belgium. In a first step, a numerical building model is developed and calibrated based on real gas consumption measurements, before being studied through 3 renovation scenarios for which the main parameters related to the renovation measures are optimised using a Surrogate Based Optimisation approach. The optimisations are carried out using Minamo, the Cenaero's in-house multi-disciplinary optimisation tool. The results of different optimisations of the parameters within the studied scenarios give combinations of values that ensure in general the same quality of thermal comfort (indoor temperature and humidity) and lead to similar results in terms of electricity consumption. The main difference in the scenarios results lies in the gas consumption reduction, which varies greatly from one scenario to another. Considering the investment costs and the complexity of implementation of the measures proposed in the scenarios (increasing from SC1 to SC3), the public authorities would have to consider other indicators such as investment costs, payback time, energy savings over time, urgency to reach objectives of CO2 emission reductions, etc. to choose a renovation strategy and how deep they want to implement the different measures.

A follow-up study is being carried out at district level, to evaluate the benefits of the connection of public buildings to the district heating network, with scenarios varying in terms of buildings number and renovation levels of connected buildings. The work detailed in this paper will serve as input to the district approach to facilitate the definition of building typologies and calibrate a district model using an Urban Building Energy Modelling (UBEM) tool. The objective is again to help the public authorities in decision-making regarding the

interests of renovation of public buildings together with / or the extension of the existing district heating network.

Abstract:
This paper presents a method to find the optimal topology, pipe sizing, and operational parameters of a district heating system under consideration of one design point. The current high costs of district heating systems set limits regarding the minimum heat demand density required for economic network expansions. Optimized routing with ideal pipe sizing and optimal operating parameters offers a potential for cost reduction. With a lower network temperature, the consideration of nonlinear transport phenomena within the district heating network becomes increasingly important. Therefore, a new nonlinear optimization method is introduced, where graph preprocessing reduces the computational effort of the subsequent nonlinear optimization. A cost penalization method, using a smooth approximation of a Heaviside function is applied to pipe investment costs to account for discrete piping diameters. To guarantee fast convergence of the optimization algorithm, the Jacobian matrixes are calculated and the problem is solved with an interior point algorithm. As a proof of concept, the district heating system for a small fictional town with 42 consumers is optimized and analyzed. The whole nonlinear optimization is performed in 19.37 sec and in most cases discrete or near discrete diameters are achieved in a nonlinear continuous optimization.

Keywords:
Energy System, District Heating, Nonlinear Optimization, Topology Optimization.

1. Introduction

District heating systems can play a key role in a socially accepted, economic transformation towards a renewable energy system due to numerous advantages over a building-specific heat supply [1]. Currently, the high total costs of district heating systems usually require a high heat demand density for economic network expansions [2], as until recently there was very strong competition in the form of cheap individual heating from oil and gas. In addition, long amortization periods frequently prevent expansions from being economically feasible without subsidies. One possibility to reduce investment costs of district heating networks is a detailed nonlinear topology optimization, allowing optimized routing with ideal pipe sizing, as well as optimized operating parameters. Especially in less urbanized or rural areas, an untapped potential of environmentally friendly heat supply could be exploited [3]. In urban areas, [4] shows that an integration of industrial waste heat into district heating systems could further improve the potential of these systems. In the next section, different optimization techniques for district heating systems are explained in the following order: Mixed-integer linear programming (MILP), mixed-integer nonlinear programming (MINLP), heuristics, and adjoint-based optimization.

The discrete nature of network expansions and commercially available pipe diameters often leads to a mixed-integer programming formulation. [5] shows that most publications on district heating topology optimization are using MILP. In [6], mixed-integer linear programming is used to solve this structural optimization for a district cooling system. In [7], a similar MILP approach is used to perform a topology optimization of a single-commodity flow network. The optimization is reduced to a power flow in the network, neglecting e.g. mixing effects at junctions. Pressure dependencies are omitted. Different supply technologies, operational parameters and network topology are optimized in [8]. Heat losses are considered by calculating the enthalpy loss in a pipe with an average heat loss per unit length and pipe. Pressure losses in pipes were considered by linearizing the Haaland equation. Similar MILP formulations can be found in [9, 10]. In [11], a method is presented to create network topologies based on Geographic Information System data. In a second step, pressure losses are estimated in the network at the heat demand's peak load, and the pipe diameters are sized accordingly. [12] improved the method presented in [7] by calculating a maximal linear power flow with the help of a linearization based on a specific pressure loss and commercially available pipe diameters. [13] further improves on [12] by reducing the number of binary variables used in the optimization problem formulation. However, all these methods are not able to depict the nonlinear effects of district heating networks. Flow patterns in systems with

multiple spatial distributed producers, mixing temperatures at junctions or loops, can hardly be linearized while respecting the physical interrelations.

To combat these problems, mixed-integer nonlinear programming is used more frequently in recent publications. In [14], an MINLP is proposed to solve an operational-based optimal scheduling strategy to minimize the daily operational cost of an energy station with a heating and cooling demand, as well as storage. However, the distribution of the heat by a district heating network is neglected. The commercial MINLP solver DICOPT within GAMS is used in [15] to solve a nonlinear and discrete representation of a steady-state district heating system. In [16], the same method is used in a small-scale district heating system with 19 consumers. Moreover, the nonlinear effects of energy, as well as momentum conservation, are considered and solved with commercial solvers in [17, 18]. However, due to the nonlinear equations and the discrete nature of some variables, these methods are limited to a few consumers. [19] shows, solving the full MINLP leads to an exponential scaling of computational costs with network size during the discrete topology optimization.

Another method for solving district heating optimization problems is the use of heuristic optimization approaches. These procedures may provide a sufficiently good solution to an optimization problem while not always guaranteeing a local or global optimum. This becomes especially difficult with scaling dimensions of the problem. A commonly used heuristic approach are nature-inspired algorithms like the ant colony optimization or the genetic algorithm. In [20], the ant colony optimization was used to minimize fuel consumption while modelling a nonlinear gas flow. A parallel ant colony system algorithm is used in [21] to find a cost-optimal route between one producer and one consumer while neglecting the nonlinear effects of pressure or temperature dependencies, only considering investment costs of piping influenced by the surface condition. Similar in [22], the genetic algorithm is used to optimize a single long-distance heat transport system considering hydraulic and thermal nonlinear aspects. The genetic algorithm is used in [18] to optimize the district heating network topology and pipe diameters of a small network with ten heat consumers. Meanwhile, in [23], a hybrid strategy with a genetic algorithm and MILP is used to minimize the fuel costs of different heat producers. In [24], a methodology focusing on the optimal sizing of pipe diameters using a genetic algorithm to generate a set of Pareto-optimal sizing choices is presented.

The last presented optimization method is adjoint optimization. In [25], the adjoint method is used to optimize robust hydraulic district heating systems while neglecting thermal aspects within the network. Another adjoint method is presented in [26] that optimizes simultaneously the district heating topology and operational parameters of a district heating system. The method is further expanded in [27] and applied to a district of 160 consumers. The discrete optimization problem is transformed into a continuous optimization problem by using Heaviside functions. Moreover, constraint aggregation is used to increase the performance of the optimization procedure. In [28], the method of [27] is further developed by introducing a solid isotropic material with a penalization approach to reach discrete diameters.

2. Methodology

In this paper, the considered heat carrier medium is water at 60 °C. It is assumed to be liquid and therefore incompressible. Additionally, by assuming temperature changes smaller than $\Delta T = 40\,^{\circ}\mathrm{C}$, temperature dependencies of the fluid properties (e.g. density ρ, heat capacity c_p and dynamic viscosity μ) can be neglected. Moreover, this reduces the dependencies between the thermal and hydraulic parts of the optimization. During the nonlinear topology optimization of the district heating system, the following two main challenges occur:

- The formulation of equations in dependence of potential pipe connection (e.g. pressure or thermal losses in a pipe)
- The direction of the flow in pipes (e.g. mixing temperature in a node)

Therefore, a new preprocessing method is proposed to solve and improve the problems mentioned above. First, a linear thermal power flow optimization is performed on the district heating topology to determine flows through the network, eliminate unnecessary piping connections, and reduce the available choice of discrete piping diameters. Afterward, a detailed nonlinear optimization is performed on the preprocessed district heating system. In this optimization the nonlinear pressure and temperature drops as well as discrete diameters are determined, thus giving a far more realistic depiction of the network. First, in section 3. the graph representation of a district heating system is introduced. In section 4., the preprocessing method is explained, while the nonlinear optimization model is introduced in section 5.. Finally, in section 6. the results for a small district heating system of 42 consumers are shown and in section 7. a conclusion is drawn.

3. Representing a District Heating System as a Graph

To represent pipes, junctions, producers, or consumers mathematically a graph representation of a district heating system has to be introduced. The pipes of the district heating systems correspond to the arcs of the graph and the network's junctions to the nodes. The district heating network consists of a feed and return network which have arcs of opposite directions. This superstructure contains all possible connections and pathways from the heat source to the consumers. The set of all nodes N can be subdivided into three diffident subsets:

$$N_{int} \cup N_p \cup N_c = N \tag{1}$$

In Equation 1, *int* refers to all nodes without a consumer or a producer. The subscript p describes all nodes with a connection to at least one producer and the subscript c all nodes with a connection to at least one consumer. Similarly, A_{int} represents the geometrical pipe connection between two different internal nodes. A_p and A_c denote the state transition between the district heating system and a producer or a consumer. The set A representing all arcs of the network is given by:

$$A_{int} \cup A_p \cup A_c = A \tag{2}$$

A certain node of the network will be referred to as n, whereas a directed arc going from node i to node j as $ij \in A$.

4. Linear District Heating Model

In order to linearize the maximal power flow in a district heating pipe with length l, the maximal mass flow m with the corresponding velocities v of each considered piping diameter d has to be determined. First, the Bernoulli equation with a head loss Δh_f is used to calculate the pressure loss between two nodes i and j with equal height connected by a pipe:

$$\frac{p_i}{\rho} + \frac{v_i^2}{2} = \frac{p_j}{\rho} + \frac{v_j^2}{2} + \Delta h_f \tag{3}$$

The head loss Δh_f is calculated according to Darcy-Weisbach:

$$\Delta h_f = f_{ij} \cdot \frac{l_{ij}}{d_{ij}} \cdot \frac{v_{ij}^2}{2} \tag{4}$$

The Reynolds number Re is calculated as:

$$Re_{ij} = \frac{\rho \cdot v_{ij} \cdot d_{ij}}{\mu} \tag{5}$$

For Reynolds numbers $Re < 2320$ the friction factor f_{ij} is calculated by:

$$f_{ij} = \frac{64}{Re_{ij}} \tag{6}$$

The friction factor f_{ij} for $Re \geq 2320$ is given by the Haaland equation with the pipe roughness ε: [29]

$$f_{ij} = \left[-1.8 \cdot \log\left(\left(\frac{\varepsilon}{3.7 \cdot d_{ij}} \right)^{1.11} + \frac{6.9}{Re_{ij}} \right) \right]^{-2} \tag{7}$$

According to [30], the specific pressure drop per meter pipe length should range from 70 Pa/m to 350 Pa/m. In this study, a maximum specific pressure drop Δp_{max} of 250 Pa/m is assumed for the optimization. An iterative calculation is used to determine the maximal velocity in a pipe with a given inner diameter. Starting at an initial velocity of 0.01 m/s, the following equation is iterated until the relative difference of v between two consecutive steps is smaller than 10^{-6}:

$$v_{i+1} = \sqrt{\frac{2 \cdot \Delta p_{max} \cdot d}{f \cdot \rho}} \tag{8}$$

Finally, the maximal thermal power flow $\dot{Q}_{max}$ is calculated with the corresponding inner diameter and the feed and return line temperature. Next, the thermal aspect of an insulated pipe buried underground is considered. Therefore, the temperature difference Θ between the water temperature in the pipe T and the outside temperature T_∞ is introduced. In this study, T_∞ is set to 0 °C. The exit temperature Θ_{ij} of a pipe segment ij due to heat loss to its environment with an entry temperature Θ_i of the corresponding node is given by:

$$\Theta_{ij} = \Theta_i \cdot \exp\left(\frac{-l_{ij}}{c_p \cdot \dot{m}_{ij} \cdot R_{ij}}\right) \tag{9}$$

The combined thermal resistance of pipe and soil per unit length is calculated with the ratio r between outer and inner diameter: [27]

$$R_{ij} = \frac{\ln 4h/rd_{ij}}{2\pi\lambda_g} + \frac{\ln r}{2\pi\lambda_{insul}} \tag{10}$$

The ratio r in Equation 10 is determined with the actual inner diameter and the insulation thickness 1 based on [31]. After the hydraulic and thermal calculations, a linear regression of the investment costs and the thermal losses per trench length, using SciPy [32], is performed and shown in Figure 1. The total investment costs for piping are adapted from [2]. In this study, pipes ranging from DN20 to DN400 are considered.

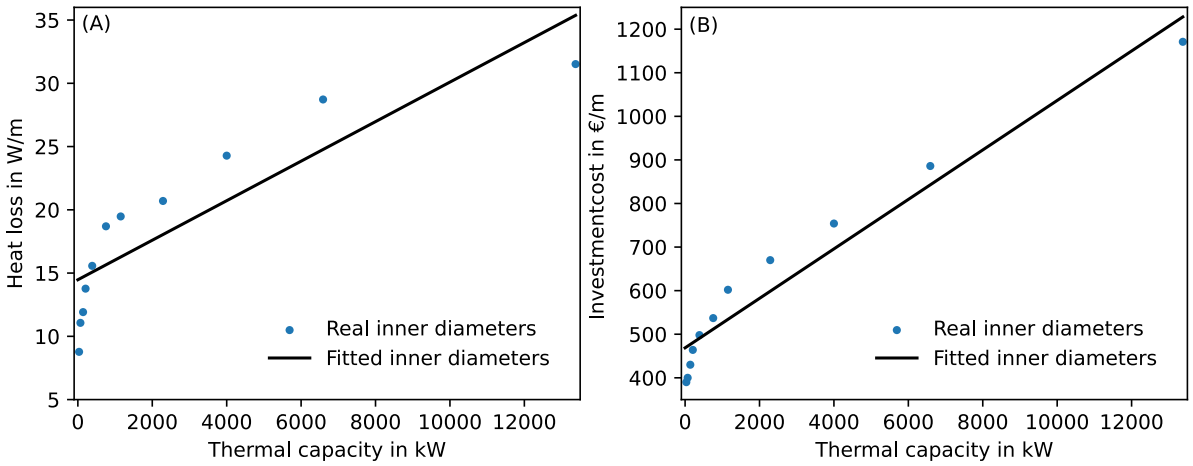

Figure 1: Optimization parameters of the district heating pipelines; (A) Thermal losses of the district heating pipes per trench length. (B) Costs of the district heating pipes per trench length.

.

Based on [7, 12], a mixed-integer linear programming model is introduced to calculate the optimal power flow through the district heating network, determine flow directions, and omit unnecessary connections. Therefore, a bi-directional pipe model is built. The thermal power input and output of every pipe are modelled according to the directed graph of the network. In order to allow flows in the opposite direction, every potential pipe ij is also modelled in the direction ji. The use of a pipe in a unique direction is assured by the objective function (see Equation 16). For simplicity, only the equations for pipes in the direction ij are provided. The heat outflow $\dot{Q}_{out}$ of each pipe results from the inflow $\dot{Q}_{in}$ minus the thermal loss $\dot{Q}_{loss}$:

$$\dot{Q}_{ij,in} - \dot{Q}_{ij,out} - \dot{Q}_{ij,loss} = 0 \tag{11}$$

$$\dot{Q}_{ij,in} \leq \dot{Q}_{max,cons} \cdot \lambda_{ij} \tag{12}$$

$$\dot{Q}_{ij,in} \leq \dot{Q}_{max} \tag{13}$$

In Equation 12, the binary variable λ_{ij} shows the usage of a potential pipe. Moreover, $\dot{Q}_{max,cons}$ can be seen as a Big-M-constraint, enforcing zero thermal flow if the direction ij of the pipe is not used. Meanwhile, in

Equation 13 the actual maximal thermal capacity $\dot{Q}_{max}$ is determined. This value is independent of the flow direction (*ij* or *ji*). The thermal losses are determined by the linear regression factor a_{therm} and b_{therm}:

$$\dot{Q}_{ij,loss} = \left(a_{therm} \cdot \dot{Q}_{ij,in} + b_{therm} \cdot \lambda ij\right) \cdot l_{ij} \tag{14}$$

Each connection of a consumer to the district heating grid is modelled unidirectional, and thus no heat feed-in from a consumer is possible. Moreover, energy conservation is assumed in every node under consideration of the consumer's heat demand and the heat source's feed-in:

$$\sum_{ij \in A_i} \dot{Q}_{ij} - \sum_{ji \in A_i} \dot{Q}_{ji} - \sum_{c \in A_c} \dot{Q}_c + \sum_{p \in A_p} \dot{Q}_p = 0 \tag{15}$$

Finally, the objective function aims to minimize the total investment costs of the district heating network under a set of given consumers which need to be connected to the grid. As every consumer's connection to the grid is mandatory, the investment costs in the objective function are not distributed over the depreciation period and no operational costs are considered. The investment costs are determined by the linear regression factors a_{cost} and b_{cost} from Figure 1:

$$min\left\{ \sum_{A_i} \left(a_{cost} \cdot \dot{Q}_{max} + b_{cost} \cdot (\lambda_{ij} + \lambda_{ji})\right) \cdot l_{ij} \right\} \tag{16}$$

The corresponding pipe diameter to the maximal heat flow $\dot{Q}_{max}$ can be calculated with fsolve from [32] with Equation 8. The initially assumed flow direction in the graph can be corrected according to λ_{ij} and λ_{ji}:

- $\lambda_{ij} = 0$ and $\lambda_{ji} = 0$: The pipe is not used and can be deleted from the graph.
- $\lambda_{ij} = 1$ and $\lambda_{ji} = 0$: The assumed flow direction in the graph is correct.
- $\lambda_{ij} = 0$ and $\lambda_{ji} = 1$: The flow direction in the graph is the opposite of the assumed one and needs to be corrected.

The linear diameter *d* and the corrected graph can be used to facilitate and speed up the nonlinear topology optimization, described in section 5.. Here, based on the linear diameter, determined by the preprocessing method, the choice of the available diameter is limited to the next and the following larger one.

5. Nonlinear District Heating Model

To account for more complex influences, such as mixing temperatures or pressure drops, a nonlinear transport model has to be developed. First, a nonlinear model for district heating pipes is presented. Subsequently, nonlinear models for consumers and heat sources are introduced. Finally, the objective functions and the pipe discretization method used are shown.

5.1. Transport Model

Similar to section 4., the pressure loss through any given pipe in the network has to be determined. By using the Haaland equation (see Equation 7) during the pressure loss calculations, the flow in the pipes is assumed to be turbulent. This flow regime is desired in a district heating network, to ensure a well-defined and continuous flow through the pipes. When Equation 3-5 are combined and the velocities converted to mass flows ($m_{ij} = (v_{ij} \cdot \pi \cdot d_{ij}^2)/(4 \cdot \rho)$), the pressure loss can be calculated as:

$$p_i - p_j = \frac{8 \cdot f_{ij}}{\pi^2 \cdot \rho} \cdot \frac{l_{ij}}{d_{ij}^5} \cdot \dot{m}_{ij}^2 \tag{17}$$

Analogical to section 4., a maximal specific pressure drop Δp_{max} in a pipe *ij* is imposed:

$$p_i - p_j \leq l_{ij} \cdot \Delta p_{max} \tag{18}$$

In each node *i* mass conservation must be fulfilled:

$$\sum_{ij \in A_i} \dot{m}_{ij} - \sum_{ji \in A_i} \dot{m}_{ji} - \sum_{c \in A_c} \dot{m}_c + \sum_{p \in A_p} \dot{m}_p = 0 \tag{19}$$

Moreover, inside a node of the district heating system, perfect mixing of the incoming fluids is assumed. All outgoing flows depart from the node with the corresponding node temperature Θ_n and energy is conserved in every node of the system:

$$\sum_{in \in A} \left(\dot{m}_{in} \cdot \Theta_{ij} \right) - \sum_{nj \in A} \left(\dot{m}_{nj} \cdot \Theta_n \right) = 0 \tag{20}$$

Heat losses are calculated analogously to section 4.. Only in Equation 10 a fixed ratio $d_{o,ij} = r \cdot d_{ij}$ between the outer and inner diameter of a pipe is assumed. In this study, r is set to 4.

5.2. Producer Model

At the producer, a fixed exit temperature of 90 °C is imposed as a boundary condition for the district heating system. In addition, a reference pressure is defined in one of the producer's return nodes to define the pressure throughout the network. As only pressure differences influence the mass flow solution, the solution is independent of the chosen reference. In Equation 21-22 *flh* refers to full load hours of the district heating network. In this study, the district heating network is assumed to have 2500 full load hours [33]. To consider pumping costs C_{pump} during the optimization, the electric power consumption of the pump is modelled with a constant efficiency η_{pump} and the specific electric power costs c_{el}:

$$C_{pump} = \frac{\dot{m}_p}{\rho} \cdot \frac{1}{\eta_{pump}} \cdot (p_i - p_j) \cdot flh \cdot c_{el} \tag{21}$$

Moreover, the optimization has to be able to benchmark different heat producers against each other. Therefore, the fuel costs C_{fuel} at each producer with the specific fuel costs c_{fuel} are considered:

$$C_{fuel} = \dot{m}_p \cdot c_{p,water} \cdot (\Theta_p - \Theta_i) \cdot flh \cdot c_{fuel} \tag{22}$$

5.3. Consumer Model

In the nonlinear optimization, every consumer is modelled with an individual substation. Each substation is composed of a heat exchanger and a throttle. This throttling configuration, shown in Figure 2, allows a variable mass flow in the district heating's and the consumer's circuit to control the heat transferred to the consumer, as well as low return flow temperatures with low flow velocities during partial load [31].

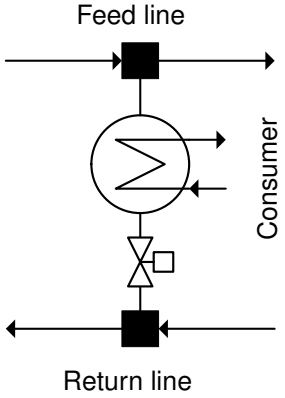

Figure 2: Configuration of a consumer substation in the district heating system.

The pressure drop over a consumer c which connects node f in the feed line and node r in the return line is assumed to be of the following form:

$$p_f - p_r - p_{throttle} = \Delta p_{des} \tag{23}$$

In this study, the design pressure drop Δp_{des} over each substation is set to 0.5 bar. To increase the numerical stability of the optimization, the heat demand of every consumer connected to the grid must be satisfied within a range of 95 % to 110 %:

$$0.95 \cdot \dot{Q}_c \leq c_{p,water} \cdot \dot{m}_c \cdot (\Theta_f - \Theta_c) \leq 1.10 \cdot \dot{Q}_c \tag{24}$$

Here, the minimal cooling temperature Θ_c at the exit of each substation is set to 55 °C.

5.4. Pipe Discretization

Thus far, the presented algorithm still allows continuous diameters. In order to perform a more realistic topology optimization, the algorithm should be able to do discrete choices in a continuous optimization. Therefore, based on [27], a numerical continuation strategy that gradually forces the continuous diameter variables into discrete diameter choices is introduced. A smoothed projection of the diameters onto the discrete diameter set is gradually enforced and intermediate diameters are more and more penalized through the piping cost relation (see subsection 5.5.). For the projection of the diameters on the discrete diameter set, a smooth approximation of a Heaviside function is used: [27]

$$P(x, \sigma, \chi) = \frac{tanh(\chi \cdot \sigma) + tanh(\chi \cdot (x - \sigma))}{tanh(\chi \cdot \sigma) + tanh(\chi \cdot (1 - \sigma))} \tag{25}$$

In Equation 25 the continuous decision variable $x \in [0, 1]$ is gradually projected onto a binary decision variable $\tilde{x} \in \{0, 1\}$. The variable $\chi \in]0, \infty[$ controls the steepness of the Heaviside approximation, while $\sigma \in [0, 1]$ determines the threshold above which the variable x is projected onto the upper limit [27]. To account for the gradient-based optimization and to improve the stability of the optimization, the projection P is interpolated with a linear function, controlled by the factor ν: [27]

$$-10^{-3} \leq \nu \cdot \left(d_1 + (d_2 - d_1) \cdot P\left(\frac{d - d_1}{d_2 - d_1}, 0.01, \chi \right) \right) + (1 - \nu) \cdot d \leq 10^{-3} \tag{26}$$

In Figure 3 different parameterizations for χ and ν of Equation 26 are shown with $d_1 = 0.1603\,\text{m}$ and $d_2 = 0.2101\,\text{m}$.

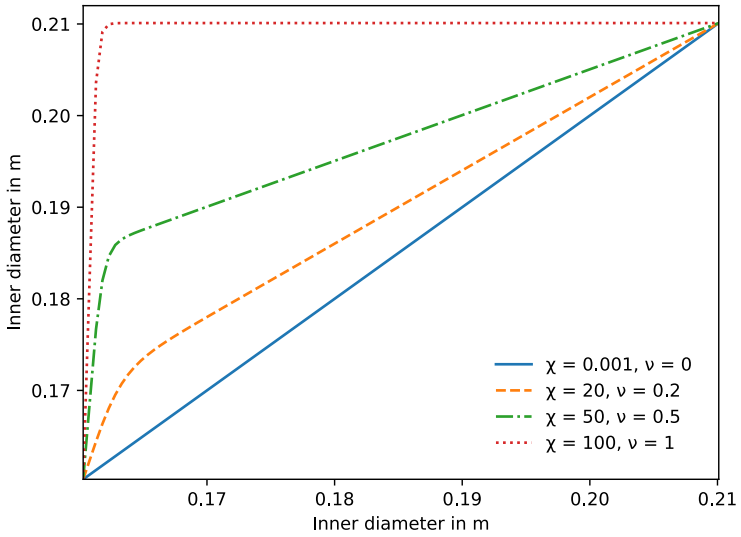

Figure 3: Function for pipe discretization for different values of χ and ν with $d_1 = 0.1603\,\text{m}$ and $d_2 = 0.2101\,\text{m}$

.

5.5. Objective Function

Similar to the pipe discretization method, the smooth approximation of a Heaviside function (see Equation 25) is used to penalize intermediate piping diameters during the optimization. To improve stability and to account for the gradient-based optimization, the projection is also interpolated with a linear function, controlled by the parameter ν. The investment costs for district heating pipes in the feed and return line C_{pipe}, connecting node i and j, are given by:

$$C_{pipe} = \left[\nu \cdot \left(c_1 + (c_2 - c_1) \cdot P\left(\frac{d - d_1}{d_2 - d_1}, 0.5, \chi \right) \right) + (1 - \nu) \cdot \left(c_1 + (c_2 - c_1) \cdot \frac{d - d_1}{d_2 - d_1} \right) \right] \cdot l_{ij} \cdot 2 \cdot A \tag{27}$$

In Equation 27, investment costs are distributed over the depreciation period n, using the annuity method. Without discounting, the annuity A is calculated with an interest rate i:

$$A = \frac{(1 + i)^n \cdot i}{(1 + i)^n - 1} \tag{28}$$

After [34], the depreciation period is set to 20 years and the interest rate i to 0.08. The objective function is formed by combining Equation 21, 22, and 27 and thus minimizing investment and operational costs. In Figure 4, different parameterizations of χ and ν for the investment costs of pipes are shown.

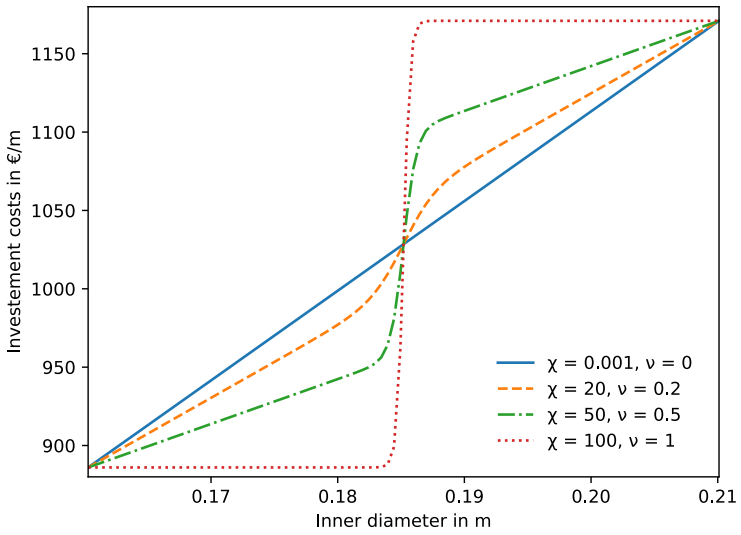

Figure 4: Heavyside projection of pipe investment cost for $d_1 = 0.1603\,\text{m}$ and $d_2 = 0.2101\,\text{m}$ with different values of χ and ν.

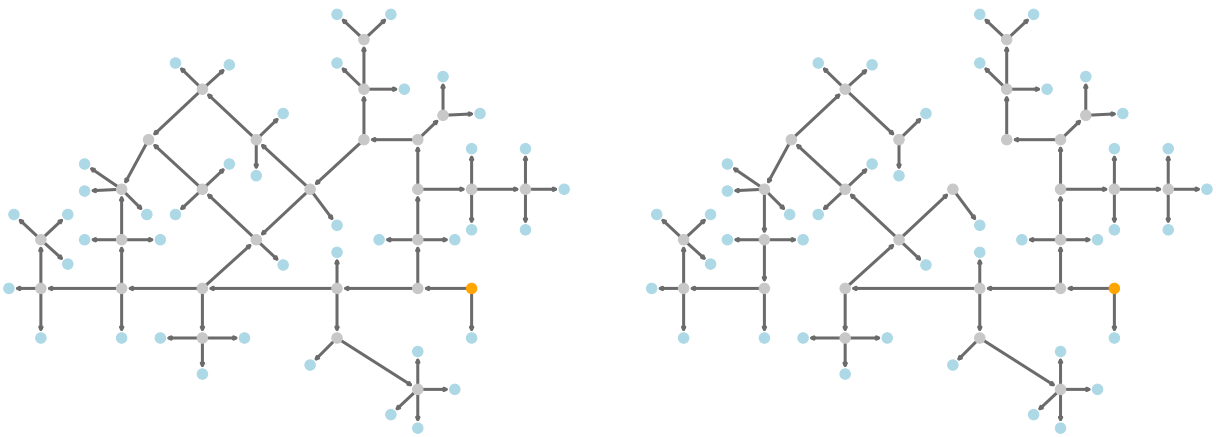
6. Example

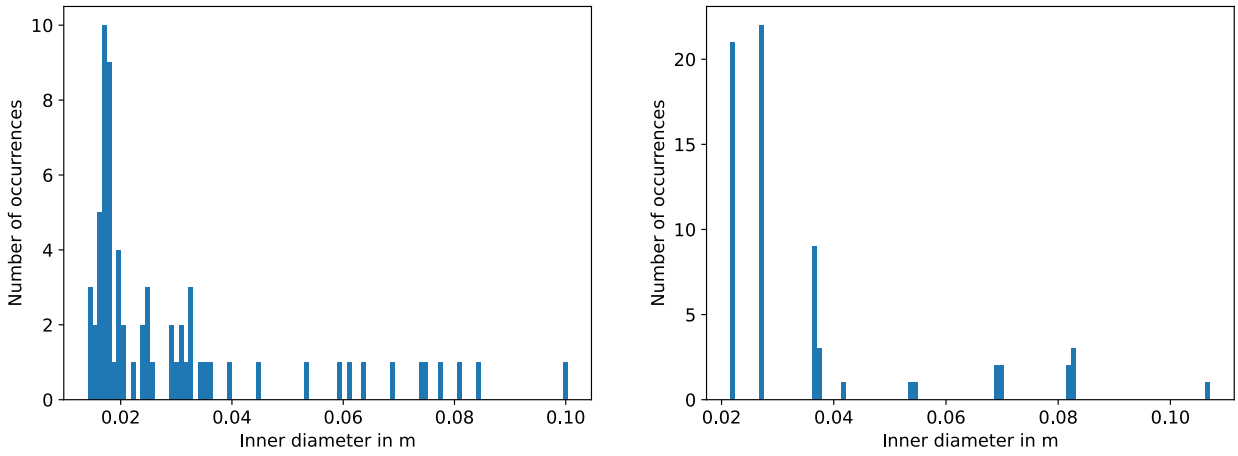
The linear optimization is solved with Cplex 12.10.0 [35] using Pyomo [36, 37]. The nonlinear optimization is formulated with pyoptsparse [38] and solved with the interior point optimizer Ipopt [39]. An exemplary district heating system with 42 consumers is used to demonstrate the presented method. As every connection of a consumer to the grid is mandatory, independent of its economic efficiency, the preprocessing algorithm can only find the most favorable pathway to connect all consumers and delete dispensable pipes in the graph. The original network consists of 72 pipes. After the linear optimization, this is reduced to 69 pipes and 5 flow directions have been corrected, as shown in Figure 5. Here, the orange point represents the producer, grey nodes junctions, and blue nodes consumer in the district heating system. During preprocessing, the linear diameters, with their corresponding mass flows are determined and handed to the nonlinear optimization to be discretized. Due to the formulation of Equation 26, slight deviations from discrete diameters are allowed, but occur only in rare cases, as shown in Figure 6.



(a) Original

(b) Preprocessed

Figure 5: Representation of the original and preprocessed network.

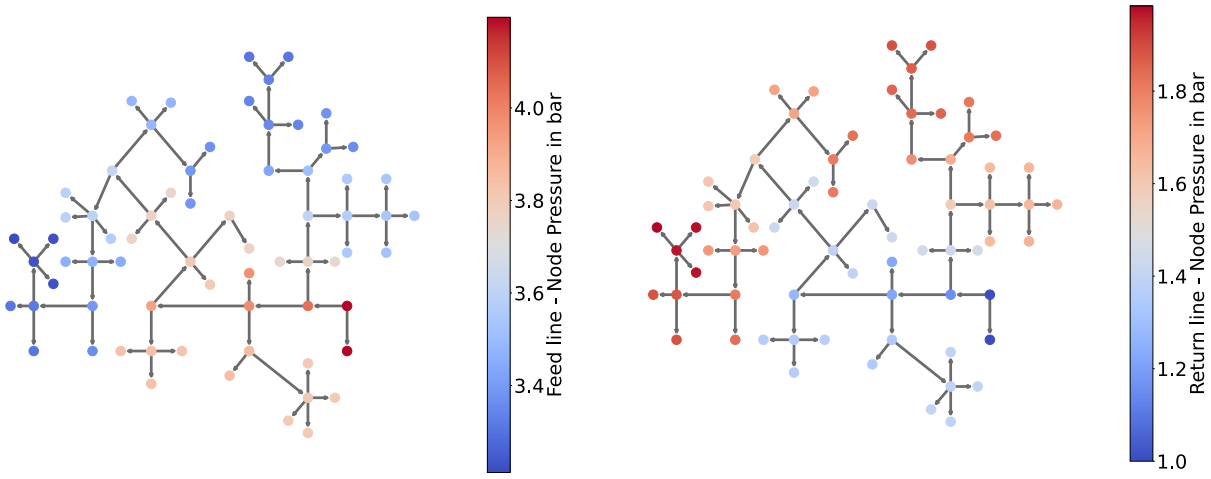


(a) Linear diameters

(b) Discrete diameters

Figure 6: Distribution of the inner diameters before and after the nonlinear optimization with 100 bins between DN20 and DN200.

The nonlinear optimization is iteratively performed while increasing in each iteration the value of ξ and ν. Over ten iterations, ξ is evenly spaced out from 0.001 to 100 and ν from 0 to 1. The whole nonlinear optimization is performed in 19.37 sec. Linear diameters below DN20 are assigned either to DN20 or DN25, as shown in Figure 6. For some connections to smaller consumers, DN25 is oversized, as the optimizer tries to find a viable solution under consideration of all thermohydraulic equations and Equation 26. If an oversized solution, respecting the constraints is found, it can be difficult for the optimizer to revert to the smaller diameter, as the differences in operational and investment costs for two subsequent diameters are rather small. The resulting pressure profile of the district heating network can be seen in Figure 7. The highest cumulative pressure losses can be observed at the most remote consumer, defining the pressure level at the heat source. By comparing Figure 7a and 7b, a maximal pressure difference, larger than the assumed constant pressure drop over a consumer's substation, can be seen. In the modelled throttle, a pressure offset occurs between the feed and the return network, which raises the pressure level in the feed network artificially. As the pressure level does not affect the sizing of the pipes but only the pressure differences and as the pumping costs are rather small compared to the investment costs of the district heating system, this offset is not reduced during the optimization.



(a) Feed network

(b) Return network

Figure 7: Resulting pressure profile in the feed and return network.

Figure 8 shows the resulting temperature profile after the nonlinear optimization. As shown in Figure 8b the consumer always tries to maximize the energy available to them in order to satisfy their demands and are

cooling the fluid down to 55 °C. The desired heat demand is met with 95 % of the desired heat, thus minimizing the operational costs. Overall a total efficiency for the heat distribution of 98.01 % is reached.

7. Conclusion and Outlook

A two-step methodology for the optimization of a district heating network, based on a thermohydraulic model, is derived and successfully implemented as an optimization problem. This method allows a fast nonlinear optimization of a district heating system. The method presented in this paper allowed the optimization of a small exemplary district heating system. Given a set of possible pipeline configurations to connect all the consumers to the grid regardless of its economic viability, the simulation was able to derive an optimal network design. The determined network configuration aimed at minimization of investment and operational costs.

In further works, the method should be applied to larger districts to prove the scalability of the method. Moreover, the discrete pipe sizing method should be improved to eliminate all non-discrete diameters in the final results of the optimization. The optimization should also be developed to account for the profitability of the considered district heating network. Therefore, the preprocessing method could be extended to determine the profitability of a potential connection of a consumer to the grid. Moreover, the nonlinear depiction of the district heating grid could be further improved. In this study, a constant ratio between inner and outer diameter is assumed. In real pipes, this ratio decreases with increasing inner diameter. Gradient-based nonlinear optimization converges always into a local optimum, a global optimum is not guaranteed. Therefore, it should be investigated how different possible local minima can be compared to one another and how the optimization can efficiently choose between the different local minima that occurred during the optimization. At last, the influence of the preprocessing method on the final results should be investigated.

Abstract:
The AIDRES database aims to support the long-term objective of a fully integrated industrial strategy in the EU-27, providing a service to the European Commission and a catalogue for industries to understand the effectiveness, efficiency and cost of potential innovation pathways for achieving carbon neutral processes in the steel, chemical, cement, glass, fertilizers and refineries sectors by 2050. The approach considers the geographical distribution of the annual production of key products quantified at EU-NUTS3 regional level. Process integration techniques are used to generate and evaluate the reference and future optimal production routes, providing a quantitative, technical and multi-criteria estimate of energy demand in Europe's major industrial sectors. Decarbonisation of the production considers routes achieving (i) substitution of less energy intensive products, (ii) electrification of the production, (iii) use of oxy-combustion, (iv) carbon capture transport and storage, (v) use of alternative fuels and (vi) biomass. This results in a per-ton-of-product database containing energy demand, direct emissions at the plant, amount of captured CO_2 and the associated investment and operation costs. Scenarios 2018-2050 for the energy prices, indirect upstream emissions, CO_2 allowance and production shift are considered to foreseen the operation expenditure and total emissions. Finally, the per-ton database is scaled-up at the NUTS3 level by the regional production capacity. The application of the database is demonstrated at the EU level for the analysis of the present and future evolution of selected heavy industrial sectors, reaching a direct emission reduction between 90-95% compared with 2015-2019 average.

Keywords:
industrial processes, heavy industry, decarbonisation, renewable energies, process integration, database.

1. Introduction

The European Green Deal [7] and aims to transform the EU into a modern, resource efficient and competitive economy while making Europe the first climate neutral continent with a 2050 climate neutrality target. To reach this ambitious goal, an economical and societal transformation process is required. Europe's energy intensive industries (EIIs), especially the sectors steel, chemical, cement, glass, fertiliser and refineries, are today an integral part, if not the foundation, of the European economy and have therefore a leading role to play in this transition. To make this transition successful, unprecedented levels of industrial investments are required while the market actors face at the same time increasing global competition.

Previous studies for a carbon neutral industrial strategy [30] and [8] were developed in close collaboration with industrial representatives to define a realistic solution space for this ambitious transition. Valuable insights are provided in these studies, identifying and quantifying in an aggregated format the steps to the envisioned 90-95% emissions reductions by 2050 for EIIs, compared to 1990 levels.

Building from many collaborative experiences with private industries, industrially representative process models have been developed in the H2020 project EPOS[23] to build, so-called blueprints. Validated by industrial sector associations, industrial blueprints provide details of energy and material requirements of the processes, using average or obfuscated values to avoid disclosure of confidential data. Described in greater detail in [4] and [18], this approach allows for data and knowledge to be shared outside of an organization without

disclosing sensitive information.

The AIDRES project is providing the next level of necessary data to develop a sharper picture of potential pathways for industries at their respective sites or industrial clusters in Europe. This study is focused on the analysis of decarbonisation options such as further energy efficiency measures, further process integration, electrification of heat for processes, electrification of processes, production and use of hydrogen, use of biomasse, electricity from carbon neutral sources, Carbon Capture and Utilization (CCU) and Carbon Capture, transport and Storage (CCS) among others.

2. Approach

2.1. Blueprint model integration

Blueprints include details of heat, electricity and material flows as well as the annual investment and operation cost required for process operation. Process integration technique [17] is used to determine the optimal size of each process in typical production route, taking into account the internal use of heat/cold streams while balancing the overall material and energy resource, product and waste flows.

For production routes integrating carbon capture, transport and storage (CCS), the captured emissions (Em^{CCS}) given by (1) are equal to a fraction (η^{CCS}), typically 90%, of the non biogenic and biogenic emissions. Uncaptured direct emissions (2) from biogenic resources are not accounted ($\eta^{CSS} = 0$) but when carbon capture, transport and storage (CCS) is integrated ($\eta^{CCS} > 0$), biogenic direct emissions removed from the atmosphere are accounted negatively. The profits from trading negative emissions are therefore included in the OPEX.

$$Em^{CCS} = \eta^{CCS} \cdot (Em^{direct,non\ bio} + Em^{direct,bio}) \qquad [t_{CO_2}/y] \qquad (1)$$

$$Em^{direct} = (1 - \eta^{CCS}) \cdot Em^{direct,non\ bio} - \eta^{CCS} \cdot Em^{direct,bio} \qquad [t_{CO_2}/y] \qquad (2)$$

2.2. Per ton of product results

Pertinent production routes are selected form the result of a parametric optimisation [32] using various energy prices and emissions and different weight for the terms of the objective function (sum of operation cost, investment cost and impact/emissions). In general, the selection criteria is minimising the direct emission at the plant, however in some cases, the criteria is reflecting the plant's design in the EU context (e.g. steam network design for fertilizer plant). The resulting mass/energy flows, capital cost and direct emissions at the plant are expressed per ton of product.

2.3. AIDRES EU Mix production routes

The concept of EU mix routes is introduced to account for the uncertainty which emerges from the unknown of future production methods for each individual industrial site (NUTS3). Rather than applying one single production route across the European Union industrial production sites, the AIDRES EU mix routes can be considered as a balanced hypothetical alternative to represent values of energy and feedstock input and CO_2 emissions, without merit to actual industrial transition plans. The AIDRES EU Mix 2030 and 2050 production routes (3) are build up by weighting single production routes per ton results (r_i) according to the emission reduction targets. The integration of the mix to the mapped production sites at NUTS3 level are to be compared and understood at European level.

$$mix = \sum_{i \in routes} w_i \cdot r_i \text{ with } \sum_{i \in routes} w_i = 1 \text{ and } w_i \leq 1 \qquad [t/t] \text{ or } [€/t] \qquad (3)$$

The AIDRES mix are done in a way to meet the MIX EU Reference Scenario emission reduction targets in 2030 and 2050, as defined by the European Commission in 2021 [6] in line with the Fit for 55 and the EU Green deal roadmap [7].

2.4. Scenarios integration

To evaluate the impact of the different production routes, nine typical cost and emissions scenarios 2018-2030-2050, given in Table 1, have been considered. The criteria and values were selected based on EU reference scenarios, to create a diversity of different outcomes. The amount of scenarios was restricted to eigth plus a reference scenario to keep the number of modeled solutions under control. The values can be seen as boundaries and sensitivity with different values can easily be done afterwards without having to re-run the AIDRES model. The AIDRES model does not take limitations of resource availability into account and does not consider competition for the resource, such as biomass [22], between and with other sectors (e.g. food). The scenarios are aligned with the EC Fit for 55 [9]. In the AIDRES database, there is a record available for all AIDRES production routes on NUTS3 and this for every scenario.

Table 1: AIDRES reference scenario 2018 and future EU scenarios at horizons 2030 and 2050.

			CO_2	Electricity		Hydrogen		Natural gas
	Horizon	Scenarios	[€/kg$_{CO_2}$]	[€/kWh]	[kg$_{CO_2}$/kWh]	[€/kg]	[kg$_{CO_2}$/kg]	[€/kWh]
0	2018	Reference	0.025	0.125	0.231	1.8	8.2	0.024
1	2030	low H_2 price	0.150	0.071	0.120	3.0	0.0	0.025
2	2030	low H_2 & high NG price	0.150	0.071	0.120	3.0	0.0	0.050
3	2030	high H_2 price	0.150	0.071	0.120	5.0	0.0	0.025
4	2030	high H_2 & high NG price	0.150	0.071	0.120	5.0	0.0	0.050
5	2050	low H_2 price	0.350	0.071	0.000	1.5	0.0	0.035
6	2050	low H_2 & high NG	0.350	0.071	0.000	1.5	0.0	0.050
7	2050	high H_2 price	0.350	0.071	0.000	2.5	0.0	0.035
8	2050	high H_2 & high NG price	0.350	0.071	0.000	2.5	0.0	0.050

2.5. Regional integration

The single and mixed production scenarios per ton of product results (r_i [t/t] or [€/t]) are scaled-up at regional level (4) considering the annual production ($p_{NUTS3,i}$ $[t/y]$) in each NUTS3 region.

$$R_{NUTS3,i} = \sum r_i \cdot \left(p_{NUTS3,i}\right) \qquad \text{[t/y] or [€/y]} \qquad (4)$$

The aggregated annual production of the EIIs at EU level is given in Table 2.

Table 2: NUTS3 annual production aggregated at EU level for the AIDRES industrial sectors in [t/y].

Sector	Product [t/y]	2018	2030	2050
Cement	Cement	173'836	173'836	173'836
Chemical	Polyethylene	31'584	31'584	31'584
	poly-ethyl-acetate	25'920	25'920	25'920
	Olefins	36'956	36'956	36'956
Fertiliser	Ammonia	10'928	10'928	10'928
Glass	Container glass	32'256	32'256	32'256
	Fibte Glass	2'100	2'100	2'100

3. Industrial production route

3.1. Cement sector

The cement sector (raw mill, kiln, calcination, product mill) has been structured with production routes using dry kiln and coal and alernative route using calcination process to produce Limestone Calcined Clay Cement (LC3).

Six types of cement have been modeled however, no distinction is made in the EU-NUTS3 level and we have therefore considered Portland cement II (BV325R with a clinker-to-cement ratio of 70%) as the reference and Calcined clay product (LC3) as a future alternative (best case). Portland cement I (cI425R) is a conservative type of cement with a clinker-to-cement ratio of 95% and has one of the highest CO_2 emissions (worst case).

In cement manufacturing, about 60% CO_2 comes from calcination process, and remaining 40% comes from fuel consumption.

The conventional route uses dry kiln, cement, coal(54%), alternative fuels mixture(30%) and biomass waste (BMW) to produce Portland cement type II with 70% clinker-to-cement ratio. The flue gases from a conventional cement plant contains 20-25% CO_2. Beside Monoethanolamine (MEA) Capture technology, Calcium looping seems to emerge as the most promising carbon capture technology in the sector.

Alternative production routes (a) replace coal by alternative fuel mixture (AFM) and biomass waste (BMW), (b) integrate monoethanolamine amine (MEA) or calcium looping (CaL) carbon capture, (c) use oxy-combustion with carbon capture and (d) use calcination process to produce Limestone Calcined Clay Cement (LC3), a new type of cement with a lower CO_2 footprint based on calcined clay. Through research and testing, LC3 aims at becoming a standard and mainstream general-use product in the global cement market [24].

Different calcination modes exist, e.g. Rotary kiln (soak calcination) and Flash gas suspension calciner. The latter is chosen for this model, as its product presents clinker subsitution rate of 30-40% (due to significantly higher reactivity of the calcined clay with cement), whereas the soak calcination product can only substitute 15-25%. Other advantages are no grinding requirement required after the calciner, and reduced CAPEX by 75% compared to the rotary kiln option. The calcination step involves mainly 2 reactions : drying of the clay (at around 100°C), and metakaolin reaction between 400 and 600°C, producing water (gaseous) as by-product.

3.2. Chemical sector

The chemical sector in Europe is highly complex, encompassing bulk chemical manufacturing, especially chemicals for the pharmaceutical industry and plastics production. This work considers the production of three main products: poly-ethyl-acetate, polyethylene and olefins. Olefins includes ethylene, propylene and other olefins products. Ethylene is an intermediate in the production of poly-ethyl-acetate and polyethylene. The production of methanol from biomass and coelectrolysis is considered as well for the production of olefins.

Three different routes are considered for the production of olefins: (a) naphtha for the reference route and methanol synthetized either from (b) renewable green biomass gasification or (c) from the co-electrolysis of carbon dioxide and water.

The reference case for the chemical sector uses light naphtha (LN) to produce Poly-ethyl-acetate (PE), Etylene and Propylene. The alternative route (LN+EL) uses an electrical furnace to provide heat for naphta cracking, thus avoiding direct emissions from combustion.

Methanol is either imported from the market (grey methanol from steam reforming process) or produced from biomass ((BM)MeOH) or coelectrolysis ((COEL)MeOH) using CO_2 from the market. One burner is included for offgas from methanol synthesis and upgrading. Crude methanol is directly fed to a methanol-to-olefin reactor with oxygen [14]. Four products are then recovered: ethylene, butene, propylene and other olefins [31]. The model was designed for a production of 600 ktonnes of ethylene per year.

Polyethylene (PE) production is modelled using four main units: preheating of the reactants (ethylene, hydrogen used as chain-transfer agent and nitrogen) to 70°C; polymerization of ethylene in a slurry; recycle of unreacted liquid and gas reagents to finishing step; and quenching with water followed by extrusion [10, 16, 20]. The model was designed for a production of 25'000 kilos of polyethylene per hour.

Ethyl-acetate is produced via the esterification of carboxylic acids [26]. A process whereby ethylene is reacted with acetic acid at 170°C to produce 15 tonnes per hour of ethyl acetate is simulated. Following reaction, the hot gases are cooled down to room temperature before being send to the separation section which consists of two flash drum in series to extract the unreacted ethylene from the hot gases and recycle it to the preheating unit. The acid is then recovered from the products and recycled. The product is purified and latter polished to remove light and medium hydrocarbons. The light hydrocarbons are stripped of acetaldehyde and recycled whereas both the high and medium hydrocarbons are disregarded following heat exchange with other cooled process streams. Finally, ethanol and water are recovered from the water rich stream exiting purification and recycled. All process conditions are based on the Blueprint model developed by [3]. The polymerization reaction requires cooling water and the injection of cold feedstock into the reactor to control temperatures between 150 and 200°C at pressures from 13 to 83 bar.

3.3. Fertilizer sector

The fertiliser sector has been structured in four routes for the production of ammonia, ammonia plus urea and ammonia plus urea plus nitric acid. The production routes use either natural gas with and without carbon capture, biomass or electricity.

The reference production route is a conventional natural gas-based ammonia production plants which is equipped with efficient energy integration networks able to recover the waste heat available throughout the chemical system [12]. Alternative routes use biomass gasification or nitrogen and hydrogen (H2)NH3 for replacing methane in the integrated ammonia production plant [11]. Hydrogen is either produced at the plan using Alkaline electrolyser (AEL) or imported from the market. In both cases, mechanical vapor recompression (MVR) can be integrated to recycle waste heat, thus lowering the natural gas demand and direct emissions.

Hydrogen is either coming from the market (grey and green hydrogen, Table 1 or alternatively produced on-site by alkaline electrolysis (AEL).

Ammonia process emissions is a particular case where CO_2 used for urea, which is captured by necessity from the SMR syngas, is accounted as direct emission at the plant and not as captured CO_2 (CSS). The

CO_2 in surplus from the gas purification unit is send to the market (beverages, plastics, slaughterhouses) and accounted as direct emission. The routes integrating diethanolamine carbon capture of CO_2 from the gas purification unit are labelled with (DEA), while the routes with CCS on the furnace using monoethanolamine carbon capture are labelled with (MEA).

Accounting and mitigation of the green house gas emission effect of NO_2 for the nitric acid production routes is out of the scope of the AIDRES project.

3.4. Glass sector

The glass sector has been structured in production routes using either natural gas, hydrogen or electric furnace with or without carbon capture technology. Hydrogen can be produced on site by an Alkaline electrolyzer (AEL) or purchased on the market.

Fibre glass consists out of roughly 10% of the total whereas majority of the glass products are container or hollow (60%) and flat glass (30%).

The high temperature requirement of the process is limiting the available options. Natural gas (NG) or Hydrogen (H_2) can be used to satisfy the heating demand. Electric melting furnaces are also been considered with an efficiency of 85% and a cost based on equipment recently installed.

3.5. Refineries sector

The Refineries sector (Distillation, Cracking, Isomerisation, Reforming Desulfurisation and Fischer-Tropsch process) has been structured in seven routes. The refinery and Fischer-Tropsch process are used with either Natural gas or Hydrogen furnace. Carbon capture (MEA) is considered only in conjunction with the use of a Natural gas furnace. The targeted product of both routes is a light liquid fuel (LHV = 42.87 MJ/kg). To produce 1 ton of light liquid fuel (LLF), 1.56 ton of crude oil is needed, which represents an LHV equivalent of 1.038 $ton_{eq_{LLF}}$ of Fischer-Tropsch fuel and 0.464 $ton_{eq_{LLF}}$ of methanol.

The reference refineries (REF) uses crude oil to produce, without carbon capture, light liquid fuel (LHV = 42.87 MJ/kg) including isomerate, heavy reformate, gasoline and gasoil (diesel) [1, 2, 15, 28].

Two routes (Biomass gasification and co-electrolysis) are producing syngas from biomass or co-electrolysis of CO_2 and water. The extra Carbon dioxide is separated from the syngas with a carbon capture unit [25, 33]. The purified syngas is further transformed into liquid fuel with two different production routes:
- methanol synthesis;
- Fischer-Tropsch (FT) process producing FT crude (C12, C18, C20).

Hydrogen from the market, steam Methane Reforming (SMR) [27] and Alkaine Electrolysis [19] (AEL) are competing options for the supply of hydrogen to the system. Hydrogen can indeed be used to avoid the water gas shift reaction in the gasifier [13].

3.6. Steel sector

The steel sector (iron making, steel making and shaping) has been structured in production routes for primary steel and one route using recycled scraps and electric arc furnace (EAF) to produce secondary steel. Steel from primary and secondary production routes have different quality that serves different purpose. The denomination does not refer to a distinction in value.

Special types of steel and stainless steel were not further disaggregated in the model. Special types of steel are produced under request and it is an alloy of iron and several other materials (such as nickel and chromium). Therefore, the desegregation was done based on the production route: primary steel (BF-BOF) and secondary steel (EAF). This approach is aligned with EUROFER [5] and World Steel reports [29] to facilitate comparison and reduce the number of products to be covered. For instance, EUROFER includes a report differentiating the production route, as it is done in AIDRED, and another report by steel quality. Both cases add up to the same annual production. Finally, the production of special steel was assumed to be included in the production of steel with EAF.

The reference case uses a blast furnace (BF) and a Basic oxygen furnace (BOF) to produce primary steel.

Alternative routes make use of (i) top gas Recycling blast furnace (TGRBF) or (ii) waste plastic injection BF to replace the BF. TGRBF is a promising technology to significantly reduce the CO_2 emission by recycling CO and H_2 from the top gas leaving the blast furnace (BF). CO and H_2 content of top gas has a potential to act as reducing gas elements, and hence their recirculation to the BF is considered as an effective alternative to improve the BF performance, enhance utilization of Carbon and hydrogen, and reduce CO_2 emission.

Other alternative for primary steel production routes are (iii) replacing the BF-BOF by an electric arc furnace (EAF) or (iv) by shaft furnaces using different fuels to feed an EAF with direct reduced iron (DRI-EAF). The use of molten oxyde electrolyser (v) is a route with low technology readiness level (TRL). Finally (vi) monoethanolamine carbon capture (MEA) can be used on the fumes of the different furnaces.

The consumption of coal of blast furnaces is much higher than the consumption of coke since the coke oven

plant is assumed to be within the boundaries of the sector. Nevertheless, the total energy intensity remains within the order of magnitude common for the BF-BOF (18-20 GJ/t).

Both alternatives, H_2 without and with electrolyzer on-site (AEL) are computed and available for comparison in all scenarios.

4. Results

A subset of the full AIDRES database, giving the specific energy flows, investment costs, emissions and captured CO_2 per ton of product for the routes of the AIDRES EU-mix 2018-2050, is reported in Table 3 of appendix A. The AIDRES EU-mix, shown in Figure 1 comply with the emission reduction targets for 2030 and 2050 based on the MIX EU Reference Scenario [6] in line with Fit for 55 and the EU Green deal [7]. The corresponding energy demand, aggregated at the EU level are reported in Figure 2. The map of Figure 3 shows the energy and direct emissions reduction, aggregated at country scale, for the AIDRES EU-mix at horizon 2050.

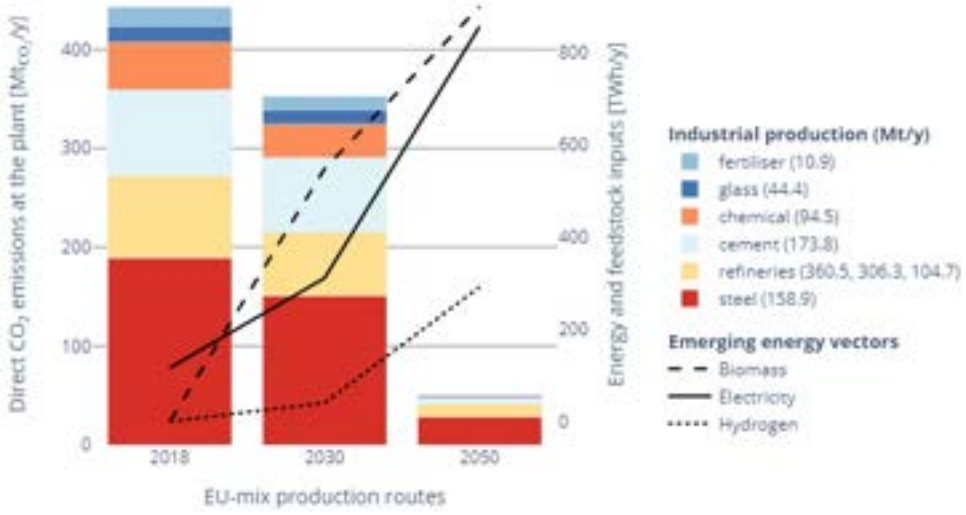

Figure 1: EU-27 EIIs direct emission at the plant [Mt_{CO_2}/y] and emerging energy vectors [TWh/y] AIDRES EU mix production routes meeting EU reference MIX scenario derived emission reduction targets.

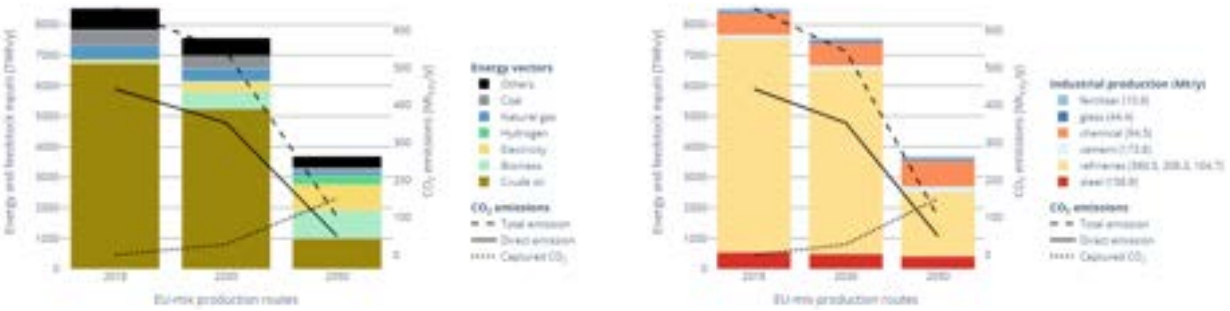


(a) Energy and feedstock inputs by vectors.

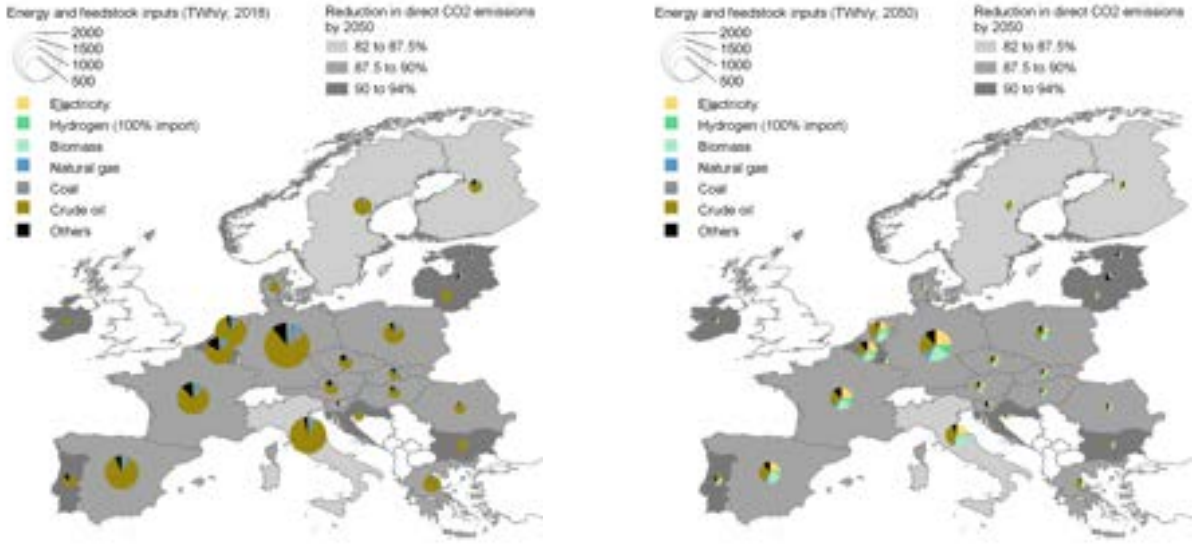
(b) Energy and feedstock inputs by sectors.

Figure 2: EU-27 EIIs energy and feedstock inputs flows [TWh/y], direct and total 2018 emissions [Mt_{CO_2}/y] for AIDRES EU mix production routes meeting EU reference MIX scenario derived emission reduction targets.

5. Conclusion

This paper presents a publicly available database for the decarbonisation of the heavy industry in Europe in line with other databases of energy intensive industries, such as EU ETS. The concept of AIDRES EU mix routes has been introduced to account for the uncertainty which emerges from the unknown of future production methods for each individual industrial site (NUTS3).

According to the AIDRES EU-EIIs decarbonisation pathway, the overall energy and feedstock inputs are expected to decrease by 57% by 2050, mainly due to the reduced refinery output, while the renewable electricity



(a) AIDRES reference 2018.

(b) AIDRES EU-mix 2050.

Figure 3: Map of the energy and feedstock inputs flows [Twh/y] for the AIDRES EU-mix 2018 and 2050 with direct CO_2 emissions reduction [%] by 2050. Scales of Luxembourg, Estonia, Latvia and Slovenia x 3.

demand will see a sharp increase by a factor of three by 2030. Biomass could play a crucial role in the chemical and refinery sectors in the future, while methanol will replace naphtha as a vital feedstock for the chemical sector. The usage of green hydrogen is moreover expected to become essential in the steel, fertilizer, and chemical sectors. The cement industry will have to rely on a mixture of biomass waste and alternative fuels, combined with carbon capture technologies such as oxy-fuel combustion and calcium looping. Although there will be a strong decline in coal and natural gas usage, they can still have a role in some sectors combined with carbon capture technologies.

However, the AIDRES EU mix routes are not the only pathways toward the decarbonisation of the heavy industry in Europe. A virtual unlimited number of different combinations of different production routes, across the EU and at specific NUTS3 locations, can indeed be simulated using the publicly available AIDRES database.

The AIDRES database has already been applied to develop regional and sectoral approaches to identify potential industrial symbiosis initiatives, highlighting the optimization potential of symbiotic profiles and recommending the inclusion of additional sectors such as paper and power plants [21]. The proposed format can be used in future studies and model applications by EU institutions, such as the Directorate-General for Energy (DG ENER) and the Joint Research Centre (JRC).

Acknowledgments

This project is carried out with the financial support of the European Commission – Directorate General for Energy. Moreover, the authors would like to thank Arcelor Mittal, the Belgian Federation for Chemistry and Life Sciences (essenscia), CEMBUREAU, CEMEX, Dechema, European Chemical Industry Council (Cefic), European Steel Technology Platform (ESTEP), Federation of the Belgian Cement Industry (FEBELCEM), INEOS, Institut du verre, Glass for Europe, Vrije Universiteit Brussel (VUB), EU Joint Research Center (JRC) and Yara International for their participation in the AIDRES project.

Abstract:

Decision-making for distributed energy systems (DES) is subject to significant uncertainties. Therefore, assuming perfect foresight for long-term system planning might result in suboptimal decisions. Long time horizons result in a variety of possible scenarios. One way of considering uncertainty in DES design is Monte Carlo analysis (MCA). However, MCA suffers from the computational burden of repeatedly evaluating energy system models. Furthermore, MCA is sensitive to distribution assumptions of uncertain parameters. In this work, we combine linear regression and systematic uncertainty modeling in MCA to consider uncertainty effectively.

We propose a method for comparing different DES designs regarding total annualized cost (TAC) while reflecting uncertain parameters. We model uncertainties by introducing a small number of representative factors that scale reference parameters. We distinguish between constant and long-term uncertainties increasing over time. We use mixed-integer linear programs (MILPs) to minimize yearly costs of DES. We solve the burdensome MILPs only for Latin Hypercube samples to parameterize linear surrogate models. We use the obtained linear surrogate models during MCA to accelerate the computation of the TAC.

We apply our method to a case study adapted from the literature to compare promising DES designs while considering multiple sources of uncertainty. We compute the TAC of the DES designs for thousands of long-term scenarios and identify the design, which results most frequently in the lowest costs. We show that using linear regression can reduce the computational time by more than 99 %, while maintaining a high accuracy measured by the goodness of fit of the linear regression.

Distributed energy systems; Long-term scenarios; MILP; Multiple uncertainties; Surrogate modeling.

1. Introduction

Designing industrial energy systems given a multi-year planning horizon is challenging yet crucial for achieving a sustainable energy supply [1]. Energy systems are commonly designed to minimize total annualized cost (TAC), the global warming impact, or both. Long planning horizons suffer from a lack of good forecasts and also involve inherent uncertainties, which are recommended to be considered [1,2]. Optimization-based techniques for identifying the optimal energy system configuration under uncertainty include robust optimization, stochastic optimization, or chance-constrained optimization [3,4]. Here, the consideration of uncertainties lead to complex optimization problems that are challenging to solve resulting in a tradeoff between solution quality and computational tractability [3]. The presence of multiple uncertain factors, e.g., arising from the long-term evolution of energy prices and demand, adds further complexity in identifying the best suited design [3]. Energy system optimization under uncertainty can also be addressed using Monte Carlo analysis (MCA), where computation time is independent of the number of uncertain parameters for a single scenario [4,5]. However, MCA typically requires evaluating hundreds of scenarios while the computational time still increases linearly with the number of scenarios and thus can become prohibitively high, particularly when complex models are involved [5]. A promising approach is to use approximation methods involving sampling techniques like Latin hypercube sampling, which can facilitate the consideration of a wide range of scenarios [6,7]. Furthermore, MCA can be quite sensitive to probability distributions for uncertain parameters [5]. Even

though only a few parameters might be influential, the specification of uncertainties is challenging and should be done systematically [2]. Overall, the issue of efficiently incorporating multiple sources of uncertainties into the energy system design process for industrial systems with a multi-year planning horizon is challenging and needs to be addressed.

In this work, we propose a method that helps to make informed decisions regarding the selection of the optimal distributed energy system (DES) design from a set of promising designs considering long time horizons and multiple sources of uncertainty. This so-called Rapid Monte Carlo analysis (RMCA) incorporates uncertainty and surrogate modeling. The economic metric TAC is used to rank the designs. As a first step, we define the procedure of calculating TAC. Determining TAC for a design involves estimating operational expenditures by solving operational optimizations and using investment cost correlations. Accordingly, the metric depends on a variety of uncertain parameters that may influence the results. To model uncertainties, the full set of uncertain parameters is reduced to a few representative factors. Each factor is classified and parameterized to define the probability distributions of the long planning horizon. Next, computationally burdensome relationships between these representative factors and the TAC are replaced by linear surrogate models. The uncertainty and surrogate models allow a large number of long-term scenarios to be considered. Finally, a statistical analysis of the TAC of the DES designs is conducted to serve as a foundation for selecting a final design.

The paper is structured as follows. Section 2 presents the proposed method in detail by first providing an overview, then presenting the uncertainty parameterization and modeling as well as the linear surrogate model generation, and finally the RMCA. Section 3 applies the method to a case study adapted from the literature and discusses the results. Finally, in Section 4 conclusions are drawn.

2. Rapid Monte Carlo analysis via uncertainty and surrogate modeling

2.1. Method overview

We propose a method to analyze a set of promising DES design alternatives to identify the best design given a multi-year planning horizon and multiple sources of uncertainty. To rate a system's performance, we use the total annualized cost (TAC) as assessment metric. The given design alternatives can be, for example, user-defined or the result of an optimization-based design method. Figure 1 shows the four main steps of using our method.

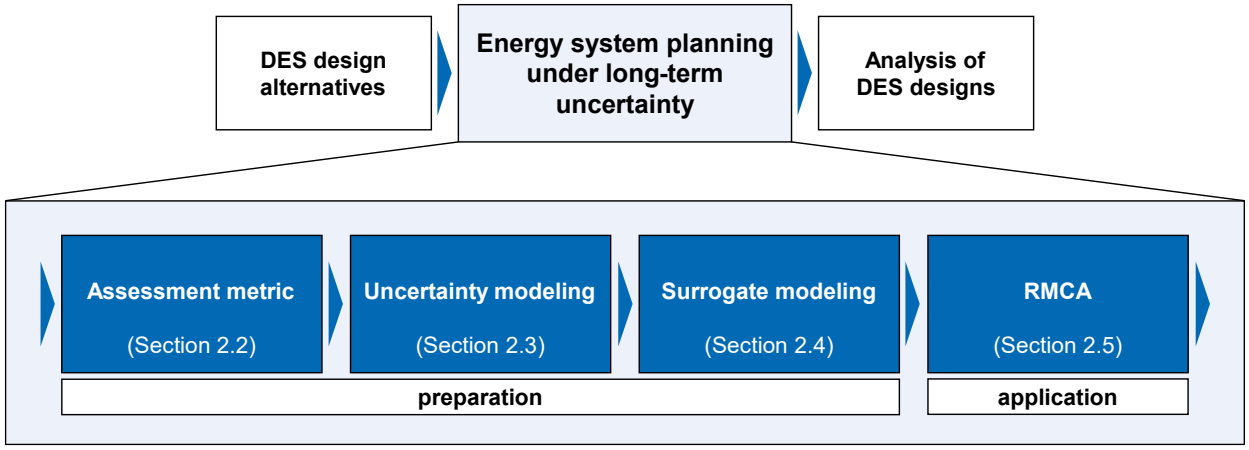

Figure 1. Energy system planning under long-term uncertainty: Steps for preparing and applying the proposed rapid Monte Carlo analysis (RMCA) via uncertainty and surrogate modeling for analyzing promising distributed energy system (DES) design alternatives to identify the best system according to an assessment metric.

Section 2.2 discusses the calculation of the assessment metric TAC and the involved optimization models. TAC depends not only on parameters such as investment costs but also on the operational expenditure (OPEX) including energy costs occurring within the multi-year planning horizon. Here, we consider the OPEX for each year of the planning horizon individually rather than resorting to only one year that is assumed to be representative for the whole horizon. We formulate mixed-integer linear programs (MILPs) for each DES design to determine the energy costs of each year. Each MILP depends on a large number of parameters (e.g., component efficiencies, heating demand for each hour of the year). As a result, the assessment metric depends on many potentially uncertain parameters.

In Section 2.3 we show, how we address uncertainties. We first identify a small number of representative factors that scale reference parameters to define the parameters of the assessment metric. We model the time-dependent development of these representative factors using probability distributions. After modeling uncertainties, probability distributions for all parameters of the TAC are defined. A direct calculation of the TAC

involves solving a MILP for each year of the multi-year planning horizon. Thus, calculating the TAC directly is computationally burdensome. Instead of solving multiple MILPs to obtain the energy costs for each year, we employ linear surrogate models.

Section 2.4 shows how we first generate Latin hypercube samples (LHS) of representative factor combinations to obtain the energy costs of representative years. We then use each combination to parameterize and solve MILPs. Afterwards, we use the LHS to parameterize linear surrogate models. These linear surrogate models allow approximating the energy costs of a single year given the representative factors specifying the respective year. The surrogate model generation is conducted for each DES design. As a result, we can approximate the TAC for long-term scenarios without solving additional MILPs. After following these three preparation steps, the RMCA is carried out.

In Section 2.5, we present the steps of conducting our RMCA. It relies on the probability distributions determined for uncertainty modeling and approximates the TAC using the generated surrogate models for evaluating the long-term scenarios. The RMCA provides decision support by evaluating a large number of multi-year scenarios and conducting a subsequent statistical analysis.

2.2. Assessment metric and energy system modeling

We evaluate DES design alternatives using the TAC as a metric where we consider the OPEX of each year individually, rather than using one representative year. The DES to be evaluated involve different technologies for converting and storing energy. The TAC of an energy system e is calculated as follows:

$$TAC_e = \frac{1}{PVF} * \left(I_{0,e} + \sum_{a=1}^{T} \frac{OPEX_{e,a}}{(1+i)^a} \right) \tag{1}$$

with the net present value factor PVF, the investment costs $I_{0,e}$ of the energy system e, the operational expenditures $OPEX_{e,a}$ of energy system e occurring in year $a \in \{1, \dots, T\}$, the time horizon length of T years, and the interest rate i. We determine the net present value factor as follows [8]:

$$PVF = \frac{(1+i)^T - 1}{(1+i)^T i} \tag{2}$$

We estimate the investment costs $I_{0,e}$ using cost correlations (e.g., cf. [9]). The OPEX $OPEX_{e,a}$ encompasses energy costs $OPEX_{e,a}^{\mathrm{e}}$ as well as maintenance costs $OPEX_{e,a}^{\mathrm{m}}$:

$$OPEX_{e,a} = OPEX_{e,a}^{\mathrm{e}} + OPEX_{e,a}^{\mathrm{m}} \tag{3}$$

The maintenance costs $OPEX_{e,a}^{\mathrm{m}}$ of energy system e are determined in accordance to [9]. To compute the energy costs $OPEX_{e,a}^{\mathrm{e}}$ of energy system e in year a, we utilize MILPs to determine the cost-optimal energy system operation to fulfil the energy demand. The objective function of each MILP is defined as the sum of costs for purchasing energy carriers in year a. Here, we assume that the costs of each year can be computed independently and obtain the energy costs $OPEX_{e,a}^{\mathrm{e}}$ by solving the respective MILP. We model the energy systems using quasi-stationary component models as used by [9] and consider part-load behavior as in [10]. As a result, the MILPs comprise equations for the objective function, energy balances, the conversion units, and the energy storage. The models for the operational optimization of energy systems encompass a variety of parameters (e.g., hourly-resolved heating demands, components' efficiencies). TAC_e of each energy system e can be determined if the parameters are known; however, some parameters like energy prices can be subject to uncertainty.

2.3. Uncertainty parameterization and long-term uncertainty modeling

The assessment metric usually depends on a large number of parameters which are potentially uncertain. We reduce the number of potentially uncertain parameters by first screening and then grouping them. Specifically, we first identify the parameters that can be assumed as constant. Afterward, we group the remaining parameters and assign each group to a representative factor that captures the shared variability. This screening and grouping, to which we refer to as uncertainty parameterization, results in a low number of representative factors. For each representative factor, we then conduct the long-term uncertainty modeling by choosing one of three uncertainty types and defining a permitted range for each representative factor. Thereafter, the uncertainty modeling is complete. The proposed procedure guides the uncertainty modeling steps (i.e., how uncertainty is modeled) and leaves case specific decisions to the user (e.g., which sources of uncertainty should be considered).

We start the uncertainty parameterization with a preliminary screening by first listing all parameters of the assessment metric. Next, parameters with known values, with negligible influence on the assessment metric, or with negligible uncertainty are set as constant. At this point, the risk of excluding influential parameters should be considered carefully and expert knowledge about characterizing uncertainty can be incorporated. For parameters assumed to be uncertain, we determine reference parameters. Following that, the uncertain parameters that are expected to be correlated (e.g., all hourly demands of one year) are grouped and assigned

to the representative factor of that group. As soon as all parameters of the assessment metric are either set as constant or assigned to a representative factor, the uncertainty parameterization is complete.

For the long-term uncertainty modeling, we distinguish three types of long-term uncertainty. The three types are adapted from [2]. Figure 2 illustrates the three types of uncertain parameter developments.

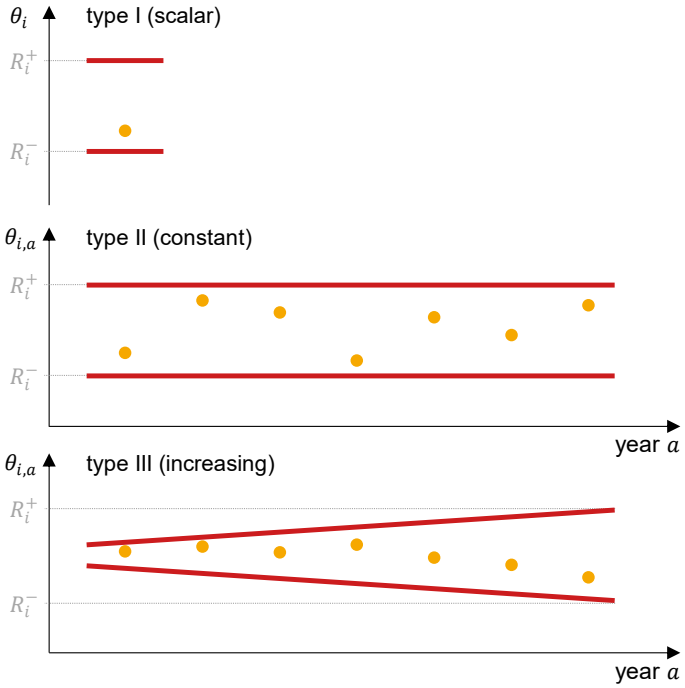

Figure 2. Three types of long-term uncertainty. Type I: Random scalar (e.g., investment costs, life expectancy of equipment). Type II: Constant long-term uncertainty (e.g., energy prices). Type III: Increasing long-term uncertainty (e.g., energy demand). The exemplary realizations (orange dots) of the representative factors (θ_i, $\theta_{i,a}$) lay within the permitted range which is defined by its bounds (R_i^+, R_i^-).

For each representative factor $i \in I = I^{\mathrm{I}} \cup I^{\mathrm{II}} \cup I^{\mathrm{III}}$, first, an appropriate long-term uncertainty type needs to be chosen. Second, a range of permitted scaling factor values needs to be selected. To parameterize the permitted range, an upper bound R_i^+ and a lower bound R_i^- need to be selected. These bounds can, for example, be derived from historical data or forecasts.

We derive the probability distributions of the representative factors as follows. We use normal (Gaussian) distributions, which are one of the most frequently used distributions [11], to model the uncertain parameters. The expected value μ_i of the normal distribution is assumed for all representative factors $i \in I$ as

$$\mu_i = \frac{R_i^+ + R_i^-}{2} \qquad \forall i \in I \tag{4}$$

The standard deviation σ_i is determined such that the permitted range matches the two-sigma interval:

$$\sigma_i = \frac{R_i^+ - R_i^-}{4} \qquad \forall i \in I \tag{5}$$

For type I factors $i \in I^{\mathrm{I}}$, we define the normal random variable $\tilde{\theta}_i$ that serves as an auxiliary variable:

$$\tilde{\theta}_i \sim N(\mu_i, \sigma_i^2) \qquad \forall i \in I^{\mathrm{I}} \tag{6}$$

Analogously, for type II factors $i \in I^{\mathrm{II}}$, we define for each year a an auxiliary variable $\tilde{\theta}_{i,a}$:

$$\tilde{\theta}_{i,a} \sim N(\mu_i, \sigma_i^2) \qquad \forall a \in \{1, \dots, T\}, i \in I^{\mathrm{II}} \tag{7}$$

We project these auxiliary variables to values within the permitted range. Thus, we obtain the probability distributions for the representative factors $\theta_{i,a}$ as follows:

$$\theta_{i,a} = \begin{cases} R_i^+ & \tilde{\theta}_{i,a} > R_i^+ \\ R_i^- & \tilde{\theta}_{i,a} < R_i^- \\ \tilde{\theta}_{i,a} & \text{otherwise} \end{cases} \qquad \forall a \in \{1, \dots, T\}, i \in I^{\mathrm{II}} \tag{8}$$

An analogous formulation for $\theta_i \in I^I$ (i.e., one where the index a is dropped) is used for type I parameters. The increasing uncertainty of type III factors $i \in I^{\mathrm{III}}$ is modeled using

$$\tilde{\theta}_{i,a} = \theta_{i,a-1} + \Delta_{i,a} \qquad \forall a \in \{1, \dots, T\}, i \in I^{\mathrm{III}} \tag{9}$$

with $\theta_{i,0} = \mu_i \ \forall i \in I^{III}$ and the random variable $\Delta_{i,a} \sim N(0, \sigma_{\Delta,i}^2) \ \forall a \in \{1, \dots, T\}, i \in I^{III}$ which corresponds to the difference of consecutive factor values. We determine the standard deviation $\sigma_{\Delta,i}$ as follows. If random variables are uncorrelated, the variance of their sum equals the sum of their variances [11]. To approximate the variance σ_i^2 for the final parameter $\theta_{i,T}$, we set the variance of each step to $1/T$-th of the final, desired variance. Thus, we determine the respective standard deviations using $\sigma_{\Delta,i} = \sigma_i/\sqrt{T} \ \forall i \in I^{III}$. After assigning each uncertain factor to an uncertainty type and parameterizing it, long-term scenarios can be generated, and the respective TAC can be computed.

2.4. Surrogate modeling via Latin hypercube sampling and linear regression

We use linear surrogate models to speed up the calculation of the assessment metric by replacing computational burdensome operations with linear approximations. For determining the TAC of a DES design, the energy costs need to be calculated for each year of the multi-year time horizon of length T. As a result, T optimization problems need to be solved for each long-term scenario. After introducing the representative factors in Section 2.3, which includes setting parameters to constant values and determining reference parameters, each optimization problem is fully defined by a small set of parameters:

$$OPEX_{e,a}^{e} = OPEX_{e}^{e}\left(\{\theta_i\}_{i \in I^{I}}, \{\theta_{i,a}\}_{i \in I^{II} \cup I^{III}}\right) \tag{10}$$

For each DES design, we obtain a linear surrogate model by first solving the respective MILP for a representative set of sampling points. We select these sampling points using Latin hypercube sampling and solve the MILPs for N^{LHS} combinations of representative factors. Afterwards, we use ordinary least squares [12] to parameterize the linear surrogate models which have the following form:

$$OPEX_{e,a}^{e} \approx \widehat{OPEX}_{e,a}^{e} = b_{e,0} + \sum_{i \in I^{I}} b_{e,i}\theta_i + \sum_{i \in I^{II} \cup I^{III}} b_{e,i}\theta_{i,a} \tag{11}$$

where $\widehat{OPEX}_{e,a}^{e}$ is the linear approximation of the energy costs $OPEX_{e,a}^{e}$ of DES design e in year a and $b_{e,i}$ is a surrogate model parameter. We assess the quality of fit using the coefficient of determination R^2 defined as [13]:

$$R^2 = 1 - \frac{\sum_{j=1}^{N^{LHS}} \left(X_j - Y_j\right)^2}{\sum_{j=1}^{N^{LHS}} \left(\bar{Y} - Y_j\right)^2} \quad \text{with} \quad \bar{Y} = \frac{\sum_{j=1}^{N^{LHS}} Y_j}{N^{LHS}} \tag{12}$$

where Y_j is the value of the observed data (i.e., the result of an optimization), X_j is the value predicted by a linear surrogate model, $\bar{Y}$ is the mean of the observed data, and N^{LHS} corresponds to the number of Latin hypercube samples. The coefficient of determination can take values $R^2 \leq 1$ and positive values of R^2 can be linked to the percentage of correctness of a regression [13]. However, a high value of R^2 cannot guarantee whether the linear surrogate model is an appropriate approximation. After having generated linear surrogate models, we approximate the TAC as follows:

$$TAC_e \approx \widehat{TAC}_e = \frac{1}{PVF} * \left(I_{0,e} + \sum_{a=1}^{T} \frac{\widehat{OPEX}_{e,a}^{e} + OPEX_{e,a}^{m}}{(1+i)^a}\right) \tag{13}$$

2.5. Rapid Monte Carlo analysis

Our rapid Monte Carlo analysis (RMCA) allows to analyze and compare promising DES design alternatives with a reduced computation burden considering multiple sources of uncertainty and long planning horizons. The RMCA is enabled by defining an assessment metric (Section 2.2), conducting uncertainty parameterization as well as long-term uncertainty modeling (Section 2.3), and generating surrogate models (Section 2.4). Our RMCA involves the typical steps of a MCA [5]. First, probability distributions are defined. Second, random values, i.e., long-term scenarios, are sampled. We use long-term uncertainty models to generate multi-year scenarios defined by a set of representative factors. Third, the samples are evaluated using approximations for the TAC. By using linear surrogate models, the computational burden of approximating the TAC can be neglected. After generating and evaluating a sufficiently large number of long-term scenarios, we conduct a statistical analysis to identify the best DES design alternative.

3. Case study and results

3.1. Distributed energy system design alternatives for a research campus

We apply our method in a case study adopted from the literature. In our case study, we seek to find the best DES design from a set of promising candidates to fulfill energy demands, i.e., the heating and electricity demands given in [9].

Figure 3 shows three user-defined DES design alternatives (i.e., ES1, ES2, ES3) which are to be analyzed. The designs are similar to the those obtained using an energy system design optimization in [9]. All designs include two boilers and a thermal energy storage. ES1 includes a combined heat and power (CHP) unit and a heat pump (HP), ES2 has two CHP units but no HP, and ES3 has two HPs instead.

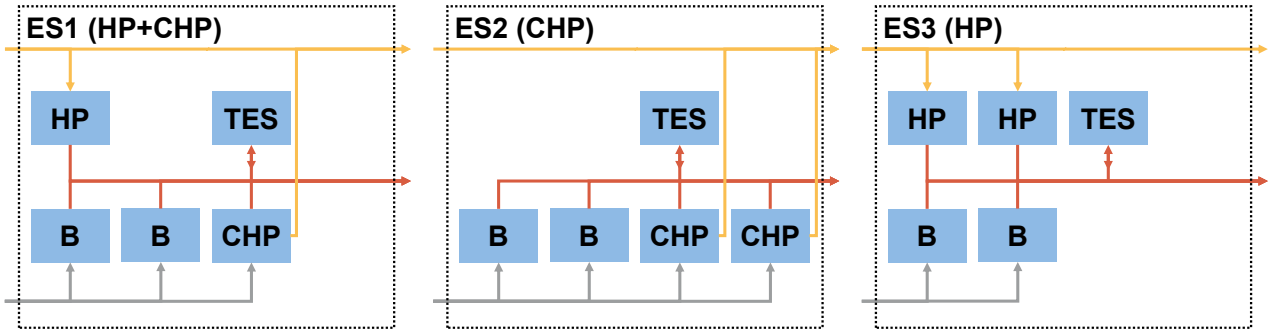

Figure 3. Promising distributed energy system design alternatives $e \in \{ES1, ES2, ES3\}$. The three designs encompass boilers (B), heat pumps (HP), combined heat and power (CHP) units, and thermal energy storages (TES) to fulfill an electricity as well as a heating demand. The systems are connected to an electricity and a natural gas grid.

Technical specifications of the conversion units are shown in Table 1. The part-load segment parameters ($\lambda_{k,\min}^{\text{in/out}}$; $\lambda_{k,\max}^{\text{in/out}} = 1$) are derived using correlations given in [9]. The thermal energy storage has for all cases a capacity of $Q^{\max} = 1000\,\text{kWh}$, charging efficiencies of $\eta^{\text{in}} = \eta^{\text{out}} = 0.95$, and a heat loss time constant of $\tau^{\text{loss}} = 200\,\text{h}$.

Table 1. Nominal power, nominal efficiency, and part-load segment parameters of the installed boilers (B), combined heat and power (CHP) units, and heat pumps (HP).

	Nominal power	Nominal efficiency	$\lambda_{k,\min}^{\text{in}}$	$\lambda_{k,\min}^{\text{out}}$
Boiler	$\dot{Q}_{\text{B}}^{\text{th}} = 530\,\text{kW}$	$\eta_{\text{B}}^{\text{th}} = 80.0\%$	0.173	0.200
CHP unit (electric)	$P_{\text{CHP}}^{\text{el}} = 380\,\text{kW}$	$\eta_{\text{CHP}}^{\text{el}} = 38.9\%$	0.582	0.500
CHP unit (thermal)	$\dot{Q}_{\text{CHP}}^{\text{th}} = 470\,\text{kW}$	$\eta_{\text{CHP}}^{\text{th}} = 48.1\%$	0.582	0.622
Heat pump	$\dot{Q}_{\text{HP}}^{\text{th}} = 200\,\text{kW}$	$COP = 2.998$	0.200	0.200

The investment costs and annual maintenance costs of each DES design alternative are determined using the cost correlations given in [9] and are shown in Table 2.

Table 2. Investment costs and annual maintenance costs of each DES design alternative.

	ES1 (HP+CHP)	ES2 (CHP)	ES3 (HP)
Investment costs $I_{0,e}$, €	383,901	551,542	216,260
Maintenance costs $OPEX_{e,a}^{\text{m}}$, €	24,331	46,089	2,574

Given the DES design alternatives, we conduct the first of the three preparation steps shown in Fig. 1: We define for each DES design an assessment metric according to Eq. (1) for a planning horizon length of $T = 10$ years. This step includes the formulation of MILPs to determine annual energy costs.

3.2. Uncertainty and surrogate modeling

Next, we present the preparation of the uncertainty and surrogate models for each DES design alternative. We start modeling uncertainty by listing all parameters influencing the assessment metric. As the designs include different components, the assessment metrics of the design alternatives depend on different sets of model parameters. Next, we identify the uncertain parameters. As the price of energy carriers can have a relevant impact in energy planning models [2], we model the gas price and the electricity price as time-dependent, uncertain parameters. Furthermore, we assume that also the heating demand and the electricity demand are relevant uncertain parameters. All other model parameters are set to appropriate constant values. Hence, due to the hourly resolution of the optimization models, a total number of $4 \cdot 8760$ parameters per year remain uncertain. We introduce three representative factors, i.e., one factor for scaling electricity prices ($\theta_{\text{c-el},a}$), one factor for scaling gas prices ($\theta_{\text{c-gas},a}$), and one factor for scaling electricity and heating demands ($\theta_{\text{d},a}$). We assign each of the $4 \cdot 8760$ uncertain parameters to one representative factor for scaling reference parameters (cf. Table 3). The representative factors serve as a low-dimensional representation of the uncertain parameters reducing the number of uncertain parameters to three per year.

Table 3. Representative factors and long-term uncertainty modeling. For all representative factors, the associated uncertain parameters of the assessment metric, the type of uncertainty, and the bounds (R_i^+, R_i^-) of the permitted range are given.

Representative factor	Associated parameters	Type of uncertainty	R_i^-	R_i^+
$\theta_{\mathrm{c-el},a}$	Hourly resolved electricity price	II (constant)	0.44	1.57
$\theta_{\mathrm{c-gas},a}$	Hourly resolved gas price	II (constant)	0.26	1.74
$\theta_{\mathrm{d},a}$	Hourly resolved electricity and heat demand	III (increasing)	0.60	1.40

We classify the representative factor $\theta_{\mathrm{d},a}$ as type III uncertainty as demand uncertainties typically increase over time. Furthermore, we assume that the demand might increase or decrease by up to 40 % over the time horizon of 10 years. This assumption results in an upper bound of $R_{\mathrm{d}}^+ = 1.4$ and a lower bound of $R_{\mathrm{d}}^- = 0.6$. We use the heating and electricity demand from [9] for defining the corresponding reference parameters. As done in [2], we assume that the accuracy of short and long-term energy price predictions is equal. Thus, we classify $\theta_{\mathrm{c-el},a}$ and $\theta_{\mathrm{c-gas},a}$ as type II uncertainties. For modeling the long-term uncertainty of the energy prices, we assume a low-price and a high-price scenario considering historical prices (cf. [14]). In the low-price scenario, we assume an average electricity price of $7.5\ \mathrm{ct/kWh}$ and a gas price of $2.5\ \mathrm{ct/kWh}$. In the high-price scenario, we assume an electricity price of $26.67\ \mathrm{ct/kWh}$ and a gas price of $17.44\ \mathrm{ct/kWh}$. We assume that within one year the energy prices remain constant. We choose the upper bound $R_{\mathrm{c-el}}^+$ such that the reference price parameters scaled with $R_{\mathrm{c-el}}^+$ result in the high-price scenario. We determine the lower bound $R_{\mathrm{c-el}}^-$ and the range of the representative factor $\theta_{\mathrm{c-gas},a}$ analogously. After defining a low-dimensional parameterization and modeling long-term uncertainty, we generate the surrogate models.

The linear surrogate models for approximating the energy costs of one year of operation are generated by first solving the respective MILPs for $N^{\mathrm{LHS}} = 25$ Latin hypercube samples and then applying linear regression to obtain the parameters of the linear surrogate models. We use Pyomo 6.4 [15,16] for modeling and Gurobi 10.0 [17] as a solver. Table 4 shows the linear surrogate model parameters for each of the DES design as well as the quality of fit given by the R^2-value.

Table 4. Linear surrogate models for approximating the annual energy costs of the energy systems. The linear surrogate models are defined by its parameters $b_{e,i}$. The coefficient of determination R^2 aids assessing the model quality.

e	$b_{e,0}$, €	$b_{e,c-\mathrm{el}}$, €	$b_{e,c-\mathrm{gas}}$, €	$b_{e,\mathrm{d}}$, €	R^2
ES1	-520,442	239,815	219,318	537,369	0.9429
ES2	-475,527	224,834	296,459	524,416	0.9617
ES3	-556,080	396,682	56,741	594,618	0.9746

Figure 4 shows by comparing observed and approximated energy costs that energy costs are predicted reasonably well by the linear surrogate models for each LHS and DES design.

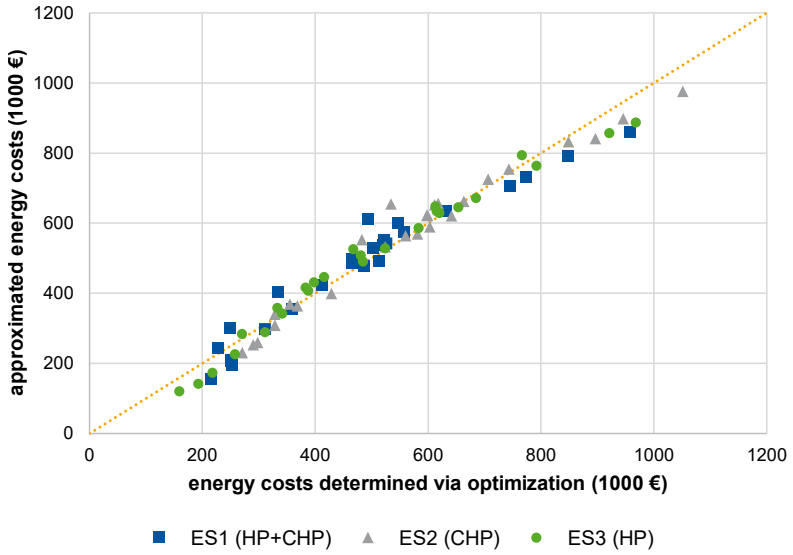

Figure 4. Scatter plot for assessing the accuracy of the three linear surrogate models based on the Latin hypercube samples. Small vertical deviations from the dotted line indicate a high approximation accuracy.

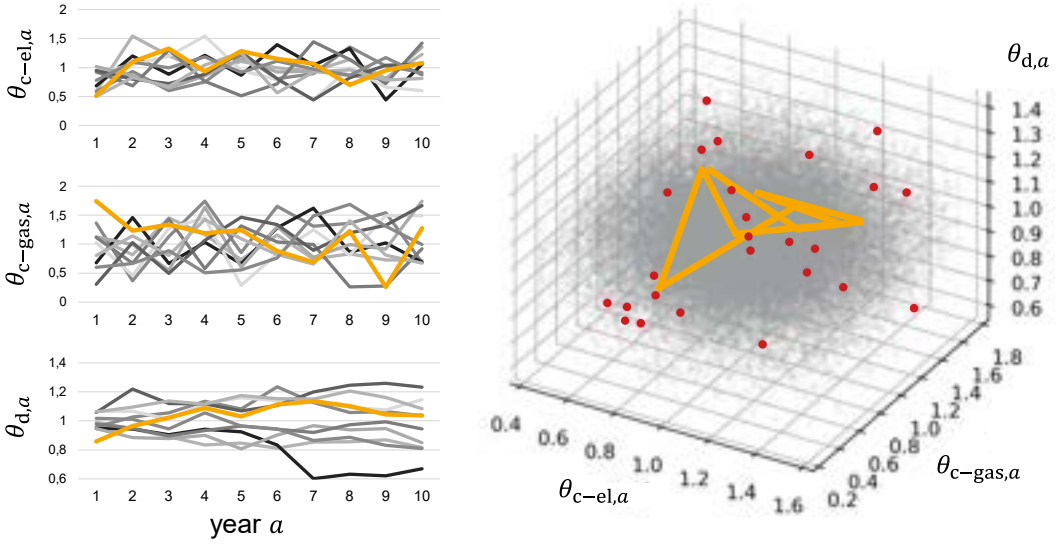
3.3. Rapid Monte Carlo analysis

The RMCA is applied employing the uncertainty and surrogate models. Our analysis is presented in three parts. First, we present the generated scenarios, which consist of $N = 5000$ long-term scenarios illustrated in Fig. 5. Next, we provide a statistical analysis from three views to evaluate the scenarios. Finally, we consider the computational burden associated with the RMCA.



(a) (b)

Figure 5. Long-term scenarios ($N = 5000$) and Latin hypercube samples ($N^{\mathrm{LHS}} = 25$). a) The subset of ten long-term scenarios showing different trajectories of the representative factors ($\theta_{\mathrm{c-el},a}$, $\theta_{\mathrm{c-gas},a}$, $\theta_{\mathrm{d},a}$). b) The parameter space is spanned by the representative factors and is densely covered by the 50,000 years contained within the long-term scenarios (small gray dots). One long-term scenario and the Latin hypercube samples are illustrated in orange and by the red dots, respectively.

We evaluate the long-term scenarios using the linear surrogate models and thus avoid solving many optimization problems with similar parameterizations. We analyze the TAC obtained for the long-term scenarios and DES design alternatives from three views. First, we analyze the distributions of the TAC for each design.

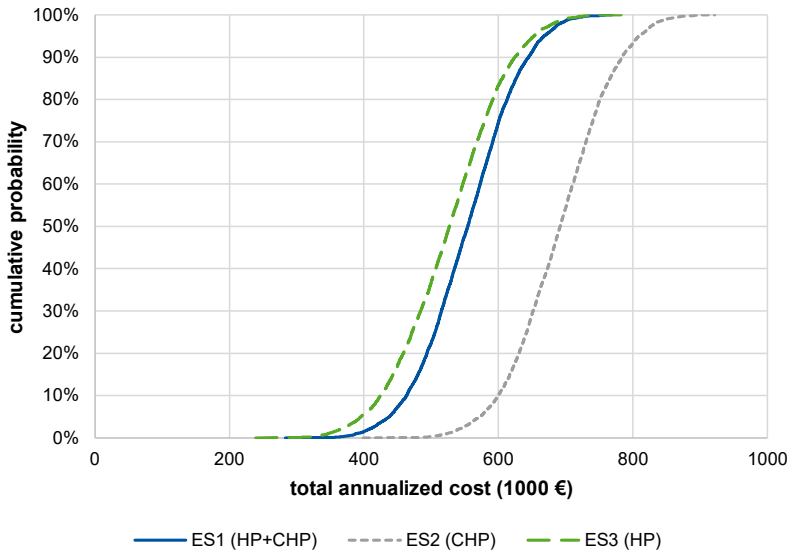


Figure 6. Cumulative probability plot for determining the probability of the total annualized cost (TAC) being lower or equal to the given TAC when choosing the respective design.

Figure 6 reveals the bandwidth of expected TAC. This view indicates that ES2 is likely to result in the highest TAC and that furthermore ES1 and ES3 lead to similar TAC. However, this visualization does not include information about the difference in TAC for specific long-term scenarios.

By comparing the TAC of the DES design alternatives in each scenario, we determine the frequency of having the lowest TAC for each design. We find that ES3 results in 87.7 % of the scenarios in the lowest TAC. In the remaining scenarios, ES1 results in the lowest TAC. However, this second view does not convey information about the differences in TAC, i.e., how high the regret is when another design would have been a better choice.

Third, we examine the differences in TAC. We normalize the differences using the expected TAC of ES3. We find that the maximal regret associated with choosing ES1, ES2, and ES3 is 19.4 %, 51.4 %, and 11.4 %, respectively. In this context, regret is defined as the difference between the TAC of the selected design and the TAC of the best design. Furthermore, we find that the average regret associated with choosing ES1, ES2, and ES3 is 5.5 %, 31.7 %, and 0.3 %, respectively. Thus, we recommend ES3 as it most likely results in the lowest TAC whereas choosing ES2 should be avoided. Overall, the different views of the statistical analysis provide insights about the probability distributions of the assessment metric. Furthermore, analyzing the differences in TAC can reveal which design should be preferred or avoided.

The computational performance of the RMCA is addressed next. Here, we use the number of MILPs to be solved as a proxy for the computational burden. We compare the RMCA to a MCA that does not employ surrogate models. When not using surrogate models, we need to solve one MILP for obtaining the energy costs for each year, scenario, and design. As a result, the computational burden increases linearly with the number of long-term scenarios. Given three DES design alternatives and a time horizon of ten years, each scenario requires solving 30 MILPs. Solving the MILPs of this work typically requires a few minutes. As MCA applied for energy system design might require hundreds of scenarios to be considered [4,5], not using surrogate models results in a significant computational burden.

Using the RMCA also requires solving MILPs. Before we can evaluate the first scenario using RMCA, we need to create the surrogate models first. We solve 75 MILPs for the three linear surrogate models in total. In comparison to solving MILPs, the computational burden of determining the parameters of the linear surrogate models and evaluating them is negligible. As a result, the RMCA is faster if three or more long-term scenarios are considered. For the considered 5,000 scenarios, the computational time is reduced by more than 99 %.

4. Conclusion

Designing distributed energy systems (DES) under uncertainty is a challenging task. One approach to address uncertainty is to use Monte Carlo analysis (MCA). However, the high computational burden associated with MCA for DES design and long planning horizons limits its application. Furthermore, MCA requires reasonable assumptions about probability distributions. To address the challenge of designing DES under uncertainty considering multi-year planning horizons, we propose a rapid Monte Carlo analysis (RMCA) approach enabled by long-term uncertainty modeling and surrogate modeling for optimization-based energy system planning under long-term uncertainty. Our method provides decision support when a set of promising DES designs is given.

To enable RMCA, three preparation steps are conducted. Firstly, an assessment metric is defined and mixed-integer linear programs (MILPs) for the operational optimization of each DES design are formulated. Secondly, a low-dimensional representation of uncertainty and a long-term uncertainty model are systematically derived. Thirdly, surrogate models are created after solving the respective MILP for representative Latin hypercube samples. The RMCA starts by generating a large number of scenarios by sampling the long-term uncertainty models. The scenarios are evaluated using the surrogate models. Subsequently, a statistical analysis reveals the expected distribution of the total annualized cost (TAC) for each design, the likelihood of a specific design resulting in the lowest TAC, and the regret of choosing one design over another.

We apply our method to a case study adapted from the literature to assess three promising DES designs for a time horizon of ten years. We formulate MILPs for the operational optimization of each DES design and represent uncertain parameters using three representative factors per year. We create accurate linear surrogate models with a coefficient of determination $R^2 \geq 0.94$ for all designs. In the RMCA, 5,000 scenarios are considered and the best design which most likely results in the lowest costs is identified. The RMCA approach is compared to a MCA that does not rely on surrogate models and thus does not require solving MILPs for representative samples but lacks the benefit of the low effort of evaluating a surrogate model. Using the surrogate models results in a speedup if three or more long-term scenarios are considered. When considering 5,000 scenarios, the computational time is reduced for the specific case study by more than 99 %.

The presented approach can be applied to a wide range of energy systems. Besides, created surrogate models could also be used in companioning sensitivity analyses, which would also benefit from the substantially reduced computational burden. The benefit of a sensitivity analysis is that it does not require information about probability distributions. For DES designs of higher complexity, nonlinear surrogate models might be required to reach a high quality of fit, increasing the effort of creating the surrogate models.

In summary, the RMCA approach enabled by uncertainty and surrogate modeling provides an efficient way of considering multiple sources of uncertainty and long planning horizons. The adaptability and the reusability of its components, i.e., of the energy system, the uncertainty, and the surrogate modeling, potentially enable wide applicability of the proposed approach for energy system design under uncertainty.

Coupling system dynamics model and multi-criteria analysis for a sustainability assessment of a district heating system's development

Janis Edmunds Daugavietis, Jelena Ziemele*

Institute of Microbiology and Biotechnology, University of Latvia, Jelgavas Street 1, Riga LV-1004, Latvia

**Presenter and corresponding author: jelena.ziemele@lu.lv, +371 29120969*

Abstract:

The study provides the hybrid model that couples system dynamics (SD) modelling and multi-criteria analysis. The SD model allows obtaining energy, economic, environmental indicators of a DH company and evaluating its dynamics in a time horizon until 2050. Considered decarbonization scenarios include the transition of the DH system towards a 4th generation DH (4GDH) system adhering to 4 strategies: the DH system uses at least (a) 50% RES; (b) 50 % waste heat, (c) 75 % cogenerated heat or (d) 50 % of combined aforementioned energy and heat. In addition, the development scenarios include various energy efficiency improvement measures on the consumer side and in the heating networks. The sustainability of each scenario was assessed with multi-criteria analysis methods - TOPSIS. The hybrid model provides a ranking of the selected transition pathways according to their sustainability score and benchmarks results of developed scenarios against a carbon neutral DH system. This model serves as a guidance to DH system developers and decision makers. The case of Riga is presented in the study.

Keywords:

4th generation district heating, Decarbonisation, District heating system, Multi-criteria Decision Analysis, sustainability assessment, TOPSIS

1. Introduction

The district heating sector is responsible for a large share of greenhouse gas emissions. The environmental impact along with economic and technical limitations is increasingly looked as a key factor in decision making in development of DH systems [1]. These different parameters impact the current operation of these systems and will influence them in the future because of new legislation, market trends and changing public outlook.

Dynamic energy system models are used as a decision support tool that can characterize existing and future DH systems because they are designed to simulate the behaviour of energy systems over time, considering the interactions between heat production, distribution and utilization [2]. Different development scenarios therefore can be modelled to find the technological mix fit for a sustainable DH system. Decarbonization, transition to renewable energy sources can be set as an optimizable goal for the system in year 2050 together with the expected economic considerations.

This modelling approach produces a set of possible development scenarios that each have a unique combination and degree of developed technologies. The assessment of these scenarios is essential for decision-making process and different methodologies exist for this purpose. Maigret et al. modelled the development of a carbon intensive industry and compared the possible development scenarios by their Pareto fronts [3]. Finke and Bertsch developed a method for multi-objective optimisation of energy systems and a framework for finding Pareto-optimal solutions and trade-offs between objectives [4]. While these methods can provide insights into the energy systems' technological limits and possible development scenarios, they still require a final judgment of the decision-maker. Yuan et al. coupled smart energy system simulation with multi-objective optimization tool MOPSO and multi-criteria analysis (MCA) method TOPSIS for an optimal heating strategy selection moving towards 100% renewable energy use [5]. The use of MCA methods can alleviate the burden of decision-makers as those can consider different viewpoints and conflicting objectives. That makes them ideal for DH system assessment where often clashing economic, technical, environmental and social aspects play a significant role.

MCA methods are used in the field of renewable energy policy planning include AHP, TOPSIS, WSM, ELECTRE, PROMETHEE and VIKOR [6]. In a previous study it was assessed that TOPSIS method is a

suitable MCA method for sustainability analysis of DH systems due to its relative simplicity and similar results to other methods [7].

The aim of the study is therefore to evaluate the performance of waste heat (WH), high-efficiency combined heat and power (CHP) and RES technology in the DH system by moving towards carbon neutrality in various development scenarios. Based on an algorithm that combines the SD model with the TOPSIS method, the economic, environmental and energy parameters of the DH system development scenarios were evaluated for creating decarbonization strategy of a city DH system.

2. Methods

The algorithm of the study is presented in Figure 1. A system dynamics model of a DH system is taken as a base for further optimization and development planning.

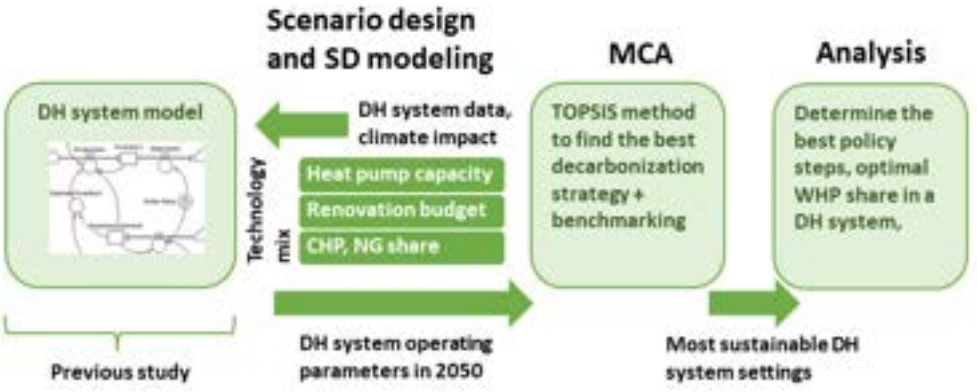

Figure 1. Algorithm of the study

Technological, climate and policy scenarios are designed based on literature review. Simulations with these scenarios and optimizable technological parameters are performed. The next step is MCA where the DH system operating parameters are assessed by the TOPSIS method to find the most sustainable technology mix within each scenario. The last step is analysis of MCA results and policy and development proposals.

2.1. DH model description for case study of DH system

In a previous study, a s SD model corresponding to the urban DH system was developed [2] and improved [1].The SD model includes all stages of DH - heat production, transmission and consumption. The model is based on the installed capacity of various technologies. Energy sources include fossil fuels (natural gas) and renewable energy sources, such as wood chips, as well as potentially developed technologies - heat recovery from treated wastewater, industrial processes, solar collectors. The DH technology block consists of eight different technologies. Heat consumption tends to decrease because of improved energy efficiency of buildings - its demand therefore can decrease by renovating buildings while also increasing due to building of new ones that correspond to the nearly zero energy standard. In addition, the possible impact of global warming on the thermal energy demand of buildings and the resulting changes in the installed capacity of DH systems with or without renovation of existing apartment buildings are evaluated to move to a sustainable 4GDH system in the long term. Table 1 shows the priority technologies in four developed scenarios clusters.

Table 1. Selection of priority technologies in various DH system development scenarios.*

Technologies	RES-NG scenarios	RES scenarios (50% renewable energy)	CHP scenarios (75% CHP& CHP priority)	WH scenarios (50% WH& WH priority)
CHP biomass	✓	✓	✓	
CHP NG	✓		✓	
HOB biomass	✓	✓		
HOB NG	✓			
Solar collectors		✓		
Large scale heat pumps		✓		✓
Heat exchangers & heat pumps		✓		✓
Wastewater heat pumps		✓		✓

* ✓ - priority technologies

The Directive on energy efficiency (2018) promotes development of technologies that allow achieving the highest cumulative end-use energy savings and lowest primary energy consumption [8]. Three scenario clusters were selected for the study considering the definition of an efficient district heating and cooling system set by the Directive 2012/27/EU: one ensures 50% of RES by using biomass as the energy source (RES); second, where 75% of heat is produced by CHPs (CHP); third that provides the use of WH in DH system. Fourth scenario cluster was considered where the DH company continued to produce part of the heat by NG (RES/NG).

2.2. Assumption and constrains of selected scenarios

The DH system of Riga city was chosen as a case study area. The initial installed capacity of the produced heat and assumptions of each development scenario is provided in Table 2.

Table 2. Current heat supply and assumption of capacity to be installed.

Scenarios	Technologies, MW							
	Boiler NG	Boiler biomass	CHP by NG	CHP by biomass	Solar collectors	Large scale HP	Industrial waste heat HP	Wastewater absorption HP (AHP)
Existing installed capacity	300*	68	47	22	0	0	18	0
RES-NG	No limit	250	No limit	No limit	19	20	14/0**	4
RES	Ban on new installations from 2025 [9]	No limit	No limit	No limit	19	20	14/0**	4
CHP	Ban on new installations from 2025 [9]	CHP priority	No limit	No limit	19	20	14/0**	4
WH	Ban on new installations from 2025 [9]	No limit	No limit	No limit	19	30	14/14**	8

*capacity of HOB by NG excluding reserve; **potential of recovered WH in DH company/ potential of recovered WH from industry

The capacity of solar collectors, large scale HP and WH shown in Table 2 are based on the technological limitations that exist in the case study area. It was assumed that solar collectors could only be installed on land belonging to the DH company (i.e. next to an existing heat source). Thus, the installed number of collectors was limited to 1,700 (approx. 21,000 m2), which corresponds to 19 MW (640 h per year). NG boilers are planned to be replaced by a large-scale HP in one of the existing heat sources, which is located on the riverbank. The use of industrial WH is currently related to the operation of condensing economizers. In all development scenarios, it is planned to expand the integration of industrial WH into DH system. The use of heat recovery from treated wastewater in Riga is limited due to the heat demands of the adjacent heating zone. It is possible to use a maximum heat capacity of 8 MW, which is much lower than the total heat potential of the treated wastewater. More details about investment and fixed O&M costs applied in the SD model can be find in previous article by Ziemele&Dace [1].

For all four scenario-clusters we applied one scenario without impact of global warming and three global warming scenarios, which include different level of representative concentration pathways (RCP) – RCP2.6 (low), RCP4.5 (medium) and RCP8.5 (high) (see Table 3). According to the selected climate change scenarios the outdoor temperature during the heating season is estimated to increase from the current +1.1 °C to 3.0, 3.4 and 4.0 °C in scenarios RCP2.6, RCP4.5 and RCP8.5, respectively. Additionally, the impact of building renovation on heat demand was evaluated. There are considered three level of renovation. The budget for building reconstruction in the selected DH area was 5.8 million EUR per year for first level, which roughly corresponds to the current financing. The depth of renovation was adopted according to national legislation, i.e. 60 kWh/m2 for heating existing apartment buildings (corresponding to class B) and 40 kWh/m^2 for heating new buildings (corresponding to class A) [10]. In addition, a scenario in which the energy efficiency policy will be implemented with acceleration and the available funding will be quadrupled is being considered.

Table 3. Description of scenarios

As a result, 36 DH's system development scenario simulation in the SD model allows obtaining input parameters to create an initial matrix for multi-criteria analysis.

2.3. Coupling system dynamics (SD) modelling and multi-criteria analysis (MCA) for DH sustainability assessment

In the framework of this study, energy, environmental and economic parameters were chosen, which fully describe the DH system transition towards decarbonization and allow to identify the most sustainable paths for the transition towards 4GDH considering various conflicting goals. Table 4 summarizes the eight identified criteria that used in the research.

Table 4. Selected criteria of multi-criteria analysis.

Type of criterion	Name of criterion	Criterion designation, unit	Criterion designation in MCA
Energy	Primary energy factor	PEF	X1
	Specific heat consumption for heating in buildings	E_{buil}, kWh/m^2 per year	X2
Environment	Avoided CO_2 emissions from DH system	SA_{CO2}, t CO_2 per year	X3
	Radiation forcing	Rad	X4

Type of criterion	Name of criterion	Criterion designation, unit	Criterion designation in MCA
	Share of renewable energy sources	Sh_{res}, %	X5
	Share of recovered heat from waste heat	Sh_{rec}, %	X6
Economy	Avoided CO_2 emissions costs	AC_{CO2}, EUR/ t CO_2	X7
	Heat tariff	T_{tot}, EUR/MWh	X8

The PEF was calculated in accordance with the ISO 5200-1:2007 [11] using the primary resource factors given in Table 2:

$$PEF = (\sum_z F_z \cdot f_{nren,j} + \sum_z F_z \cdot f_{ren,z})/Q_{con} \quad (1)$$

where F_z is the energy source (fuel, electricity) consumption in the DH system, MWh per year; $f_{nren,z}$ is the primary resource factor of non-renewable energy of z^{th} sources; $f_{ren,z}$ is the primary resource factor of renewable energy of zth resources. The study uses the primary resource factors according to ISO 52000-1:2017 [11].

The calculation of CO2 emissions was done according to national legislation [12] that based on Emission factors from the IPCC methodology [13] and is part of the SD model. The avoided CO2 emissions (SA_{CO2}, %) are calculated as follows:

$$SA_{CO2} = A_{CO2_{init}} - A_{CO2_{fin}} \quad (2)$$

$$A_{CO2} = \sum_z F_z \cdot e_z \quad (3)$$

where $A_{CO2_{init}}$ is the initial amount of CO_2 emissions, t_{CO2}/yr; $A_{CO2_{fin}}$ is the amount of CO_2 emissions in end of period, t_{CO2}/yr; $\cdot e_z$ is the CO_2 emission factor for z^{th} resources.

Heat tariff in each scenario (T, EUR/MWh) is calculated using the following equation:

$$T = \sum_z T_{prod,z} \cdot \varphi_z + T_{tr} + T_s \quad (4)$$

where $T_{prod,z}$ – production tariff for j technology, EUR/MWh; φ_z – the share of z technology; T_{tr} – transmission tariff, EUR/MWh; T_s – sales tariff, EUR/MWh.

Investment and O&M costs for the technologies used in this study were assumed according to data reported in previous studies by the authors. [1]. For instance, investments for constructing wood chips CHP are 3000/2500 kEUR/MW_e for 2020/2050 years, but for wood chips boiler - 350/300 kEUR/MW_{th} for 2020/2050 years [14].

The values of these criteria for each scenario were used to create a decision matrix (Equation (Eq.5) and were normalized according to the linear 'Max' method (Eq.6 and 7).

$$\begin{array}{c} \\ A_1 \\ A_2 \\ \vdots \\ A_{11} \\ \vdots \\ A_{36} \end{array} \begin{array}{c} \begin{array}{cccccccc} X_1 & X_2 & X_3 & X_4 & X_5 & X_6 & X_7 & X_8 \end{array} \\ \begin{bmatrix} x_{11} & x_{12} & x_{13} & x_{14} & x_{15} & x_{16} & x_{17} & x_{18} \\ x_{21} & x_{22} & x_{23} & x_{24} & x_{25} & x_{26} & x_{27} & x_{28} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ x_{111} & x_{112} & x_{113} & x_{114} & x_{115} & x_{116} & x_{117} & x_{118} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ x_{361} & x_{362} & x_{363} & x_{364} & x_{365} & x_{366} & x_{367} & x_{368} \end{bmatrix} \end{array} \quad (5)$$

$$r_{ij} = \frac{maxX_{ij} - X_{ij}}{maxX_{ij} - minX_{ij}} \quad (6)$$

$$r_{ij} = \frac{X_{ij} - minx_{ij}}{maxX_{ij} - minX_{ij}} \quad (7)$$

where r_{ij} – normalized value of criterion x_{ij}; $maxX_{ij}$ – maximal value of the criterion; $minX_{ij}$ – minimal value of the criterion; X_{ij} – criterion value; I – number of alternatives; j – number of criteria.

The set of weights was calculated taking into account the dispersion of the input data and using the entropy method [15]:

$$p_{ij} = \frac{r_{ij}}{\sum_{i=1}^{m} r_{ij}} \; i = 1, \dots, m; \qquad j = 1, \dots, n \tag{8}$$

$$E_j = -\frac{\left(\sum_{i=1}^{m} p_{ij} \ln(p_{ij})\right)}{\ln(m)} \qquad j = 1, \dots, n \tag{9}$$

$$w_j = \frac{1 - E_j}{\sum_{i=1}^{n}(1 - E_j)} \quad j = 1, \dots, n \tag{10}$$

where r_{ij} – normalized value of criterion x_{ij}; E_j – information Entropy method; w_j – Entropy method weight.

The scenario ranking was done by the TOPSIS method. It is a MCA method that finds the ranks scenarios by calculating their closeness to an imaginary positive ideal scenario. It is done by weighting the input matrix (Eq.11), finding the positive and negative ideal scenarios (Eq.12 and 13) and the closeness of each scenario to the ideal scenario (Eq.14).

$$v_{ij} = w_j r_{ij} \tag{11}$$

where r_{ij} - normalized value of criterion x_{ij}, w_j – weight of criterion j, v_{ij}- the weighted normalized value of criterion x_{ij}.

$$S_i^+ = [\sum_{j=1}^{n} (v_{ij} - v_j^+)\,]^{1/2} \tag{12}$$

$$S_i^- = [\sum_{j=1}^{n} (v_{ij} - v_j^-)\,]^{1/2} \tag{13}$$

(S_i^+) – positive ideal scenario, (S_i^-) – negative ideal scenario, v_{ij} – weighted normalized value of alternative i with respect to criterion j; v_j^+ – maximal normalized value with respect to criterion j; v_j^- – minimal normalized value with respect to criterion j.

$$C_i^* = \frac{S_i^+}{S_i^+ + S_i^-} \tag{14}$$

where C_i^* – closeness to the ideal scenario.

2.4. Analysis

The results of the MCA can be expressed as a ranking of the technology combinations from best to worst for each of the climate scenarios. At first, the effect of different weights is evaluated. The best method for weight determination is then chosen. The most sustainable technology mixes for each of the climate scenarios are compared by determining trade-offs between the economic, technical and environmental parameters. The further choice of the development strategy of the DH company is made based on the policy makers' opinion of preference regarding the design of the DH company and its development strategy and based on balancing the components of the energy trilemma: economic feasibility, environmental sustainability, and security of energy supply.

3. Results and discussion

3.1. Results of MCA

The multi-criteria analysis includes 36 different scenarios for the development of the DH system, which differ in the amount of renovation of buildings, the mix and share of heat energy production technologies and outdoor air temperature during the heating season due to climate change (see assumption in table 2 and 3). The initial matrix of criteria of the multi-criteria analysis presented in Table 5.

Table 5. Multi-criteria analysis decision matrix.

*scenarios with global warming RCP2.6 marked in bold

To achieve the highest degree of decarbonization, each criterion ought to be either minimized or maximized (table 5 – optimal value), thus creating a multi-objective optimization task.

Considering that the common trends of clusters of different global warming scenarios (RCP2.6, RCP4.5 and RCP8.5) are similar, scenarios with the level of representative concentration pathways RCP2.6 are analysed below. The sustainability of a DH system is determined by the optimal values of eight criteria, which tend towards the maximum (avoided CO_2 emissions from DH system, share of renewable energy sources, share of recovered heat from waste heat) or minimum values (primary energy factor, specific heat consumption for heating in buildings, radiation forcing, avoided CO2 emissions costs, heat tariff). The table 5 shows that more optimal criteria values are provided by the scenarios in which the waste heat is integrated into the DH system. Determining the sustainability of other scenarios is not straightforward, because, for example, scenario CHP/1/RCP2.6 compared to scenario RES/1/RCP2.6 achieves the biggest share of RES and most avoided CO2 emissions, but the heat tariff and avoided CO2 emissions costs are higher. The TOPSIS multi-criteria analysis method was used for sustainability evaluation of different scenarios the TOPSIS method was used.

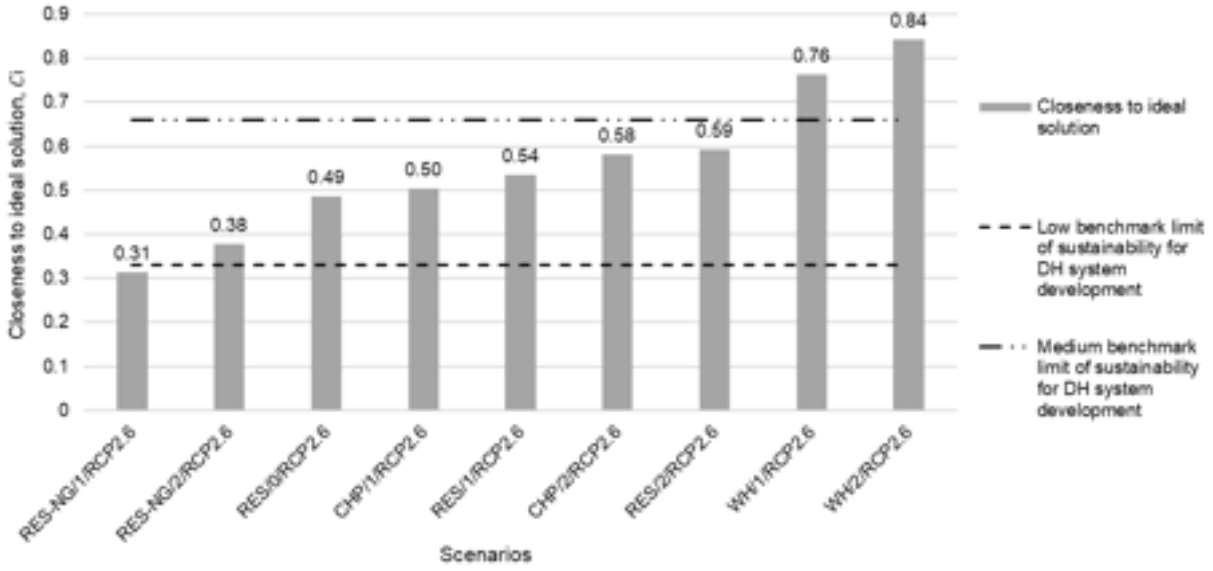

Figure 2. Results of sustainability assessment of DH development scenarios.

Figure 2 depicts the results of the multi-criteria analysis, which shows the ranking of all scenarios from the least sustainable to the most sustainable by expressing the closeness to the most ideal (sustainable) scenario.

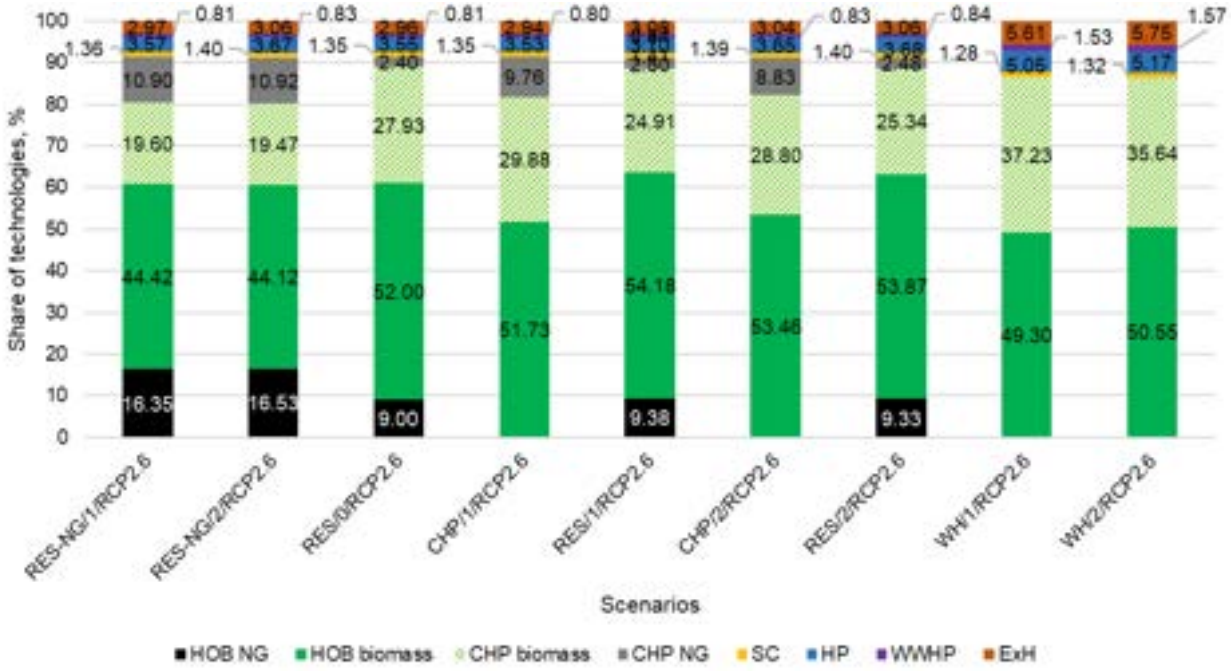

Figure 3. Share of technologies in different development scenarios in 2050.

The graph also includes low and average benchmark limits of sustainability for DH system development. The decarbonized scenarios, which characterize the sustainability vision, are defined by the penetration of several sustainable technologies in the DH system. Therefore, one of the main criteria determining the placement of the DH system's development scenario in the limits of the low, medium, or high level of sustainability is the mix of technologies used in heat energy production.

Figure 3 depicts share of technologies in all researched development scenarios. The scenarios in which the DH company continues to use natural gas in boilers and cogeneration plants show less sustainable results of performance. For example, scenarios RES-NG/1/RCP2.6 and RES-NG/2/RCP2.6 show the lowest sustainability level of the DH system performance (closeness to ideal solution - 0.31 and 0.38 for scenario RES-NG/1/RCP2.6 and RES-NG/2/RCP2.6, respectively), because in these scenarios the share of natural gas technologies is the highest and achieve approximately 27%. As described above, the highest level of sustainability is shown by scenarios (WH/1/RCP2.6 and WH/2/RCP2.6) that use RES for heat production, but also envisage the integration of waste heat into the DH system. Parameters of the closeness to ideal solution are 0.76 and 0.84 for these scenarios respectively. Six scenarios are within medium sustainability. Competing among these scenarios are scenarios that envisage CHP technology as a priority (CHP/1/RCP2.6 and

CHP/2/RCP2.6) and scenarios in which the RES is used in biomass chips (RES/1/RCP2.6 and RES/2/RCP2.6). Even though the CHP/1/RCP2.6 and CHP/2/RCP2.6 scenarios have higher avoided CO_2 emissions (109,744 tCO_2/year and 113,323 tCO_2/year) compared to RES/1/RCP2.6 and RES/2/RCP2.6 scenarios (107,330 tCO_2/year and 109,222 tCO_2/year), the latter generally show the best sustainability (closeness to ideal solution - 0.54 and 0,59 opposite 0.5 and 0.58), because the heat tariff and the cost of avoided CO_2 emissions are the lowest in them. Higher costs in scenarios that prioritize CHP technology are determined by the relative cost of these technologies compared to boilers (see chapter 2.3).

3.2. Results of decarbonization assessment of DH development

The choice of heat production technologies and related fuels determines the amount of CO2 emissions that will be emitted and the costs of these technologies. As a result, the costs of avoided emissions are calculated, which are then compared with CO_2 emission quotas.

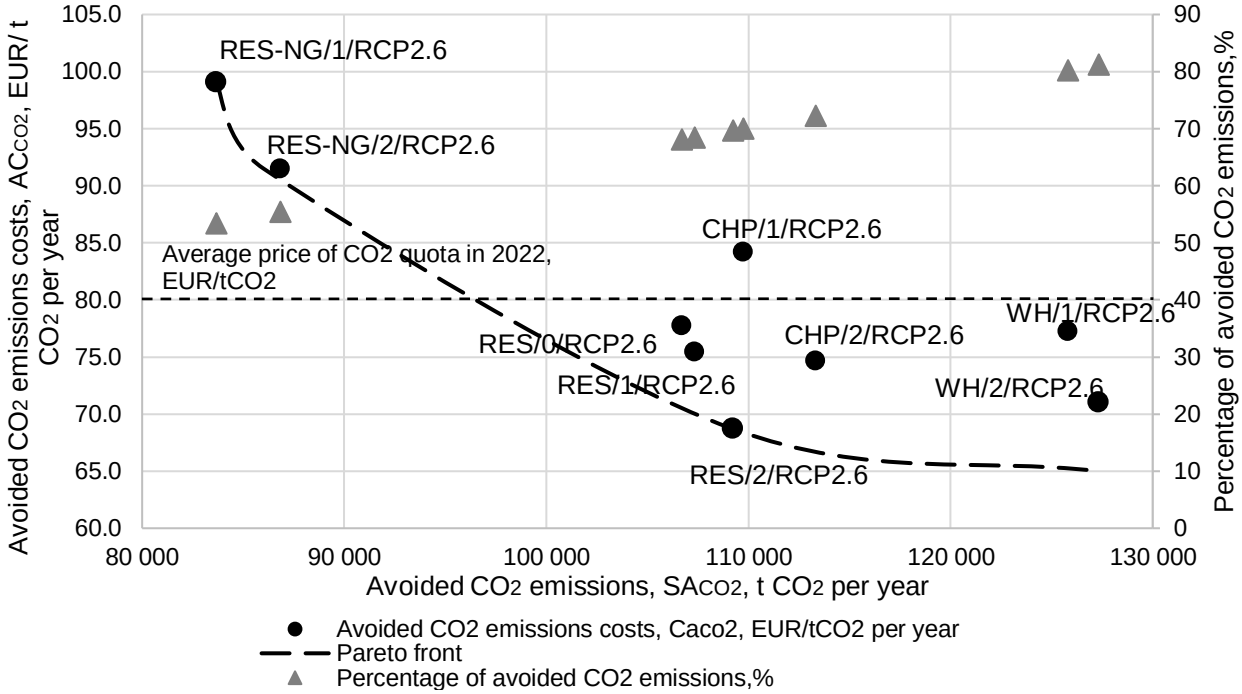

Figure 4. The corelation between the avoided CO_2 emissions costs and the amount of avoided CO_2 emissions.

Figure 4 shows the corelation between the avoided CO_2 emissions costs (economy criteria) and the amount of avoided CO_2 emissions (environmental criteria) and is based on one-objective optimization, where the economic objective function includes both the amount of avoided emissions and also indirectly used heat production technologies, that are strongly connected with the energy parameters of heat production. As a result, we can conclude that acquired dependence characterizes both environmental and economy criteria and indirectly also energy. A Pareto front limits the potentially possible solutions of DH development scenarios, in which we will be able to achieve the maximum amount of avoided CO_2 emissions by lowest their cost. Despite the fact that both scenarios including waste heat integration into the DH system have the highest closeness to the ideal solution, they ensure the highest amount of avoided CO_2 emissions (125,800 tCO_2/year and 127,311 tCO2/year for scenarios WH/1/RCP2.6 and WH/2/RCP2.6 respectively). The costs of avoided CO_2 emissions are not the lowest because the implementation of scenarios with waste heat need installation of heat pump technologies with relatively higher investment comparison to biomass boilers. Nevertheless, both scenarios (WH/1/RCP2.6 and WH/2/RCP2.6) allow to achieve the highest CO_2 emissions reduction and, as a result, a higher level of DH system decarbonization – 80.3% and 81.2%. The lowest costs of avoided CO2 emissions are in scenarios RES/1/RCP2.6 and RES/2/RCP2.6. These are 75.45 and 68.70 EUR/tCO_2 per year in scenarios respectively. The DH system decarbonization level in these scenarios is lower and achieve just 68.5 and 69.7 for these scenarios. The indicators of the worst-case scenarios coincide with the results of the multi-criteria analysis and provide only 53.4% and 55.4% reduction of CO_2 emissions (RES-NG/1/RCP2.6 and RES-NG/2/RCP2.6). The price level of quotas of CO_2 emissions in 2022 was 80.6 EUR/tCO_2 [16]. This price could be an additional argument for decision makers by choosing the implementation of a specific scenario.

4. Conclusions

The paper presents an evaluation of the DH systems' transition towards carbon neutrality by the implementation of WH and by using AHP, high-efficiency CHP and RES technology in various development scenarios. Based on an algorithm that combines the SD model with the TOPSIS method, the economic,

environmental and energy criteria were considered, and development scenarios were evaluated to find the best decarbonization strategy for the DH system of Riga.

The application of MCA allows to determine the closeness of each specific DH system development scenario to the ideal solution considering eight energy (Primary energy factor, specific heat consumption for heating), environmental (avoided CO_2 emissions from DH system, radiation forcing, share of renewable energy sources, share of recovered heat from waste heat), and economy (avoided CO2 emissions costs and heat tariff) parameters. The result of the multi-criteria analysis is a list of scenarios sorted in one of three sustainability classes: high, medium, or low.

The highest level of sustainability is shown by scenarios WH/1/RCP2.6 and WH/2/RCP2.6 that use 100% RES for heat production including approximately 7% of waste heat integration into the DH system. Parameters of the closeness to ideal solution are 0.76 and 0.84 for these scenarios respectively. These scenarios allow to achieve the highest CO_2 emission reduction by 80.3% and 81.2% (WH/1/RCP2.6 and WH/2/RCP2.6 respectively).

The correlation between the avoided CO_2 emissions costs and the amount of avoided CO_2 emissions is presented and provides one-objective optimization. A Pareto front depicts the potentially possible solutions of the DH development scenarios, in which the maximum amount of avoided CO_2 emissions can be achieved with the lowest cost. The lowest costs of avoided CO_2 emissions can be achieved in scenarios RES/1/RCP2.6 and RES/2/RCP2.6, there are 75.45 and 68.70 EUR/tCO_2 per year, for abovementioned scenarios respectively.

The hybrid model provided in this paper couples SD modelling and multi-criteria analysis and allows, on the one hand, the ranking of the selected transition scenarios according to their sustainability score and, on the other hand, to benchmark the results of developed scenarios against a carbon neutral DH system. In the future, decision makers can evaluate strengths and weaknesses in each case of specific scenarios.

Integration of Life Cycle Impact Assessment in Energy System Modelling

Jonas Schnidrig [a,b] (CA), Justine Brun [b], François Maréchal [b] and Manuele Margni [a]

[a] University of Applied Sciences Western Switzerland (HES-SO), Sion, Switzerland, jonas.schnidrig@hevs.ch
[b] Ecole Polytechnique Fédérale de Lausanne, Sion, Switzerland

Abstract:
The Paris agreement is the first-ever universally accepted and legally binding agreement on global climate change. It is a bridge between today's and climate-neutrality policies and strategies before the end of the century. However, government and private companies still struggle to develop cost-effective carbon-neutral strategies. Energy system modeling has proved essential in creating strategies to generate carbon-neutral scenarios under minimal costs.
However, cost minimization does not necessarily lead to publicly acceptable solutions nor generate configurations that minimize environmental impacts.
Here we show a methodology to integrate LCIA indicators in an energy system model, assessing the impact of energy system configurations on economic and environmental aspects.
Here we show a methodology to integrate life cycle assessment metrics in an energy system model to account for (i) emissions and impacts beyond the operation of the energy system itself and (ii) identify configurations optimizing both economic and environmental aspects. The model is applied to the case study of Switzerland and shows that with little modifications to the energy system configuration, carbon neutrality can be reached under the cost minimization objective while identifying trade-offs with other environmental issues.
This work allows the generation of MOO of energy systems, minimizing burden shifting of environmental impacts and generating robust solutions for the energy transition, increasing social acceptance towards the biggest challenge of the 21st century.

Keywords:
Energy System, LCA, LCIA, Multiobjective optimization, Renewable Energy

1. Introduction

1.1. Background

With the increasing strength and frequency of climate change events, the urgency to mitigate climate change impact is ever so important as today.
The IPCC reports highlighting the importance of the international coalition to reduce GHG from human activities to limit global warming to 1.5 - 2°C, compared to pre-industrial levels.
As a response, the Paris Agreement, resulting from the COP21 in 2015, required all signers to submit ever more ambitious NDC every five years, listing mid and long-term emissions reduction objectives.
Companies, such as [1] and IRENA, evaluate whether NDCs are on track with the 1.5 - 2°C scenarios and advise countries for improvement.
Interest in energy system modeling has increased due to growing concern for sustainable development and the transition towards renewable energies.
LCA, which studies other environmental impacts, such as ozone layer depletion or particulate matter formation, has also grown exponentially in the past two decades [2].
When planning for a low-carbon energy system, one has to consider other impacts of AoP to monitor potential environmental burden shifting. Thus, this project's methodology aims to integrate LCA and LCIA within Energy System Modelling to monitor and optimize climate change impacts, human health, and ecosystem quality.

1.2. Literature review

In addition to the economic optimization classically used in energy system designs and operations, the focus on Life Cycle Analysis calculation is rapidly gaining momentum. While LCA is mainly applied to small-scale technologies [3–5], more complex systems such as processes [6], plants [7] and buildings [8] were analyzed in recent years. This evolution depicts a will to shift from small-scale towards bigger-scale energy systems. Small-scale systems are optimized on multi-objective functions (OF), integrating economic and environmental impacts. On the contrary, more extensive systems assess LCA indicators, using either post-calculation or solely focusing on the Climate Change indicator, which represents emissions of GHG emissions.

Therefore, energy system modeling at regional and national levels is currently based on economic optimization, while LCA indicators take a secondary place. [9] assessed the impact of a biomass-based energy system in Europe while optimizing the economic OF and monitoring LCA indicators with post-calculation on the energy system structure. [10] analyzed the electricity demands of the German energy system, focusing on the MOO of economic and Climate Change OFs.
A global energy system model has been developed by [11], generating robust solutions by optimizing the Swiss energy system on economic and environmental aspects by integrating the climate change indicator. [12] went one step further by not only assessing the climate change indicator but integrating the carbon mass flow conservation to the model by Moret.

While LCA optimization is a hot topic in current research, none of the previously cited literature integrates at the same time (i) the generation of a national model with all global energy demands, (ii) the direct optimization of multiple AoP within one model, (iii) and uncertainty.

1.3. Objectives and contribution

This project is based on ES using MILP to define a Swiss energy model through point-average consumption assumption [13]. It is also based on integrating LCA endpoint indicators for environmental impact optimization over three different AoP to compare resulting energy systems with purely economic optimization [14]. The goal is to analyze Switzerland's potential to decarbonize its energy system by 2050 while accounting for other environmental impacts and avoiding shifting the environmental burden.

Several research questions have been identified to tackle this project, which can be divided into three central problems.

- Single-objective optimization of LCA impacts in energy systems modeling
- MOO of LCA impacts in energy systems modeling
- Application of regional LCA modeling to the Swiss energy system

These questions will be treated by answering the following questions:

- How to characterize technologies in LCA?
- How to integrate LCIA in energy systems modeling?
- How to monitor LCA indicators in energy systems modeling and assess the resulting system's performance?
- Does a low-carbon Swiss energy system lead to environmental impact shifting?
- What is the effect of MOO on the energy systems configuration?

2. Methodology

2.1. Modelling Framework

Integrating LCIA in energy system modeling has been accomplished by Brun et al. [14], adapting the existing MILP EnergyScope framework developed by Moret et al. [11], Li et al. [12] and Schnidrig et al. [13]. *EnergyScope* models a global multi-energy model at a monthly averaged basis under the constraint of mass and energy conservation between demands and resources. The demands are categorized into four sectors (households, services, industry, and transportation) and three energy demand types: (i) electricity at four voltage levels, (ii) heat distinguished between process heat, space, and water heating, and (iii) mobility split in passenger and freight mobility. The resources are either available within the studied region or imported from outside. ES is written as MILP Problem in AMPL and optimizes the configurations, which are determined through the key decision variables $\mathbf{F}$ and $\mathbf{F_t}$, modeling the installation size and the temporal use of the technologies.

2.1.1. Economic objective

The primal OF of EnergyScope has been previously the total cost $\mathbf{C_{tot}}$ (Eq. 1). The total cost is calculated as the sum of the technologies' ($tec \in \mathcal{TEC}$) annualized investment $\mathbf{C_{inv}}$ and maintenance $\mathbf{C_{maint}}$ (Eq. 3) cost affected by $\mathbf{F}$, and the temporary variable as of the resources ($res \in \mathcal{RES}$) operation cost $\mathbf{C_{op}}$ (Eq. 4).

$$\mathbf{C_{tot}} = \sum_{tec}(\mathbf{C_{inv}}(tec) \cdot \tau(tec) + \mathbf{C_{maint}}(tec)) + \sum_{res} \mathbf{C_{op}}(res) \tag{1}$$

$$\mathbf{C_{inv}}(tec) = c_{inv}(tec) \cdot (\mathbf{F}(tec) - f_{ext}(tec)) \tag{2}$$

$$\mathbf{C_{maint}}(tec) = c_{maint}(tec) \cdot \mathbf{F}(tec) \tag{3}$$

$$\mathbf{C_{op}}(res) = \sum_{t} c_{op}(res) \cdot \mathbf{F_t}(res, t) \cdot t_{op}(t) \tag{4}$$

$$\forall \quad res \in \mathcal{RES},\ tec \in \mathcal{TEC},\ t \in \mathcal{PERIODS},$$

2.1.2. Carbon emissions objective

Li et al. [12] integrated the carbon balance and thus the resulting net emissions secondary objective, measured by the CO_2 equivalent **Emissions**. These emissions are modeled by considering technology-specific layers containing CO_2. The different CO_2 layers are categorized into five classes $c \in \mathcal{C} - \mathcal{LAYERS}$ (captured, sequestrated, stored, emitted to atmosphere). The technology conversion factor η [tCO_2/GWh] is valid for all periods t (Eq. 5) and is either positive or negative, allowing to model net emission limits ϵ (Eq. 6).

$$\mathbf{Emission}(t) = \sum_{tec} \mathbf{F_t}(tec) \cdot t_{op}(t) \cdot \eta(i, c) \quad \forall \quad tec \in \mathcal{TEC}, t \in \mathcal{PERIODS},\ c \in \mathcal{C} - \mathcal{LAYERS} \tag{5}$$

$$\sum_{t} \mathbf{Emission}(t) \leq \epsilon \quad \forall \quad tec \in \mathcal{TEC}, t \in \mathcal{PERIODS} \tag{6}$$

2.1.3. LCIA objectives

The environmental OF variable $\mathbf{LCIA_{tot}(i)}$ is constructed by combining the total cost composition, splitting in a constant (investment) and variable (operation) part and the technology-specific impact of the carbon flow model, where the impact of resources is integrated into the use of technologies: For each indicator i (Eq. 7 & table 3), $\mathbf{LCIA_{tot}(i)}$ is defined as the construction of the technology related to the installation size $\mathbf{F}$ (Eq. 8), and the operation of the technology proportional to its use $\mathbf{F_t}$ (Eq. 9). Finally, the construction impact is divided by the technologies' lifetime n.

$$\mathbf{LCIA_{tot}}(i) = \sum_{tec}(\mathbf{LCIA_{constr}}(i, tec) \cdot \frac{1}{\boldsymbol{n}(i)} + \mathbf{LCIA_{op}}(i, tec)) \tag{7}$$

$$\mathbf{LCIA_{constr}}(i, tec) = lcia_{constr}(i, tec) \cdot \mathbf{F}(tec) \tag{8}$$

$$\mathbf{LCIA_{op}}(i, tec) = lcia_{op}(i, tec) \cdot \sum_{t} \mathbf{F_t}(res, t) \cdot t_{op}(t) \tag{9}$$

$$\forall \quad i \in \mathcal{IND},\ tec \in \mathcal{TEC},\ t \in \mathcal{PERIODS},$$

2.2. Life Cycle Impact Assessment

LCA aims to evaluate the environmental impacts of a product throughout its life cycle. The approach usually considered is the cradle-to-grave, which starts with the extraction of raw materials and ends in the disposal of the product through recycling, landfill, or incineration. The fur stages of LCA consist of [15] (i) Definition of goal and scope phase, (ii) item Life cycle inventory (LCI) phase, (iii) Life cycle impact assessment (LCIA) phase, and (iv) Interpretation phase

2.2.1. Definition of goal and scope

Each technology is characterized separately to integrate an LCIA into the energy system model correctly. Every technology is defined by two products, one related to its construction and one for its operation, modeling the cradle-to-grave approach. Their functional units depend on the end-use categories the technology belongs to, where their units are reported in table 1.

2.2.2. Life cycle inventory

The LCI was computed using a matrix approach instead of a sequential one. The matrix method easily integrates feedback loops in product systems and avoids the explicit computation of scaling factors when the final demand vector f is known (Table 2).
The technology matrix A defines the exchanges between products. Its columns represent products, processes,

Table 1: Functional unit of the ES technologies' operation and construction products, depending on the end use category it belongs to.

End use categories	Unit of the technologies	
	Operation	**Construction**
Electricity	GWh	GW
Heat (low and high temperature)	GWh	GW
Mobility freight	Mtkm	$\frac{\text{Mtkm}}{h}$
Mobility passenger	Mpkm	$\frac{\text{Mpkm}}{h}$

or services, with each row representing its respective input or output. A is square, and its columns are linearly independent; thus, it is invertible. The matrix F defines the elementary flows for each process related to direct emissions. Both matrices are defined inside the Ecoinvent database [16]. The final demand f was defined as an all-ones vector; thus, the LCI represents each specific technology's total emissions per functional unit (table 1). The scaling factor vector s and the life cycle inventory vector g are defined as follows:

$$s = A^{-1} \cdot f \tag{10}$$

$$g = \text{LCI} = F \cdot s = F \cdot \left(A^{-1} \cdot f\right) \tag{11}$$

Table 2: Notation used in the life cycle inventory phase of the LCA

Notation	Name
A	Leontief technology matrix
F	Matrix of elementary flows
f	Final demand
s	Scaling factor
g	Life cycle inventory

2.2.3. Life cycle impact assessment

Seventeen mid-point indicators are categorized as endpoint levels into three main AoP for the LCIA: HH, EQ, and CC. Twenty-three endpoint indicators were considered in the matrix IW^+, based on the impact assessment method IMPACT world+ [17] (table 3). IW+ is multiplied by the LCI g to get the impact result matrix R:

$$R = \text{IW}^+ \cdot g \tag{12}$$

2.2.4. Technology characterization

EnergyScope was run on a national scale on economic optimization to identify which technologies to characterize in LCIA, allowing to make a trade-off between characterization time and methodology development.
Data collection was then performed, mainly with the Ecoinvent 3.8 database. The tools used to create the Leontief matrix A and the elementary flow matrix F directly from the database were given by [18]. The initial Leontief matrix directly resulting from the ecoinvent database was modified as follows :

$$A_{ES}^{nxn} = \mathbf{I}^{nxn} - A_{ecoinvent}^{nxn} \tag{13}$$

n represents the total number of products in the database, and $\mathbf{I}^{nxn}$ is an identity matrix of size n to align with the convention used in ES. Namely, negative values represent input flows or products, and positive values represent output flows or products, with an all-one diagonal to yield an invertible matrix.
In EnergyScope, conversion technologies are characterized by their construction and operation impacts. A similar decomposition of impacts was used for the LCIA. First, the products representing a technology's construction and operation were identified using data collection. In LCA, the impact of a technology's operation intrinsically considers the impact of its construction. Hence, to avoid the impacts of double counting, the construction of a technology needed to be discarded from matrix A. Then, new columns and rows are added to the matrix A to create a new matrix A', illustrated in figure 1. The size of the new technology matrix and the number of operation products will increase A' characterized by n' for a final dimension of $A'^{(n+n')x(n+n')}$.

New columns are added to the emission flows matrix $F^{(fxn)}$, where f is the number of emissions flows in the database for matrix multiplication compatibility. The new columns correspond to the emission flows related to P'_{op}, which are the same as the flows of the original product P_{op}, creating the new matrix $F'^{(fx(n+n'))}$.

Table 3: Table summarizing mid- and endpoint indicators, with the respective ones used for their integration in ES and the AoP they belong to according to IMPACT World +.
The unit of the endpoint indicators is expressed in $kgCO_2$-eq for Climate Change (CC). The impact of Ecosystem Quality (EQ) is given in PDF·m^2·year, representing the Potentially Disappeared Fraction of species on a one m^2 surface during a year. Finally, the impact on Human Health (HH) is expressed in DALY, the Disability Adjusted Life-Years, representing the loss of the equivalent of one year in perfect health.

Midpoint level indicator	Endpoint level indicator	Abbreviation	AoP
Climate change	Climate change, short term	CCST	CC
Freshwater acidification	Freshwater acidification	FWA	EQ
Freshwater ecotoxicity	Freshwater ecotoxicity, short term	FWEXS	EQ
Freshwater eutrophication	Freshwater eutrophication	FWEU	EQ
Human toxicity cancer	Human toxicity cancer, long term	HTXCL	HH
	Human toxicity cancer, short term	HTXCS	HH

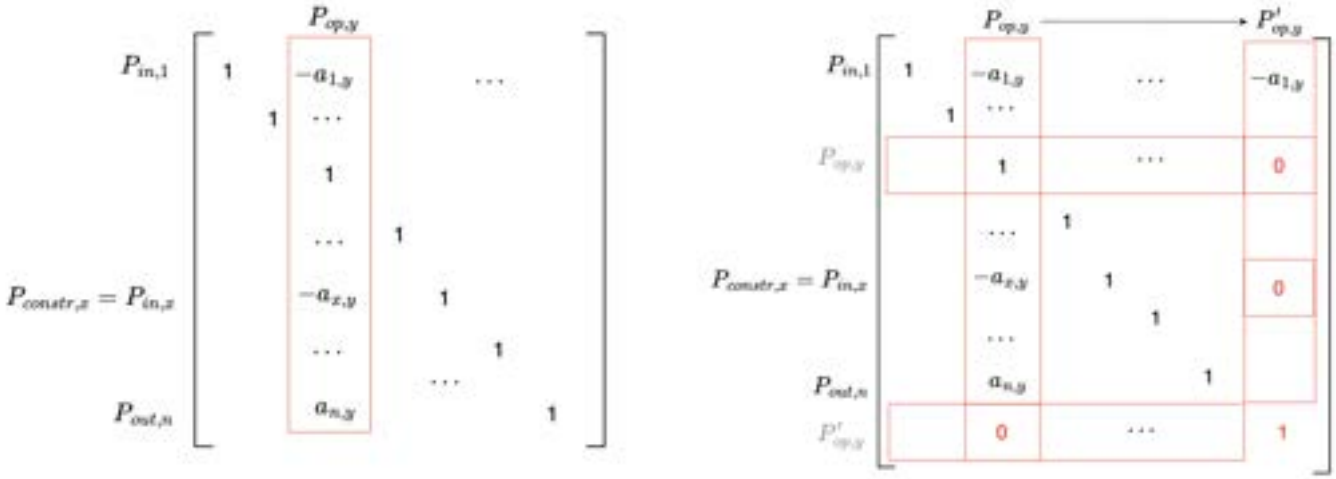

Figure 1: On the left-hand side : Initial technology matrix A^{nxn}. On the right-hand side: New technology matrix $A'^{(n+n')x(n+n')}$. n represents the total number of products in the database, and n' represents the number of conversion technologies characterized.
Example for a single technology: P_{op} represents the ecoinvent product for operating a certain technology. P_{constr} is the ecoinvent product related to the construction of the same technology. The matrix A' contains an additional column and row, with P'_{op} representing the operation of the technology while disregarding its construction, allowing later to compute the isolated impact of the operation

To assess the impact on the selected region, provincial data was selected. The following best resolution was used when unavailable: national, continental, or global. This methodology was applied to the technologies installed on economic optimization.

2.2.5. LCIA Integration in Energy System Modelling

After adding the technologies' operation products, they discarded their relations with their respective construction products (defined as P'_{op}) in the technology matrix A. Their respective LCI was computed by multiplying the new elementary flow matrix F' by the new technology matrix A'.

The subsequent step of the LCIA was to convert the emissions to their functional units (table 1.)
Most construction technologies are characterized by "units." Therefore, to convert the input-output and emissions flow to the ES functional unit, the capacity was defined as :

$$\text{Capacity} = \frac{GW^1}{\text{unit} \cdot \mathbf{c}_{p(i)} \cdot time_{tot} \cdot n_i} \tag{14}$$

[1] : [GW[] is only for electricity and heat, but [Mtkm] for freight mobility and [Mpkm] for passenger mobility.

Each technology LCI was multiplied by the impact matrix $IW+$, as in equation 12. This resulted in the impact matrix R as defined for the construction and operation per technology and region.

2.2.6. Assumptions

Regarding mobility, ecoinvent car products are defined per km. For unit conversion, 1.6 people per car are estimated for Switzerland, according to [19].

Technology maintenance and transportation impact are mainly accounted for within the operation. However, it is not always explicitly detailed. Therefore, the choice was not to isolate the technologies' maintenance and transport impacts but to keep them as part of the operational impact.

2.3. MOO

MOO (MOO) is a field of multi-criteria decision-making that deals with mathematical optimization problems in which multiple OFs must be optimized simultaneously. MOO has proven to be a valuable tool in energy planning, where the decision-maker has to select between two or more competing objectives. For example, EnergyScope traditionally optimized one OF only [11, 12, 20] or proceeded to bi-objective optimization with environomic Pareto curves generation in specific cases [19]. MOO consists of finding a single solution that fulfills the arbitrary preferences of the human decision-maker, locating a sample collection of Pareto optimum solutions, and quantifying the trade-offs involved in achieving various goals.

This work has realized the MOO by integrating the LCIA OFs $l \in \mathcal{LCIA} - \mathcal{I} \subset \mathcal{OF}$ as constraints under the economic optimization (Eq. 15), defining the technology size $\mathbf{F}$ and use $\mathbf{F_t}$. The weighting (Eq. 16) allows processing through the multidimensional Pareto-Curve in between the extreme points identified at mono-objective optimization, where $\omega(j) = 1$ and $\omega(i) = 0$, $\forall i \in \mathcal{OF} \setminus \{j\}$.

$$\min_{\mathbf{F},\mathbf{F_t}} \mathbf{C_{tot}} \tag{15}$$

$$\text{s.t.} \quad \mathbf{f_{obj}}(i) \leq \omega(i) \cdot f^{\max}_{obj}(l) + (1 - \omega(i)) \cdot f^{\min}_{obj}(l) \tag{16}$$
$$\forall \quad i \in \mathcal{OF} = \mathcal{COST} \cup \mathcal{LCIA}$$

To account for the solution space of the MOO, a Monte-Carlo approach [21] on the weights ω is applied. The decision variables define the modeled solution space under varying weighting parameters $\omega(i)$ (Eq. 17). The probability of appearance of $\omega(i)$ follows a uniform distribution U(0, 1) (Eq. 18).

$$\mathbf{F}(i), \mathbf{F_t}(i) : \quad f((\mathbf{F}(i), \mathbf{F_t}(i)), \omega(i)) \tag{17}$$
$$\text{s.t.} \quad \omega(i) = P(\tilde{\omega}, \text{U}(0, 1)) \tag{18}$$

3. Results

3.1. Case study

The methodology above is applied to the case study of Switzerland, aiming at following the energy strategy *Energieperspektiven 2050+* (EP50+) [22]. EP50+ analyzes the development of an energy system compatible with the long-term climate goal of net zero greenhouse gas emissions in 2050 while ensuring a secure energy supply without nuclear power. While EP50+ defined several variants of this scenario, differing in terms of a different mix of technologies and a different speed of expansion of renewable energies in the power sector, we consider within this study only the demands estimation, the potentials of energy vectors, and the constraints of carbon-neutrality and no nuclear power.

Demands

EP50+ decomposed the final energy demand evolution by sector in 5 years interval [22]. Taking the energy demand of 2019 [23] being split into the energy categories, allows us to extrapolate the specific energy demand by category to the sectoral energy demand estimation for 2050 (Tab. 4).

Table 4: Annual final energy demand per sector and energy type 2050.

		Households	**Services**	**Industry**	**Mobility**
Electricity LV	[GWh]	9818	9154	0	0
Electricity MV	[GWh]	0	1407	3173	0
Electricity HV	[GWh]	0	0	5350	0
Electricity EHV	[GWh]	0	0	0	0
Heat HT	[GWh]	0	183	5855	0
Heat LT SH	[GWh]	31849	6994	1965	0
Heat LT HW	[GWh]	6322	1605	393	0
Freight	[Mtkm]	0	0	0	21106
Passenger	[Mpkm]	0	0	0	74590

Potentials

We model an independent energy system, limiting the imports of any energetic vector to zero to achieve the goal of security of supply. Therefore all primary energy needs to originate from the studied region, defined by the potentials (Tab. 5). Furthermore, contrary to EP50+, we model the technical potential of the resources, as economic potential is subject to arbitrary and uncertain estimation of future renewable energy markets.

Table 5: Annual resources and renewable energy technologies potential.
The values in brackets for the hydropower technologies correspond to the potential with reinforcement.

Resources	**Waste Fossil**	**Waste Biomass**	**Wood**	**Wet biomass**	**Hydro Storage**
[GWh]	10833	8917	15278	12472	8900
Technologies	**Geothermal**	**Hydro Dam**	**Hydro River**	**PV**	**Wind**
[GW]	4.8	8.08 (8.52)	3.8 (4.65)	67	20
[GWh]	42.08	17.48	19.726	66.4	40.3

3.2. Mono-Objective Optimization

In the first step, every single OF is optimized individually, allowing to determine the maximum value $f_{obj}^{\min}$ and $f_{obj}^{\max}$ necessary for the normalization in the MOO. The tracking of the OF values on individual optimization is represented in Figure 2. For each optimization, the other OF values are at their maximum value, indicating significant differences in configurations and operations.

By digging into the energy system configurations of the respective individual optimizations via the cost composition (Figure 3), only the cost minimization is distinguished in a major way from the other configurations. The LCIA indicators minimization leads to higher investment costs at an almost equal level, similar to the observation in Figure 2). From the point of view of investments, the main difference is the deployment of massive quantities of PV, reaching the potential of PV (50 GW) in addition to geothermal electricity generation, while the wind share is reduced.

The discrepancy between wind and PV leads to a higher dephasing between the generation of electricity in Summer and consumption and winter, which affects the necessity of installing seasonal storage in the form of

Figure 2: OFs values comparison for mono-objective optimizations. Each sub-figure corresponds to an individual optimization. The height of the segments corresponds to the OF's relative variation to the 2020 reference scenarios OFs values [%].

natural gas between 7800 GWh-12 450 GWh. Hydro Dams are used in pumping and storing at their respective maximum capacity of 8900 GWh, leading to a combined maximum seasonal storage potential of up to 21 350 GWh.
The switching towards methane storage furthermore affects the service sector; on one side, while biomass still is converted in gaseous energy carriers, the excess electricity is converted into hydrogen via fuel cell technologies, such as SOEC, PEM, or Alkaline Electrolysis for a cumulative electrolysis capacity of 0.6 GW - 2.8 GW.
The additional gas production is transported in the existing methane infrastructure, while only minor investments in the construction of local Hydrogen infrastructure have to be made (0.8 GW-1.4 GW). Therefore, minimizing LCA indicators tends to limit the reinforcement of energy transportation infrastructure to a minimum.

The LCA indicators can be split into indirect (construction) and direct (operation) emissions (Figure 4), where we can identify the highest contributor sectors to the respective OFs. While cost minimization leads to a highly operation-intensive energy system environmental impact, the LCIA OF configurations have a lower impact on the operation side of the technologies and minimize the technologies' constructions individually while reaching the maximum value in the other indicators construction.
The sectors of mobility, hydropower, and electricity generation dominate the LCA indicators. The mobility sector mainly affects the operation, as technologies using methane release CO_2 in operation, which is not captured

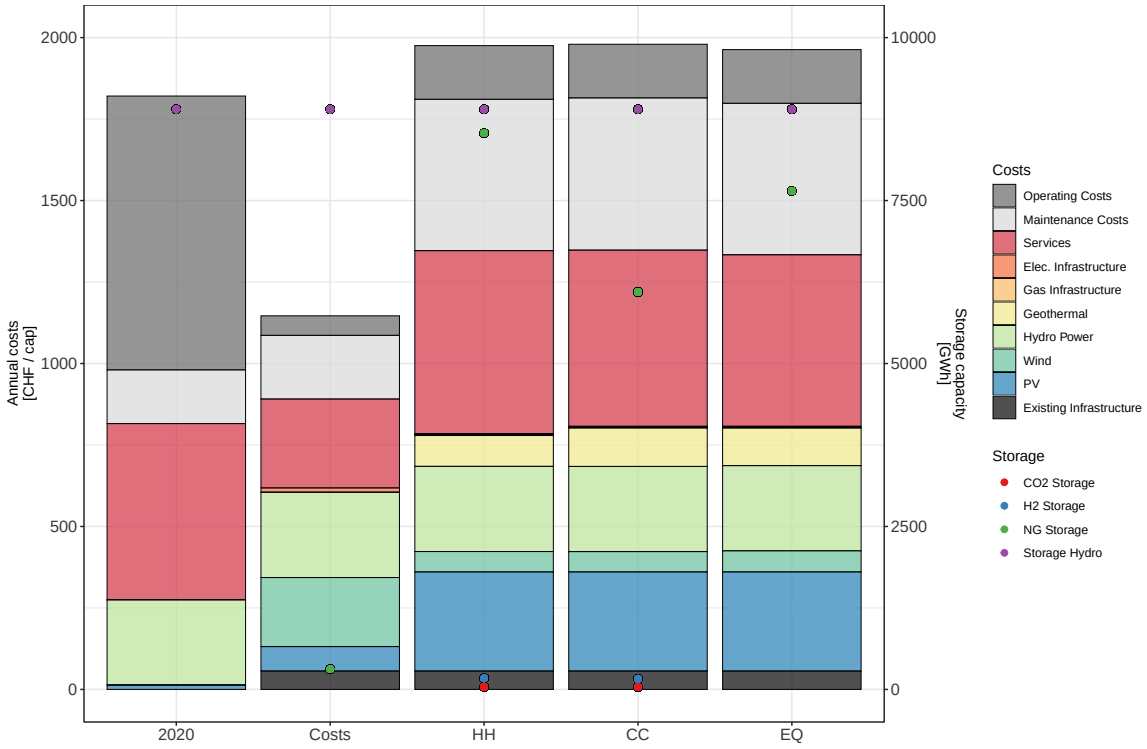

Figure 3: Total costs energy systems composition for mono-objective optimizations. The secondary axis displays the installed storage capacity. Case study Switzerland 2050 independent and CO_2-neutral, without nuclear power.

yet. Methane-powered vehicles are used for road freight transport in the cost minimization, while lower shares of methane-powered fuel cell vehicles in public transport are used in the LCA minimizations.
The hydro dam construction impact significantly impacts the EQ indicator while minimizing CC due to deploying new hydro dams. Differences in the operation between the optimizations can be explained by a different operation strategy of the hydro dams in the cost minimization scenario.
The electricity generation impact is visible on the construction side, where the impacts are shifted to minimize the respective indicator in the optimization. In this category, the concurrence between the installation of new hydro dams for CC minimization, installation of Hydrothermal gasification CHP in the HH minimization, and combined cycle gas turbines for the EQ minimization is visible, as the respective technologies have a minor impact on the specific indicator and similar impacts in the other ones.

3.3. MOO

Running the multi-objective optimization (Equation 17) 500 times results in 500 different configurations. The comparison between those configurations has been made by generating the Pearson correlation coefficient matrix of the technologies and the OFs. Figure 5 represents the main renewable energy resources installation capacities. In the upper half, clear correlations between technologies and between OFs are visible. The biggest correlation is between the OF cost and PV $r = 0.94$, indicating that further installing PV leads to higher total costs, or vice-versa; the more money is available, the more PV is installed. A high negative correlation is visible between geothermal power and wind ($r = -1$), as geothermal power is only installed as a backup to the missing wind. Lower correlations are visible between PV and EQ ($r = -0.61$) and between PV and HH ($r = -0.53$). This negative correlation can be interpreted as the lower the indicator; the more PV must be installed.
Meaningful correlations $r \geq 0.5$ between OFs can only be observed between costs and EQ ($r = -0.56$) and HH ($r = -0.55$), respectively, showing a negative correlation between the environmental indicators and the costs. The weak correlation between costs and climate change can be explained by the analyzed case study, modeling a carbon-neutral energy system, where CO_2 emissions highly contribute to the CC indicator.

The lower half represents the scatter plot of the different solutions. Observing the Pareto-front between the environmental indicators is possible when taking the total cost column. The points outside the Pareto-front are due to low weighting on the cost indicator. The strong correlation between cost and PV can be observed, as the points almost perfectly line up on $E^{PV}[\text{GW}] = \frac{20}{3}[\frac{\text{GW}}{\text{GCHF}}] \cdot C^{tot}[\text{GCHF}] - 91.7[\text{GW}]$ between 15 GW-35 GW.

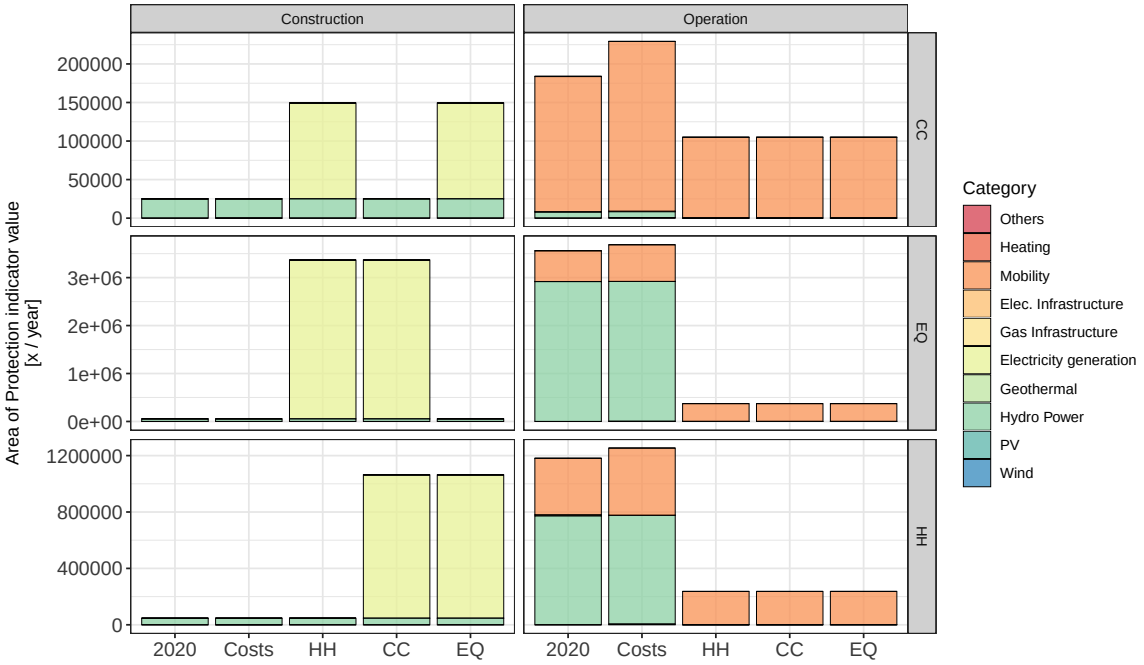

Figure 4: LCIA impacts composition for mono-objective optimizations. The secondary axis displays the installed storage capacity. Case study Switzerland 2050 independent and CO_2-neutral, without nuclear power.

Observing the other scatter point patterns in the LCA indicator columns allows us to identify the reason for the low correlation: The point distributions fill out the observed area in a well-distributed pattern, generated by the Monte Carlo method (Eq. 18).
Comparing the effect of the primary renewable resources, we can observe that PV is generating a Pareto-curve for all OFs; generating an upper border for PV, which is validated with the positive correlation, a lower horizontal border with CC and concave lower borders for the EQ and HH indicators.
Wind (20 GW) and geothermal (0 GW) are almost constant throughout the scenarios, except for only three outliers can be identified, installing 16 GW (-4 GW) of wind, which is compensated by 0.8 GW of geothermal power. This low variation also explains the low correlation validity ρ between those two technologies and the other indicators.

4. Conclusion

This work generated an LCIA database of technologies within a global energy system by characterizing over 200 technologies. This database allowed us to assess the impact of the energy system on environmental indicators by integrating their impact directly into the optimization rather than post-calculating it. The integration was achieved by splitting the LCIA impact into direct (operation) and indirect (construction) emissions related to the installation and use of the technologies within the global energy system MILP model EnergyScope.

The results have been generated by applying the framework to the case study of a CO_2 neutral and energy-independent Swiss energy system 2050. The individual optimizations show different configurations, where the economic and environmental burden is shifted to the other indicators depending on the objective. Independent of the scenario, the deployment of high shares of renewable energy in the form of PV, wind, hydropower, and biomass gasification is observed. The scenarios are distinguishing, in the end, uses sector, where different mobility types for long-distance public and freight mobility are selected: While cost-optimization prefers to reinforce the electric distribution grid, environmental aspects limit the reinforcement to a maximization of the use of existing infrastructure, leading to the gasification of the mobility sector.

The correlations between the main renewable technologies and the OFs are strongly dominated by economic optimization, drawing Pareto-fronts. The quantity of PV installed depends on the weight put on the environmental indicators, where the economic optimum is located at 16 GW. In contrast, more substantial weights on the LCA indicators lead to more deployed PV and higher costs. Wind and Geothermal energy stay constant, with some outlier exceptions ($< 0.6\%$), which needs further investigation with more runs. While low correla-

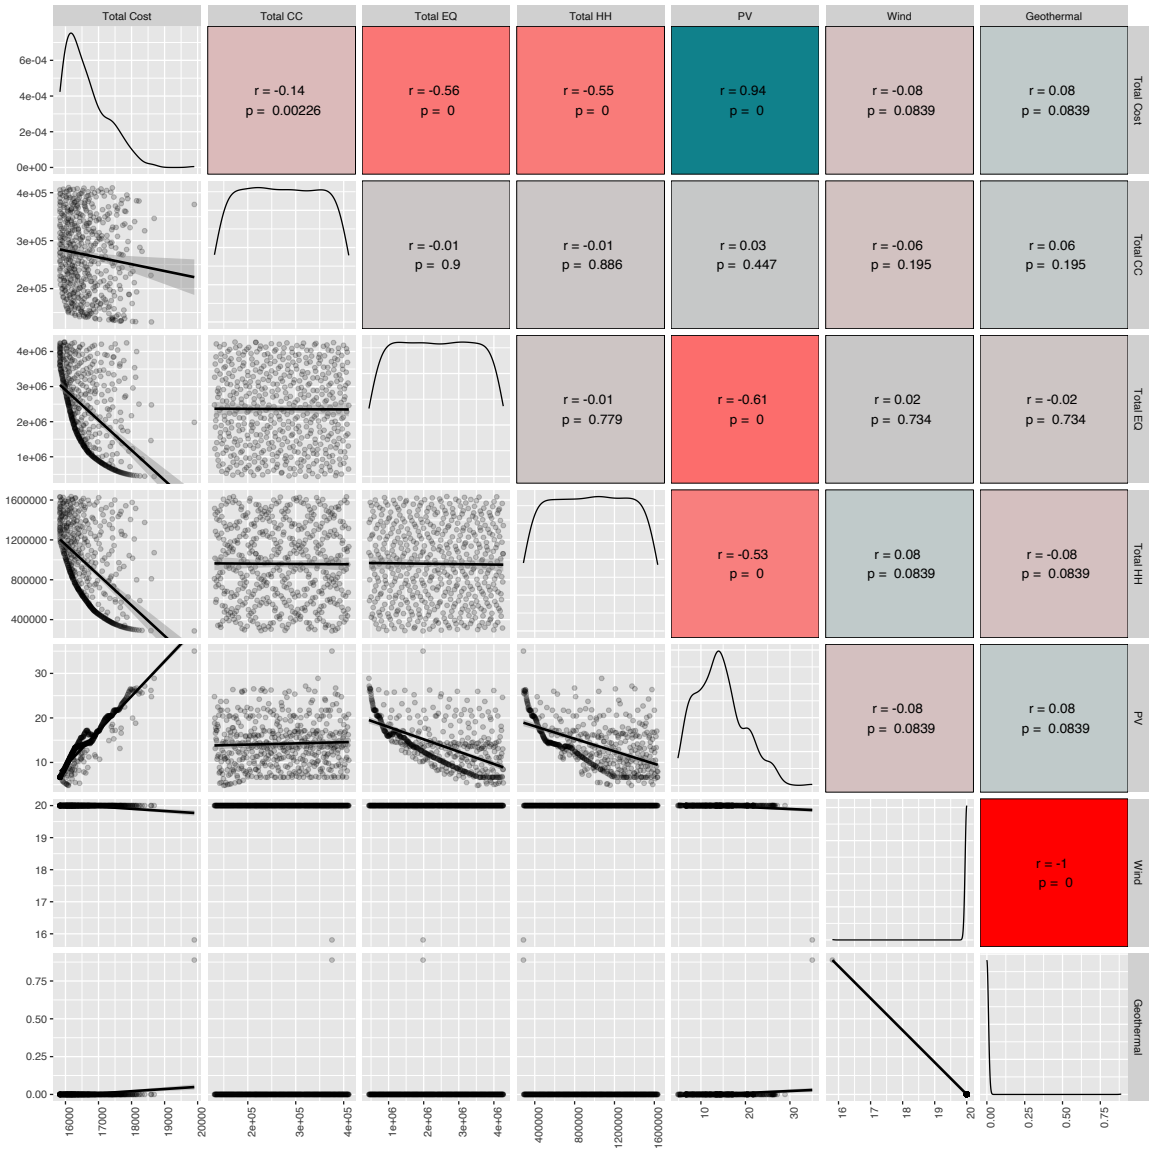

Figure 5: Pearson correlation coefficient matrix. The upper triangle depicts the correlation factor *r* with the color gradient and the significance *p* with the transparency. The diagonal depicts the distribution of the appearance of the individual variables. The lower triangle represents the observation distribution with the corresponding trend line and confidence interval.

tions between the LCA indicators are observed, the negative correlation between environmental impact and additional costs could be assessed, except for the climate change indicator, which is intrinsically integrated into the case study for carbon neutrality, where the carbon emissions are highly affecting the CC indicator.

While already general conclusions on the effect of economic and environmental indicators through the deployment of renewable technologies have been drawn, further work needs to be done in (i) separating the effect of double-counting in impact analysis by assessing the impact of midpoints, including resource depletion, endpoints and areas of protection, (ii) validating the multi-objective approach on economic optimization under parametrized environmental variables to generate the LCA-indicators Pareto-fronts, (iii) identifying the most-optimal solutions by applying multi-criteria decision methods, (iv) dig deeper in correlations between all technologies and the different indicators, and (v) identify typical energy system configurations by applying suitable clustering methods.
Further improving the methodology is necessary to (vi) remove the double-counting of energy system internal flows throughout scopes II and III. While, for example, electricity has been removed from the operational phase of using a heat pump, the construction phase still uses electricity based on the current energy system. The identification of those flows will allow the definition of a prospective LCA database coupled with the energy system.

Based on this paper's database and modeling framework, points (i)-(v) are subject to a future publication in preparation. Point (vi) is subject to a research project over several years in collaboration with CIRAIG.

Abstract:

According to the Intergovernmental Panel on Climate Change (IPCC), greenhouse gas emissions (GHG) have increased since 1990. Electricity and heat generation, along with transportation, accounted for more than two-thirds of emissions in 2018. As CO_2 represents the largest percentage of GHG, the term carbon has come to be adopted as a synonym for these gases in climate debates. In order to control emissions, the carbon market helps industries/sectors that are not able to meet the emission reduction goals to buy credit from the ones that have reduced their levels below the required. Thermoeconomics plays a fundamental role in the analysis of thermal systems. Therefore, this study aims to detail how thermoeconomic modeling can be used to include expenses or revenues related to the carbon market through an example in a gas turbine cogeneration system. In addition, it highlights that this modeling can be used in the internalization of other expenses such as environmental control devices, licenses, and permits. Results show that the environmental device is capable of internalizing carbon credits and systematically distributing them to the cost of final products.

Keywords:

Thermoeconomic modeling; Carbon credit; Carbon market; Environmental cost.

1. Introduction

According to the Intergovernmental Panel on Climate Change (IPCC) [1], greenhouse gas emissions (GHG) have increased since 1990. The combination of electricity and heat generation (cogeneration), along with transportation, accounted for more than two-thirds of emissions in 2018 [2]. As CO_2 represents the largest percentage of GHG, which can cause global warming, the term carbon has come to be adopted as a synonym for these gases in climate debates.

In order to control emissions, the carbon market provides industries/sectors that are not able to meet the emission reduction goals the possibility to buy credit from the ones that have reduced their levels below the required. One carbon credit corresponds, by convention, to one ton of carbon dioxide. Therefore, it can be considered an asset (financially and environmentally), representing the reduction or removal of one ton of CO_2 equivalent, which has been recognized and issued as a credit in the carbon market, regardless of whether it is voluntary or regulated [3].

This market is already regulated in some countries, such as in the European Union, which has well-defined credit values [4]. Nonetheless, in many others, such as Brazil, this market is still voluntary. Recently, the Brazilian government issued a decree [3] to regulate this market and institute the National System of Greenhouse Gas Emissions Reduction (SINARE); however, there are still no deadlines for implementation. According to the World Bank's 2022 report [5] and IPCC 2023 [6], the carbon market (associated with environmental preservation measures) is expanding worldwide, but still below the necessary levels to mitigate environmental problems and meet the environmental agenda signed in the Paris Agreement against the threats of climate change.

Thermoeconomics combines thermodynamic and economic concepts to provide pieces of information that are unavailable in conventional energetic and economic analyses. The information provided is fundamental in the design and operation of thermal systems [7]. The original objective of thermoeconomics was to mathematically combine the Second Law of Thermodynamics with economics. However, these analyses must also incorporate environmental issues [8]. In thermoeconomics, exergy is the most appropriate thermodynamic magnitude to use, because it takes into account aspects of the Second Law of Thermodynamics considering the quality of energy, locating and quantifying the irreversibilities of the

process [7]. The exergy is also the most appropriate connection between the Second Law and the environmental impact because it measures a system's state deviation in relation to the environment [9].

Multiproduct thermal system analyses such as cogeneration, in which two products (useful heat and power) are generated collectively from a single combustible, require rational criteria for distributing the cost of the combustible to the various final products. In these circumstances, thermoeconomics allows rational allocation (through physical criteria) of monetary, exergetic, and environmental costs for the final products. Therefore, it is possible to compare exergetic/monetary [10–14] and/or environmental [15–18] costs of each product with the production cost of each one in separate systems.

Thermoeconomic methodologies have already been used to include environmental aspects, such as specific CO_2 emissions. However, they were not used in the internalization of monetary costs associated with environmental issues, such as carbon credits. Therefore, the novel concept introduced in this study is to exemplify how to perform this internalization thermoeconomically.

Furthermore, it is observed that thermoeconomics has a fundamental role in energy conversion systems analyses. The main goal of this study is to detail how thermoeconomic modeling can be used as a tool to include the expenses or revenues relative to the carbon market in thermal systems analyses and allocate them to internal and final products of the system. The conventional modeling used to calculate the monetary costs of internal flows and final products can be adapted to address these environmental costs. This adaptation is detailed in matrix notation, through a case study of a gas turbine cogeneration system. It also shows how this inclusion can influence the monetary costs of the system's final products. In addition, it highlights that this modeling can also be used to internalize other costs such as environmental control devices, environmental licenses, and permits.

It is important to emphasize that the methodology used herein to exemplify and detail this internalization of environmental costs, which is the case of carbon credits, defines a device to represent the environment in the thermoeconomic diagrams and thus allocates environmental costs exactly on the environmental device. This study uses the H&S Model as the method; however, any other exergy-based thermoeconomic methodology that defines this device in a consistent way to represent the environment can be used to conduct the analysis in a similar way.

2. Thermoeconomic modeling

In addition to the conventional modeling used to determine the monetary and exergetic unit costs of the system's internal flows and final products, this section shows how the modeling is generally adapted to allocate specific pollutant emissions and further details how carbon credits can be included in thermoeconomic modeling.

2.1. Conventional Modeling

Equations (1) and (2) are used to determine the monetary (c) and exergetic (k^*) unit costs, respectively, of the internal flows and the systems' final products. The allocation of specific (λ) pollutant emissions, such as CO_2, NOx, and SOx can be performed through Eq. (3). In these equations, the subscripts "*out*" and "*in*" are associated with the outputs and inputs of flows, respectively. Y represents the generic thermodynamic magnitude which can be evaluated by power, heat, exergy flows, or its components. E_F is the exergy of the external combustible. c_F and k_F^* represent its monetary and exergetic unit cost, respectively. λ_F is the amount of emission generated due to the combustion of one unit of exergy from the external fuel. Z, conventionally, is the external hourly cost of the subsystem due to capital and equipment operation and maintenance.

$$\sum(c_{out}.Y_{out}) - \sum(c_{in}.Y_{in}) = Z + c_F.E_F \quad (1)$$

$$\sum(k^*_{out}.Y_{out}) - \sum(k^*_{in}.Y_{in}) = k^*_F.E_F \quad (2)$$

$$\sum(\lambda_{out}.Y_{out}) - \sum(\lambda_{in}.Y_{in}) = \lambda_F.E_F \quad (3)$$

Equation (2) is obtained through Eq. (1). In this case, the Z term should be zero and the exergy unit cost of the external fuel (k_F^*) is generally considered to be equal to its exergy; therefore, the exergy unit cost is equal to 1 kW/kW [7].

The monetary and exergetic unit costs can be interpreted as an economic and thermodynamic efficiency measure of a flow production process, respectively [7]. On the other hand, the balance represented by Eq. (3) can be interpreted as an environmental efficiency measure production process of this flow [16].

In all cases, Eqs. (1) - (3), auxiliary equations are generally necessary to complete the modeling equations system. These equations are defined according to the applied thermoeconomic diagram. In the case of productive diagrams, the equality criterion [19] is used. Following this criterion, all products of a subsystem have the same unit cost because they were generated in the same productive process under the same irreversibilities.

2.2. Inclusion of monetary costs of environmental charges

Equation (3) is used to allocate specific emissions to the internal flows and the thermal systems' final products, and, therefore, it is an analysis that considers environmental aspects in thermoeconomic modeling. However, it does not take into account monetary costs associated with environmental issues, such as carbon credits and environmental treatment/control equipment.

The Z term (Equation 1) is a key point in the allocation of environmental costs. In a conventional monetary cost evaluation, it represents the subsystem's external hourly rate due to the capital, operation, and maintenance. Nevertheless, it can also be used for the allocation of environmental costs through a device that represents the environment in the thermoeconomic diagrams. An energy conversion system can be defined as a set of components that interact with each other and with the environment through a set of flows of matter, work, or heat [20]; therefore, the environment is part of the system. Thus, it can be represented by an environmental device in thermoeconomic diagrams according to some models.

Equation (4) shows how a conventional thermoeconomic model of monetary unit cost (Equation 1) can be adapted to decompose the term (Z) in hourly costs due to environmental charges (Z_{env}) and capital, operation, and maintenance costs (O&M).

$$Z = Z_{cap} + Z_{O\&M} + \boldsymbol{Z_{env}} \tag{4}$$

The environmental device has no acquisition cost, but it is through it that environmental charges can be internalized and redistributed to the other equipment and the final products. For instance, when installing waste control devices in a plant, such as an electrostatic precipitator for ash disposal in flue gas or a bag filter for air pollution control, one can attribute the costs associated with its capital and O&M to the environmental device or any other equipment, that has the function of mitigating environmental impacts by decreasing the amount of GHGs emitted into the atmosphere.

The same can be done for devices used in the capture and storage of carbon, environmental permits, licensing costs, fines for emitting pollutants, and any other abatement cost (cost of resources employed in the treatment or proper waste disposal). Thus, allocating the environmental charges exactly on the device in the diagram defined to represent the environment. Since the term Z is always associated with some equipment, an adequate option is to associate environmental cost with the device that represents the environment in the diagrams.

2.2.1. Inclusion of carbon credits

In addition to the monetary costs mentioned in the previous section, this paper suggests that through the environmental device, it is also possible to take into account the pricing of carbon and internalize the expenses or revenues generated by carbon credits. In this case, the Z_{env} term can be positive or negative. Negative in case of a revenue generated due to the reduction or removal of emissions (which can generate a credit to be sold) and positive in case of an additional cost of buying carbon credits by a plant that failed to meet the emission reduction targets and had to buy credits from those that reduced theirs below the stipulated levels. The full detail of the thermoeconomic modeling taking this carbon market into account is presented in section 3.

3. Case study – gas turbine cogeneration system

The thermal system chosen to exemplify how thermoeconomic modeling can be used as a tool for internalizing carbon credits is a cogeneration system with a simple gas turbine as shown in Fig. 1. This system is composed by an air compressor (AC), combustion chamber (CC), gas turbine (GT), and recovery boiler (RB). Part of the power generated by the turbine is used to drive the compressor (W_{AC}). Two final products, net power (W_N) and useful heat (Q_U), are generated from a fuel (Q_F).

The parameters of the main flows of the physical structure (obtained with the Engineering Equation Solver - EES software [21]) can be found in Table 1. Table 2 indicates the quantities of the main productive flows. The reference conditions are defined by $T_0 = 25$ °C and $P_0 = 1.0132$ bar, and under these conditions the CO_2 mass flow from the exhaust gases is $\dot{m}_{CO_2} = 2228$ kg/h considering natural gas as fuel. More information of this system is available in [22]. The monetary unit cost of fuel (natural gas) is 24.04 $/MWh, according to the average value for the year 2022 in the international market [23].

Table 3 shows the external monetary flows due to the equipment of the cycle. These values were obtained from [22] and updated through the Chemical Engineering Cost Index (CEPCI) until the year 2022 [24]. The cost of the carbon credit used was 85 $/ton, which represents the average for the year 2022, according to [4].

The thermoeconomic modeling can be performed through different types of diagrams: physical, productive, and comprehensive. Since modeling with the physical diagram is not enough to identify the waste cost formation process [22], most methodologies use the productive diagram.

The description of the cost formation process of thermal systems based on productive flows is an original feature of the functional methodologies: Thermoeconomic Functional Analysis (TFA) [19] and Engineering Functional Analysis (EFA) [8]. However, other thermoeconomic methodologies, such as the H&S Model [22] used in this paper, have also adopted this feature.

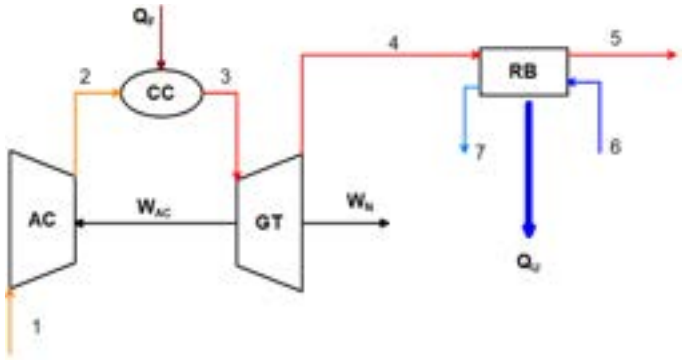

Figure 1. The physical structure: cogeneration system.

Table 1. Main physical flow parameters of the system.

Physical flow		ṁ [kg/s]	T [°C]	P [bar]
n. º	Description			
1	Air	14.72	25.00	1.0132
2	Air	14.72	230.20	5.1040

Equipment	Flow	Quantity [kW]
Air compressor (AC)	W_{AC}	3113.03
Combustion chamber (CC)	Q_F	11630.96
Gas turbine (GT)	W_{GT}	5546.50
	W_N	2433.47
Recovery boiler (RB)	Q_U	2246.32

Table 3. Equipment external monetary cost.

Equipment	Z [$/h]
Air compressor (AC)	25.33
Combustion chamber (CC)	9.04
Gas turbine (GT)	34.37
Recovery boiler (RB)	21.71

3.1. Thermoeconomic models

Thermoeconomic modeling can be carried out with the well-known E Model that uses total exergy flows to define the physical and/or productive flows of the diagrams. However, in some cases, it becomes necessary to disaggregate the exergy into components, such as to isolate dissipative equipment and carry out an adequate allocation of the waste cost in thermal systems. One such exergy disaggregation model is the H&S Model [22] which describes the behavior of thermodynamic cycles in the h-s plane considering the enthalpy

and entropy variation of the working fluid, as suggested by [25]. This is a model for disaggregating the physical exergy into its enthalpic(E^H) and entropic (E^S) parts, according to Eq. (5). The total exergy (E^{TOTAL}) can be defined by Eq. (6) as the sum of the physical (E^{PH}) and chemical (E^{CH}) components, disregarding nuclear, magnetic, electrical, surface tension, kinetic and potential effects [26].

$$E^{PH} = E^H - E^S \tag{5}$$

$$E^{TOTAL} = E^H - E^S + E^{CH} \tag{6}$$

The H&S Model defines the environmental device (ENV) in the productive diagram that interacts with the other plant subsystems. In this methodology, this device plays a fundamental role in the analysis of thermal systems, especially in the treatment of waste and the internalization of environmental costs. Both the physical (represented by $E^H_{5:1}$) and chemical ($E^{CH}_{3:2}$) components of the waste are dissipated in (ENV), see Fig. 4, and this is where the system receives air from the compressor inlet. The chemical component is generated in the CC due to the combustion reaction in which the air and fuel mixture is transformed into combustion gases. The E Model does not define a device to represent the environment in the diagram.

In addition, the environmental device (used in the H&S Model) is also responsible for closing the cycle (Figure 2); thus, redistributing the waste costs to the other plant components and consequently to the final products.

Figure 2 represents the cogeneration cycle in the h-s diagram and the numbering in this diagram represents the processes performed by the following components:

- 1-2: compressor (1-2s would be isentropic compression);
- 2-3: combustion chamber;
- 3-4: gas turbine (3-4s: isentropic expansion)
- 4-5: recovery boiler.

At the exit of the recovery boiler (point 5), the exhaust gases have exergy (therefore, they are waste). Although this equipment (RB) slightly reduces the entropy of the working fluid, the cycle is not fully closed. In the case of a Rankine cycle, for example, the condenser completely closes the cycle by reducing the entropy of the turbine's output steam to that of the saturated liquid at the pump entrance.

The device representing the environment in the diagram (ENV) performs process 5-1 and completely closes the loop. In this device, flow 5 represents the exhaust gases and flow 1 is the air drawn in by the compressor.

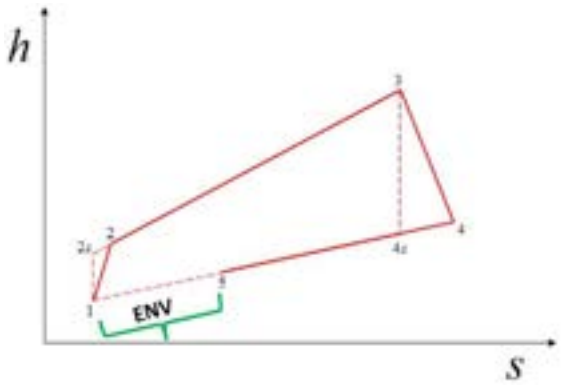

Figure 2. The environment device in open cycles.

3.1.1. Productive diagram

Figures 3 and 4 represent productive diagrams of the gas turbine cogeneration system according to E and H&S Models. In E Model, the flows represent exergy variations between two physical states (*i* and *j*) according to Eq. (7). In the H&S Model, the productive flows represent variations of the enthalpic, entropic and chemical components of the exergy between *i* and *j* according to Eqs. (8) - (10), respectively.

$$E_{i:j} = E_i - E_j \tag{7}$$

$$E^H_{i:j} = E^H_i - E^H_j \tag{8}$$

$$E^S_{i:j} = E^S_i - E^S_j \tag{9}$$

$$E^{CH}_{i:j} = E^{CH}_i - E^{CH}_j \tag{10}$$

In Figs 3 and 4 the system components are represented by rectangles that are real units (or subsystems); the rhombuses and circles are fictitious units called junctions (J) and bifurcations (B), respectively, which are used to interconnect the subsystems.

The fuel and product definitions follow the SPECO approach [27] as follows: if the variation of specific exergy (or of its components with a positive contribution to the exergy definition) is positive throughout the process, this variation plus the exergy of flows of energy generated in the component define the product. On the other hand, if the variation of the specific exergy (or of its components with a positive contribution to the exergy) is negative throughout the process, this variation is added to the exergy of the energy flows supplied to the component in the input definition. The opposite happens with the components with a negative contribution in the exergy definition, such as the entropic component in the H&S Model. In this case, the H&S Model defines the productive flows of the entropic ($E^{H}_{5:1}$) and chemical ($E^{CH}_{3:2}$) components as input from the environment, and the entropic ($E^{S}_{5:1}$) component as a product, see Fig. 4.

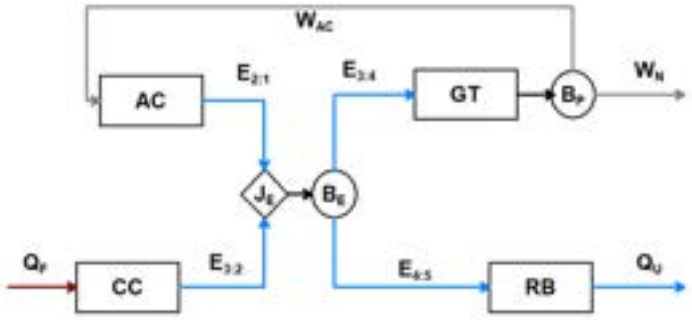

Figure 3. Productive diagram - E Model.

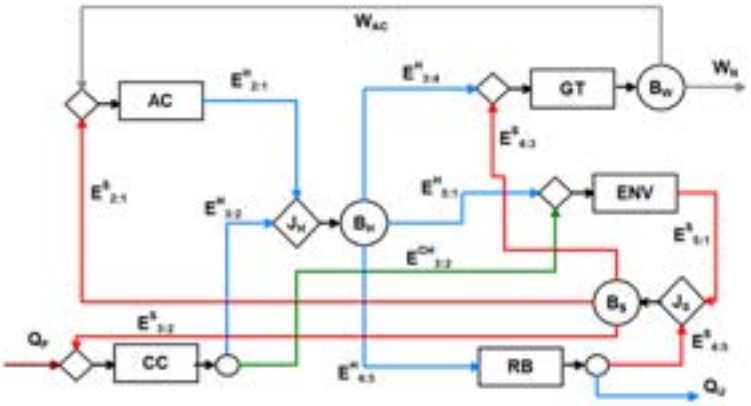

Figure 4. Productive diagram - H&S Model.

3.1.2. Monetary cost balance

Figure 5 shows the monetary cost balance for the H&S Model, expanded in matrix form, which is obtained by applying the cost balance from Eq. (1) to each of the 5 subsystems (AC, CC, GT, RB, and ENV) and at enthalpic (J_H-B_H) and entropic (J_S-B_S) junctions-bifurcations of the productive diagram (Figure 4).

$$\begin{bmatrix} E^{H}_{2:1} & 0 & -W_{AC} & 0 & 0 & 0 & -E^{S}_{2:1} \\ 0 & E^{N}_{3:2}+E^{CH}_{3:2} & 0 & 0 & 0 & 0 & -E^{S}_{3:2} \\ 0 & 0 & W_{AC}+W_{N} & 0 & 0 & -E^{N}_{3:4} & -E^{S}_{4:3} \\ 0 & 0 & 0 & E^{S}_{4:5}+Q_{U} & 0 & -E^{N}_{4:5} & 0 \\ 0 & -E^{CH}_{3:2} & 0 & 0 & E^{S}_{5:1} & -E^{N}_{5:1} & 0 \\ -E^{H}_{2:1} & -E^{H}_{3:2} & 0 & 0 & 0 & E^{H}_{3:4}+E^{H}_{4:5}+E^{H}_{5:1} & 0 \\ 0 & 0 & 0 & -E^{S}_{4:5} & -E^{S}_{5:1} & 0 & E^{S}_{2:1}+E^{S}_{3:2}+E^{S}_{4:3} \end{bmatrix} \cdot \begin{bmatrix} c_{AC} \\ c_{CC} \\ c_{GT} \\ c_{RB} \\ c_{ENV} \\ c_{JB-H} \\ c_{JB-S} \end{bmatrix} = \begin{bmatrix} Z_{AC} \\ c_{F}.Q_{F}+Z_{CC} \\ Z_{GT} \\ Z_{RB} \\ Z_{ENV} \\ 0 \\ 0 \end{bmatrix}$$

Internal valuation | Cost | External valuation

Figure 5. Monetary cost balance in matrix form.

It is visible that the internal valuation matrix is composed of flows of the exergy components, power, and useful heat. It represents the process from the distribution of external resources to the formation of the final

products' cost. The cost matrix (or vector) is the modeling's unknown factor and is composed of the monetary unit cost of the flows generated in each of the subsystems. For instance, c_{AC} is the monetary unit cost of the compressor (AC) product, i.e., the flow $E^{H}_{2:1}$.

Due to the use of the equality criterion, some flows have the same unit cost. Examples are: $E^{H}_{3:2}$ and $E^{CH}_{3:2}$; $E^{S}_{4:5}$ and Q_U; W_{AC} and W_N. In addition to those, all entropic component flows which leave J_H-B_H have the same unit cost as all entropic component flows leaving J_S-B_S.

The external valuation matrix contains the exergy of the fuel and its respective unit cost, plus the external hourly cost of each subsystem due to capital, and equipment O&M (Z). Because they are dummy components, the junction-bifurcations have zero Z-cost, as shown in the external valuation matrix in Fig 5.

The Z term, along with the device representing the environment in the diagrams, are key pieces in internalizing environmental costs in thermoeconomics. Figure 6 details this device and its input and output flows that are part of the monetary cost balance. The environmental device itself has no costs for acquisition, operation, and maintenance because it is a representation of the atmospheric environment itself. Nevertheless, in the case of the installation of some environmental treatment component (filter, electrostatic precipitator, among others) that generally is not represented in the physical diagram of the thermal system, the cost of this component can be internalized in the environmental device through the first two terms on the right-hand side of Eq. (4), and thus be redistributed to the entire system.

As for the cost of fines, environmental licenses, and permits, they should be internalized by Z_{env}, as well as the carbon pricing values. Nevertheless, the latter depends on whether it is revenue or expense in the carbon market.

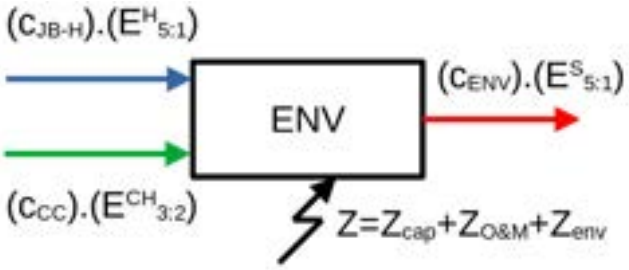

Figure 6. Cost balance in the environmental device.

In the case of revenue, which can occur due to a reduction in emissions below the stipulated which generates a saleable credit, the term Z_{env} enters negative on the balance sheet. Since the environmental device closes the loop and redistributes the costs to the other equipment and final products in the plant, this credit reduces the other monetary costs and can influence the plant's production decisions.

On the other hand, an expense related to carbon credits, such as the need to buy credits since the company was not able to reduce emissions as stipulated, makes the term Z_{env} positive and similarly ends up increasing the costs of other internal flows and final products of the plant.

In summary, the equation shown in Fig. 6 is highlighted in the text as Eq. (11) and its analysis can be done as follows:

- The environmental device (ENV) has no hourly cost due to capital and O&M, but in the case of using environmental treatment equipment (which is generally not represented in the physical structure of the system), these terms can be considered within Z_{ENV};
- The environmental costs of licenses and permits are internalized through the environmental device term Z_{env};
- The costs associated with the carbon market are also internalized through the term Z_{env}. In the case of revenue, this term is negative and in the case of expenditure, it is positive.

In all three cases, as device ENV closes the loop (Figure 2), the costs are systematically redistributed to the other subsystems and consequently to the final products of the plant in the case of the H&S Model (Figure 4).

$$Z_{ENV} = Z_{cap} + Z_{O\&M} + Z_{env} \tag{11}$$

3.1.3. Results

Figure 7 represents a generic cogeneration (combined heat and power – CHP) system in which out of one fuel (Q_F), two products (W_N and Q_U) are generated, as is the case with the gas turbine system in Fig. 1. By applying the cost balance of Eq. (1) to this generic system, one obtains Eq. (12), in which c_{W_N} and c_{Q_U} are the monetary unit costs of the final products. Note that Eq. (12) is the equation of a straight line of the type $y = A.x + B$, and can be written according to Eq. (13).

$$c_{W_N} = -\frac{Q_U}{W_N} c_{Q_U} + \frac{c_F . Q_F + Z}{W_N} \quad (12)$$

$$c_{W_N} = -A . c_{Q_U} + B \quad (13)$$

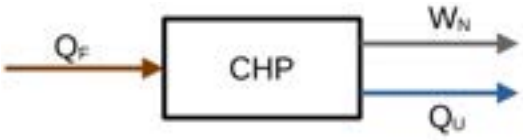

Figure 7. Accounting flows in cogeneration.

Regardless of the applied thermoeconomic methodology, the solution to Eq. (12) will be an ordered pair of the monetary unit cost of the net power (c_{W_N}) and of the useful heat (c_{Q_U}). Some studies [13,28–30] have already compared several methodologies in problems of this type and confirmed that these ordered pairs belong to the same straight solution when the system has its operational conditions defined, such as the net power/useful heat ratio and the global exergetic efficiency.

Figure 8 represents possibilities for this straight solution generically. In all the possibilities, the higher the unit cost of power, the lower the unit cost of heat, and vice versa.

Considering the central straight line (solid blue line) as the specific condition for a cogeneration system, changes in the thermodynamic model move the straight line to new positions parallel to the initial one [28,31], as shown by the dashed lines in Fig. 8.

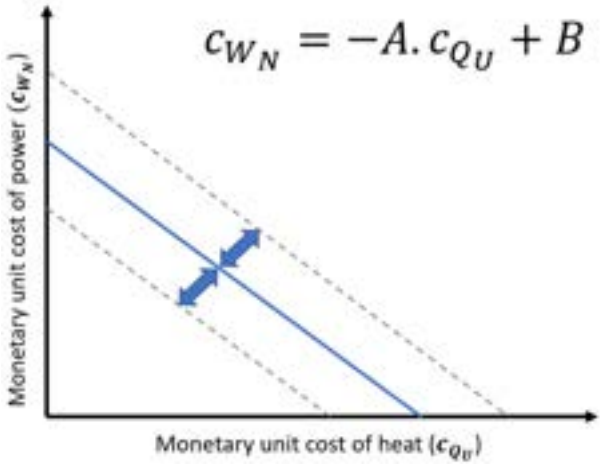

Figure 8. Unit cost solution line.

Figure 9 shows the monetary unit cost of the final products (ordered pair) of the cogeneration system for some situations. The values were obtained through the cost balance of Eq. 1 when applied to the diagrams of Figs 3 and 4 for E and H&S Models, respectively. For this second model, the balance is detailed (matrix form) in Fig. 5 to highlight the Z_{ENV}.

The points that belong to the central line, identified as the base case in the caption of Fig. 9, represent the case in which no carbon credit values are being internalized.

Note that the increase in emissions represents a reduction in the efficiency of the process and a consequent increase in production costs. Thus, the straight solution moves away from the origin and the costs of the final products increase. On the other hand, the reduction of emissions approximates the solution line to the origin, reducing the costs of the final products as a result of an improvement in the process's efficiency.

In order to analyze the expenses and revenues of the carbon market, some hypotheses were considered and realized. Starting from the base case, and considering that the increase in CO_2 emissions means that the system is emitting above the established, carbon credits must be purchased and thus an expense is generated for the plant. In the case of reduction/removal of emissions, the system generates a credit that could be sold and thus generate revenue. In the case of the H&S Model, the value of carbon credits is internalized in the environment device with ($Z_{env} > 0$) in the case of expenses and ($Z_{env} < 0$) for revenue. In E Model, internalization is done via CC with ($Z_{carbon\ credit} > 0$) in the case of expenses and ($Z_{carbon\ credit} < 0$) for revenue.

Hypotheses of increase (10% to 50%) and reduction (-10% to -50%) of emissions in relation to the base case were simulated. Table 4 shows the monetary unit costs of the final products ($k^*_{Q_U}$ and $k^*_{W_N}$) for all these

situations, in addition to the amount of carbon credits that these variations in emissions could generate and the costs (revenue and expense) associated.

When analyzing (c_{Q_U}) and (c_{W_N}), it is verified that in E Model the costs of the final products vary approximately 5% and 25% for the cases of increase/reduction of 10% and 50% in the emissions compared to the base case. In the case of the H&S Model, for these same situations, the variations in the costs of the final products are approximately 5% and 26%. The variations in the costs obtained are due to the different criteria of each model, such as the internalization of carbon credits in the CC and the environmental device.

When analyzing the carbon credits for the simulated situations, it is observed that a 10% variation in emissions generates 5.3 credits/day which corresponds to an expense/revenue of $455/day. In the most extreme case of variation (50%) in emissions, expenditure/revenue can reach $2276/day. The use of value generated by the purchase or sale of the carbon credit can be used as an indicator for the decision-making of companies concerning the installation of environmental equipment or the purchase of carbon credits.

Remembering that this work aims to demonstrate the thermoeconomic methodology to be used for the inclusion of carbon pricing in cogeneration systems and not in the behavior of the system that generates an increase or reduction/removal in emissions, nor in the definition of the emissions parameters that will regulate the carbon market.

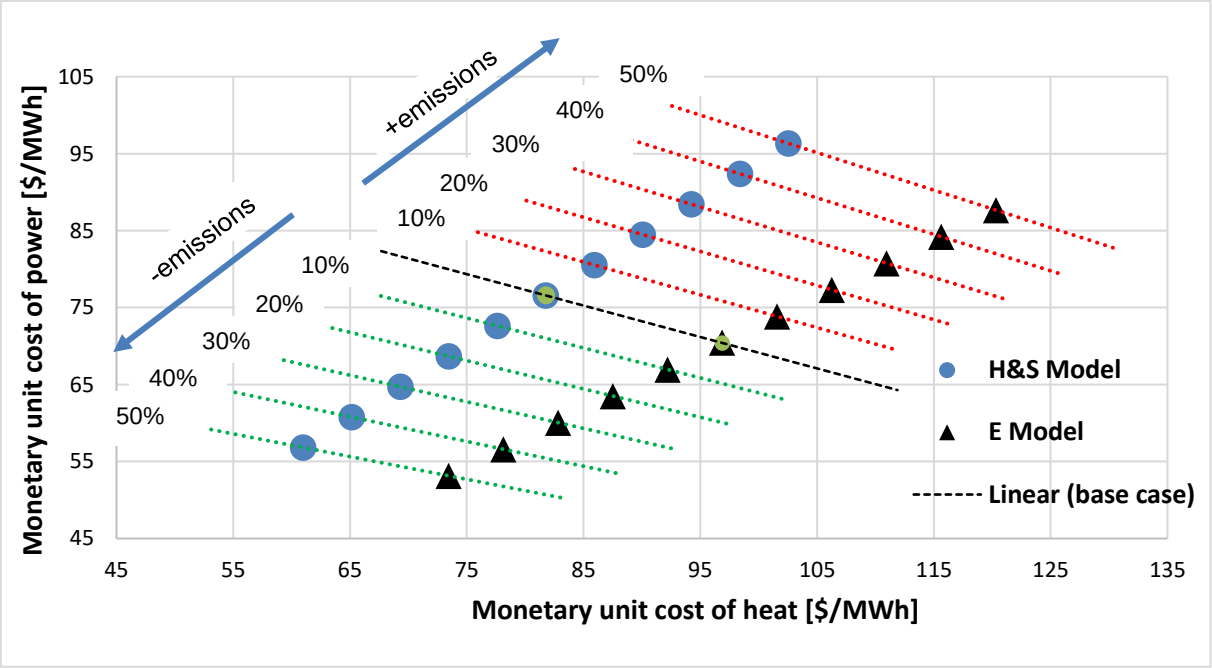

Figure 9. Monetary unit cost variation due to emissions.

Table 4. Monetary unit cost [$/MWh] and carbon credit for the simulated situations.

Emissions	E Model		H&S Model		Carbon credit/day	$/day
	(c_{Q_U})	(c_{W_N})	(c_{Q_U})	(c_{W_N})		
+50%	120.33	87.66	102.57	96.32	26.7	-2273
+40%	115.64	84.21	98.41	92.37	21.4	-1818
+30%	110.95	80.76	94.26	88.42	16.0	-1364
+20%	106.26	77.31	90.10	84.47	10.7	-909
+10%	101.57	73.86	85.95	80.52	5.3	-455
Base case	**96.88**	**70.41**	**81.79**	**76.57**	**0**	**0**
-10%	92.19	66.96	77.64	72.62	5.3	455
-20%	87.51	63.51	73.48	68.67	10.7	909
-30%	82.82	60.06	69.33	64.72	16.0	1364
-40%	78.14	56.6	65.17	60.77	21.4	1818
-50%	73.45	53.15	61.02	56.82	26.7	2273

Analyzing the inclusion of environmental costs, such as carbon pricing, one observes in Eq. (12) that the Z term, and consequently the Z_{env}, change the B coefficient of the straight line equation (Equation 13), and, therefore, would also shift the initial straight line (base case) to parallel lines compared to the initial condition. In the case of revenue ($Z_{env} < 0$), the straight line approaches the origin by decreasing product costs since revenue was generated from the sale of carbon credits. For expenses ($Z_{env} > 0$), the straight line moves away from the origin since it is necessary to buy carbon credits, that is, there is an increase in production costs. It is worth noting that the straight line moves to different but parallel positions. In any case, since coefficient A is not changed, the slope remains the same. Furthermore, by defining the system conditions and including the environmental cost, different thermoeconomic methodologies that consider the environmental device define ordered pairs of power and heat cost belonging to the same straight line solution.

4. Conclusions

This study described and detailed a thermoeconomic methodology to internalize monetary environmental costs in thermal system analyses through an example of a cogeneration system with a gas turbine.

The costs focused on the paper are the pricing of carbon emissions. However, the internalization of other environmental costs, such as the licenses, permits, and acquisition of environmental treatment/control equipment were also considered.

The cogeneration system was chosen because it is one of the main emitters of greenhouse gasses according to data from the International Energy Agency (IEA).

Models E and H&S were used. However, the focus is on H&S because it is a methodology that defines the device to represent the environment in the diagrams. This device is responsible for dissipating the cycle waste and has a key role in the internalization of environmental costs and in the systematized redistribution of costs for the remaining components and final products of the system. Nevertheless, any other thermoeconomic methodology, based on exergy, which coherently defines this environmental device, could be used following the same methods. Moreover, this model was proposed to take into account the treatment of waste (exhaust gases in the case of this work) and its costs, which are directly associated with pollutant emissions and, consequently, with the carbon market.

Since energy conversion systems generate environmental damage, their full analysis must take into account technical, economic, and environmental aspects to meet the environmental agenda signed in the Paris Agreement.

The current study presented the H&S Model as a feasible tool to reach this purpose by detailing how the carbon market can be taken into account and the pricing of carbon and other environmental costs internalized into the analysis. Besides detailing the calculation methodology, it also showed the behavior of the results of the cogeneration systems' final products' monetary costs. Incorporating costs associated with climate change into economic decision-making through carbon pricing can help encourage changes in production, consumption, and investment patterns. Thus, assisting in the energy transition process toward the planet's decarbonization.

This study concludes that the proposed methodology is coherent from the theoretical perspective of thermodynamics and thermoeconomics and can be used to allocate carbon credits to the internal and final products of thermal systems.

Abstract

Human activities are currently at an unsustainable level and a significant reduction in greenhouse gas emissions is essential to limit global warming. Industry, which accounts for a large share of these emissions, has an important role to play, particularly in its energy consumption for heat production. One of the issues of this transformation is to assess, among all the possible energy solutions, those that are most likely to achieve the objective of reducing emissions of greenhouse gases without incidentally increasing other environmental impacts. The study proposes a method for classifying non-dominated solutions found using an optimisation model based on life cycle analysis (LCA), energy and economic indicators. This is complemented by integrating constraints represented by sustainability limits, i.e. an acceptable level of impact defined by planetary boundaries. A case study of a paper industry process in Italy is presented to highlight the capability of the method. For this example, the ranking shows that - with the current LCA weighting factors - waste heat recovered using a heat pump powered by electricity has the highest ranking. However, a scoring for which exceeding sustainable levels is penalized gives a higher ranking to solutions composed of a mix of several energy sources. Moreover, if one focuses only on the global warming indicator, the most effective solutions far exceed sustainable levels for other indicators. It is therefore necessary to adopt a comprehensive environmental approach to avoid shifting environmental burdens to other impact categories. On the other hand, no solution compatible with all sustainable levels has been found. It is therefore necessary to go further by proposing a global approach detailing the level of impact that each sector can have while ensuring an overall sustainable level.

1. Introduction

It is unequivocal that human influence has warmed the atmosphere, ocean and land since pre-industrial times, which *is a consequence of more than a century of net greenhouse gas (GHG) emissions from unsustainable energy use, land-use and land use change, lifestyle and patterns of consumption and production* [1], [2]. There are now a large number of climate scenarios that attempt to estimate the consequences of human activities on future global mean surface temperature (GMST), which are compiled in the last intergovernmental panel on climate change (IPCC) assessment report [3]. The higher the increase in GMST, the larger the irreversible changes in natural cycles and the consequences on livelihoods of people, which is why it is essential to hold this temperature increase well below 2 °C above pre-industrial levels. The latest Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services report [4] shows that global warming is not the only concern at the moment, and that other issues (land use, direct exploitation, pollution etc.) are at unsustainable levels leading to a huge decrease in biodiversity. This conclusion is also highlighted by the Stockholm Resilience Center in their proposed definition of planetary boundaries [5].

Many global warming mitigation options are already technically and economically viable or are going to become so in the near future [2]. Nevertheless, they can have other environmental impacts, which are necessary to evaluate. Therefore, an increasing number of studies, often called the 4E study, combined energy, exergy, economic and environmental approaches to reach this goal. For example, Chen et al. [6] proposed a comprehensive 4E approach applied to cascading systems, which has been shown to be beneficial in reducing greenhouse gas emissions. Yu et al. [7] go further in the environmental assessment by conducting a full life cycle analyses (LCA) to evaluate the most significant environmental impacts. Although these studies quantify the environmental impacts of a technical solution and the elements that significantly contribute to it, they do not relate them to sustainable thresholds, i.e. the maximum level of impact generated by the process that can be achieved without causing significant adverse effects on the environment, society or the ability of future generations to meet their own needs. Indeed, Bjørn et al. [8] have pointed out that one solution that is better than another from an environmental point of view is not necessarily an acceptable solution in the face of global limits..

In this study, we propose a 4E assessment framework including the sustainable levels defined by Vargas et al [9] to analyse the issue of sustainable heat production in industry. Starting with an industrial need defined by dynamic heat requirements at a certain temperature level, a set of mature solutions are compared to analyse the best compromise according to different energy, environmental and economic constraints. The main purpose of this article being to present the method, a simple case study is used for this purpose. It takes as example the paper production, which is a continuous industrial process, located in Italy, being able to benefit from a continuous flow of waste heat at a temperature lower than the process temperature. A period of one year is considered.

2. Methods and Material

2.1. Overall methodology

This study deals with the heat production for an industrial process at a defined temperature T, for a variable hourly demand. The objective is to define the best way to meet the dynamic heat demand by using combinations of different possible technologies like electric, gas and biomass boilers or heat pumps fed with waste heat or thermal storage. All the energy sources used to cover this need (including those used to generate grid electricity, with or without carbon capture and storage) have different environmental impacts and different costs that can vary at each time step. The aim is to analyse what is the best possible solution to produce this industrial heat according to environmental and economic criteria. The analysis being multicriteria, it is possible to find a set of possible solutions answering the optimization problem. The general assessment framework used to calculate and rank the optimal solutions is presented in Fig. 1.

From environmental, technological, energy, process-related and economic input data, it is possible to feed the economic, energy (yearly performance simulation) and environmental (LCA) models used in the optimization algorithm. The latter produces a set of non-dominated solutions capable of meeting the needs of the process. Note that for the sake of brevity, this article focuses only on the environmental impact presentation. The set of non-dominated produced solutions, also called Pareto front, is such that

there is no one solution that exhibits a best performance in all dimensions. Eventually, these solutions are ranked based on considerations related to global limits and economy. The different steps of this general assessment framework are detailed in the following sections.

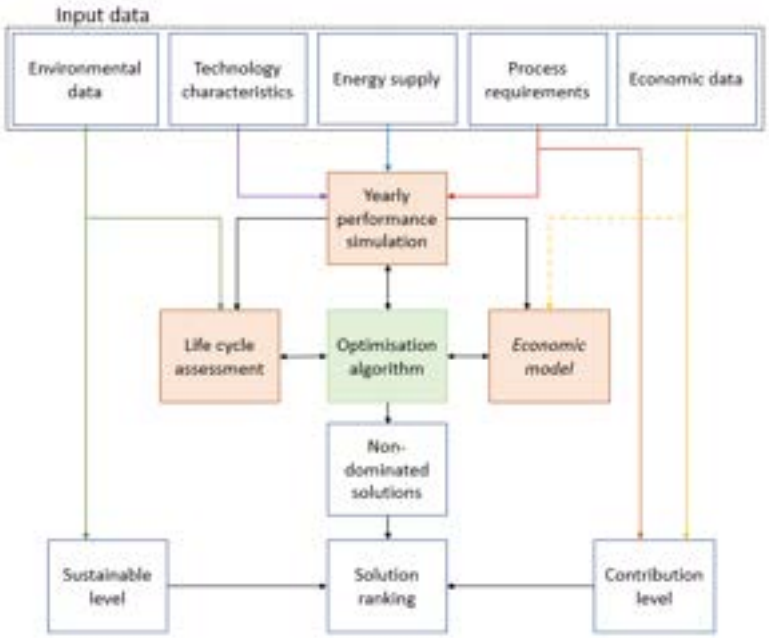

Fig. 1 - Assessment framework; dotted arrows and the block in italics are not presented in this study.

2.2. Input data

2.2.1. Environmental data

The environmental data are derived from Ecoinvent 3.7.1 LCI database [10]. This assessment considers the marginal process for all environmental data, which is defined by Hauschild et al. [11] as the transformation on the economy caused by the introduction of a new product system, i.e. the product system's consequence. For the proposed application, namely the heat production in industry sector, which represents a significant share of the energy market, the change of energy system will lead to a change in electricity production to satisfy this new demand. Considering marginal process requires to assess the environmental impacts caused by the change in energy supply over the average values.

2.2.2. Efficiency of the technologies

The efficiencies of the technologies considered in the study are summarised in Table 1. They include the heat loss to the environment due to the generation of heat and consider a reduction of the efficiency when the system operates in partial load. In addition to these efficiencies, a ramp-up power is considered for biomass production with a limited ramp-up equal to 4.2% per hour of the maximum available power as defined by Veyron et al.[12]. For the Mechanical Heat Pump (MHP), the power is limited according to the available waste heat at the considered time step. In this study, the source of waste heat is external to the process and corresponds to a contribution equivalent to 80% of the process requirement.

A thermal storage facility is also modelled to allow a phase shift between production and use. There are currently many options for thermal energy storage as reviewed by Sarbu et al [15]. As this work focuses on industrial applications, only short-term storage (water tank) is considered as a first step. Storage losses are estimated at 5% of the stored energy for a charge cycle of 8 hours and a discharge cycle of 16 hours [16]. Considering the charging and discharging times, the hourly storage efficiency is equal to $\varepsilon_{sto} = 0.996$.

Table 1 – Final energy consumption $E_{in,T}$, Process energy demand $E_{out,T}$ at temperature T, for the four technologies considered in the study. $S_{eff,T}$ is the system efficiency for a process temperature T in °C, with T_{up} the process temperature level and T_{rec} the waste heat temperature level, ε is the share of final

energy losses by the system in % which represents the heat losses to the environment of the heat generation technology as proposed by Bülher et al. [13].

Technologies	Final energy consumption $E_{in,T}(t) = \frac{E_{out,T}(t)}{S_{eff,T}(t).(1-\varepsilon)}$	Partial load efficiency
Electric boiler	$S_{eff,T}(t) = 1$ $\varepsilon = 0.00096(T + 273.15) - 0.115$	No partial load efficiency losses
Natural gas boiler	$S_{eff,T}(t) = 1$ $\varepsilon = 0.001154(T + 273.15) - 0.138$	No partial load efficiency losses
Biomass boiler	$S_{eff,T}(t)$ depends on the partial load $\varepsilon = 0.001154(T + 273.15) - 0.138$	Regression from [12] At 100% design load: $S_{eff,T}$ = 86.5% At 50% design load: $S_{eff,T}$ = 83.0%
MHP	$S_{eff,T}(t) = 1.91(T_{up}-T_{rec}+0.0884)^{0.89094}(T_{up}+0.0442)^{0.67895}$ $\varepsilon = 0.00096(T + 273.15) - 0.115$	Linear regression from [14] At 100% design load: $S_{eff,T}$ = COP At 50% design load: $S_{eff,T}$ = 0.985COP

2.2.3.Energy supply

The electricity production considered in this study is scenario BL2050 for Italy from the heat road map Europe [17]. Italy is a relevant study case to assess the impact of Carbon Capture & Storage (CCS) option because of its large share of thermal generation of electricity. The new installed electricity production relative to the current electricity mix is described in Table 2.

Table 2 – New installed electricity production sources in scenario BL2050 for Italy

Dammed hydro	Geothermal	Offshore wind	Onshore wind	Solar	River hydro	CHP Biomass	Condensing powerplants	Nuclear
5.7%	3.8%	0%	20.9%	23.9%	0%	2.1%	43.6%	0%

The proportion of CCS in the power generation mix as well as for on-site industrial CCS is derived from the scenario AIM/CGE 2.2 publish by Riahi et al. [18] from IPCC AR6 [3]. The data are presented in Table 3.

Table 3 – Average CCS share in electricity production and industrial heat production system

	2015-2040	2040-2065	2065-2090
Electricity production	8%	32%	71%
On-site industrial CCS	0%	2%	39%

The CCS captured efficiency, which is defined as the share of CO_2 not rejected by the CCS, is set at 88% according to García-Freites et al. [19]. The environmental impact of CCS is based on the LCA carried out by Bisinella et al. [20]. The efficiency penalty of CCS, which is the relative change on energy output, is set at 15% for gas [21] and 22.6% for BECSS and oxy-fuel [22]. For the gas boiler, a feed with 100% of conventional gas is assumed (no shale gas).

2.2.4.Process requirements

The consumption profile of the study is based on average data from a continuous paper production process [23]. The typical week is shown in Fig. 2 and is repeated throughout the year. The process temperature requirement is set at 130°C and the waste heat temperature is recovered at 80°C. The continuous heat requirement profile of the paper industry has the advantage of presenting a minimum of operating constraints for the heat production technologies. A batch profile would have higher constraints such as the ramp-up time of a biomass boiler or lower efficiencies at partial load. The same

method can of course be applied to more complex profiles, but the lack of space does not allow to deal with them in this article.

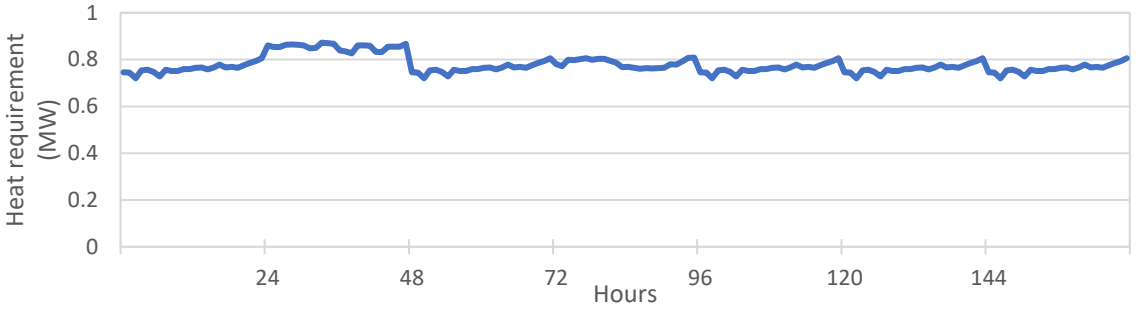

Fig. 2 - Weekly heat requirement profile for paper production process at a temperature level of 130°C

2.3. Yearly performance simulation

The energy model creates solutions that verify all the operating conditions of the technologies to meet the process demand. These solutions give for each time step the heat produced by each of the technologies:

$$\sum_{j=1}^{n} P_j(t) = D(t) + \frac{\mathrm{S(t)} - \mathrm{S(t-1)} - \mathrm{S(t)} * (1 - \varepsilon_{sto})}{\Delta t} \quad (1)$$

Where P_j is the heat production from source j in MW, D the process demand in MW, S is the amount of energy in thermal storage at time step t in MWh and Δt the time step. The size of the heat production facilities for CAPEX and LCA calculations is based on the maximum demand required for each technology over the year, no safety factor being considered.

2.4. LCA model

The LCA focuses on the generation and supply of heat to the industrial sector in Italy. The functional unit is therefore defined as the production of heat at 130°C to meet the industrial demand presented in part 2.2.4 over one year in Italy for both 2015-2040 and 2065-2090 periods. Background data specified in Sections 2.2-2.3 are used for the life cycle inventory modelling. The Life Cycle Impact Assessment method used is EF 3.0 [16] and the weighting scores (Ws) proposed by this method are presented in Table **4** as well as the 16 environmental indicators used in this study. The weighting scores are not used in the optimization algorithm but are considered to rank the obtained solutions in the final step of the assessment framework. Furthermore, as explained in section 2.2.1, this study considers consequential modeling.

Table 4 - Weighting score from LCIA EF 3.0

	Climate change	Ozone depletion	Ionising radiation	Photochemical ozone formation	Particulate matter	Human toxicity, non-cancer	Human toxicity, cancer	Acidification	Eutrophication, freshwater	Eutrophication, marine	Eutrophication, terrestrial	Ecotoxicity, freshwater	Land use	Water use	Resource use, fossils	Resource use, minerals and metals
Weighting EF 3.0 (Ws)	21%	6%	5%	5%	9%	2%	2%	6%	3%	3%	4%	2%	8%	9%	8%	8%

2.5. Optimisation algorithm

The non-dominated solutions are calculated using the genetic optimisation algorithm package from Matlab [24]. The genetic method works by combining initial solutions and adding mutations to test the solution space as efficiently as possible. This method is well suited to our case as the solutions with one single energy source can be combined to make any possible solution. The initial solutions are therefore easy to generate. The number of obtained solutions depends on the size of the studied population; in this study a population of 100 is considered which generates a number of 35 final non-dominated solutions. This method has been widely studied in the literature [25], [26] and is already applied for energy optimization [27], [28], although reproducibility may be a minor issue.

2.6. Ranking of the non-dominated solutions

2.6.1. Sustainable & contribution levels

The environmental sustainability limitfor each environmental impact category is derived from Vargas et al. [9], except for marine eutrophication which is based on Willett et al. [29] and climate change which is based on the scenario AIM/CGE 2.2 published by Riahi et al. [18] and used in IPCC AR6 as one of the reference scenario to limit warming to 2°C without overshoot [3].

In order to assess the sustainability of non-dominant solutions, it is necessary to evaluate the share of the considered industrial process in relation to all human activities, and this for all environmental impacts. The aim is to define the safe operating space for the process, that can be described as the maximum acceptable impact that a process can have to remain below sustainable thresholds [30]. Several methods can be used for that purpose. The allocation principle that is used in this study is derived from the economic value added of the process as described in Jovet et al. [31]. To evaluate the deviation of each impact category of a non-dominated solution with respect to the sustainable level, the sustainability ratio defined by equation (2) is used.

$$Sr_{\mathrm{i}}(x) = \frac{\mathrm{I}_i(\mathrm{x})}{\mathrm{I}_{i,sustainable}} \tag{2}$$

where $Sr_{\mathrm{i}}(x)$ is the sustainability ratio of solution x for impact category i, $\mathrm{I}_i(\mathrm{x})$ the impact of category i and $\mathrm{I}_{i,sustainable}$ the sustainable level for the impact category i for the considered industrial process, which is derived from the share of the process in relation to its value added as described in Jovet et al. [31]. Another criterion was introduced in [31] to assess the sustainability of an industrial process: the contribution level $C_i(x)$. This criterion compares the ratio of the impact I_i to the total impact $I_{i\ tot}$ of the category i to the share of the economic value added of the process $EVA_{process}$ to the total economic added value EVA_{tot}:

$$C_i(\mathrm{x}) = \frac{I_i(x)}{I_{i\,tot}} \cdot \frac{EVA_{tot}}{EVA_{process}} \tag{3}$$

This criterion puts the importance of the sustainability ratio into perspective. Indeed, if the sustainability ratio is above 1 (i.e. non-sustainable), but the contribution level is below 1 (i.e. less than the average for human activity), reducing the environmental impact of this process may not have a major impact on the global sustainability but remains a needed target. On the contrary, reducing the environmental impact of a process having a high contribution level can have a significant effect on the impact category even if the impact level of this process is below the threshold. As an example, Fig. 3 shows the sustainability ratio versus the contribution level for three different impact categories A, B and C. Impact category B has a high sustainability ratio but a small contribution level, while impact category C behaves in the opposite way. This work considers the contribution of impact categories B and C to be equivalent in their ability to achieve or maintain a sustainable level for their respective category. For this reason, we propose to use a corrective contribution level C* in this paper to consider the importance of a sector in the total contribution and not only the sustainable level. This corrective factor is based on the orthogonal projection of the impact category coordinate on the linear function y = x.

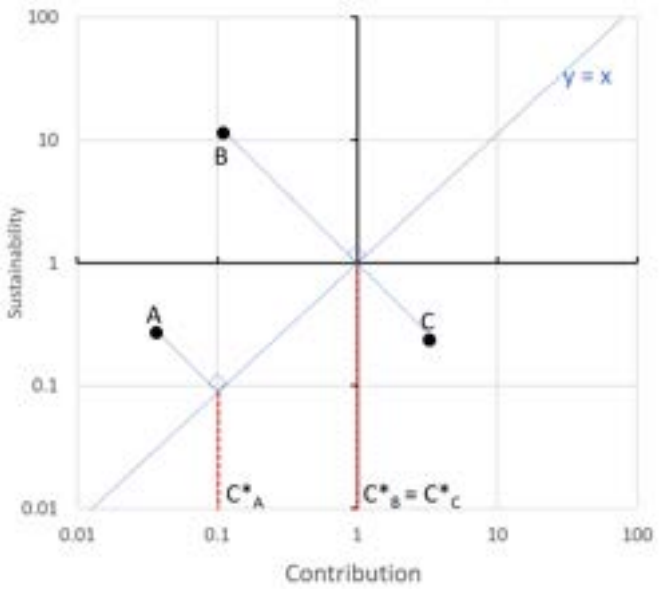

Fig. 3 – Contribution level corrected for each impact categories (A, B and C in this example) based on their sustainability level and contribution.

2.6.2. Classification

The classification of non-dominated solutions is realised using three different methods, (i) ranking 1 (R1) based on weighting the different impact categories with the EF 3.0 impact weighting scores Ws_i (

Table 4), (ii) ranking 2 (R2) by adjusting the previous score with the C* factor, (iii) ranking 3 (R3) using the C* factor to calculate a penalty score C' which becomes more penalizing the more the sustainability threshold is exceeded, according to equation (4).

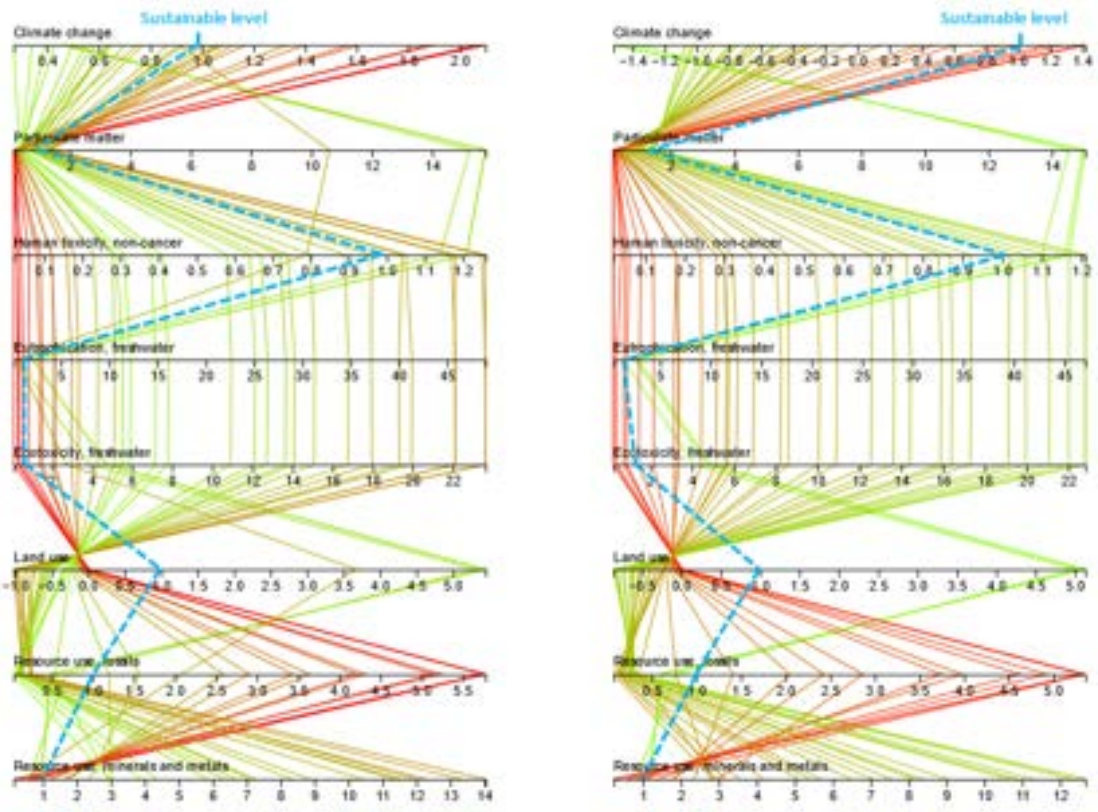
$$\begin{cases} C'_i(x) = e^{C^*_i(x)-1} & \text{if } C^*_i < 0 \\ C'_i(x) = C^*_i(x)^2 & \text{if } C^*_i > 0 \end{cases} \quad (4)$$

The final score for each non-dominated solution and the three different ranking methods is obtained using equation (5).

$$\begin{cases} R1 = \sum_i Ws_i . Sr_i(x) \\ R2 = \dfrac{\sum_i Ws_i . |C^*_i(x)| . Sr_i(x)}{\sum_i |C^*_i(x)|} \\ R3 = \dfrac{\sum_i Ws_i . C'_i(x) . Sr_i(x)}{\sum_i C'_i(x)} \end{cases} \quad (5)$$

3. Results & Discussion

The results of non-dominated solutions before ranking are presented in Fig. 4 for 2015 - 2040 and 2065 - 2090 periods for the impact categories that are not always sustainable. The following impact categories are always sustainable for the considered industrial sector whatever the technological solution studied and are not presented in Fig. 4: ozone depletion, Ionising radiation, photochemical ozone formation, human toxicity, cancer, acidification, marine eutrophication, terrestrial and water use. In this figure, each line represents the ratio between the impact of the process and the sustainable level of one heat production solution across all environmental impacts. Each value at the left of the blue line can be considered as sustainable while the value at the right is not. The changes between the 2015-2040 and 2065-2090 periods come from the development of CCS technology and the evolution of the sustainable climate change thresholds (which uses a budgeting approach). For the period 2065-2090, which presents greater uncertainties, it cannot be excluded that the current challenges will evolve according to the choices made by then. It is already possible to do some projection for climate change based on the willingness to limit the temperature increase. On the other hand, this approach helps to evaluate which impact categories could be an issue if the process were to continue as it does today.



(a) (b)

Fig. 4- Sustainability ratios of non-dominated solutions for periods (a) 2015-2040 and (b) 2065-2090 for impact categories exceeding the sustainable threshold value. The blue dotted line shows the sustainability limit corresponding to all values below 1. Each line is one of the 35 non-dominated solutions. The colour code varies from green to red, from the lowest to the highest value of climate change indicators to present the trades-off.

The first observation is that none of the 35 non-dominated heat production systems respects all the sustainable thresholds for both periods of time, i.e. all impact indicators lower or equal to 1 for a same heat production solution. The dispersion of the non-dominated solutions on the climate change indicator shows a result well above the sustainable level on indicators such as toxicity with a result up to 20 times the limit, freshwater eutrophication with a factor up to 50 or mineral resource use with a factor up to 13. The largest exceedances of sustainable levels are seen for solutions that meet the sustainable level for the climate change indicator. In contrast, the solutions that exceed the limit for climate change are below the sustainable levels for the other indicators, except for the fossil fuel consumption and freshwater eutrophication indicators.

Using the ranking method R1, the MHP technology performs the best achieving a ranking of 1 and 2 for both periods as presented in Fig. 5. As the environmental constraint increases over the period 2065-2090, it can be seen that the biomass solution ranks 7 to 10 times behind the MHP. The R1 score is very stable for all solutions combining MHP and gas boiler despite a high weight for climate change with over 20% of the ranking based on this indicator. Electrical boilers are heavily impacted by their lower electricity to heat conversion factor compared to MHP that results on a ranking of these solutions among the least efficient. It can be noted that the storage solution does not provide any gain with a ranking that decreases with the increase in storage use. This is due to different factors such as the low share of intermittent energy, which results to a low variation of the environmental impact of the electricity between the different time steps, but also due to the lack of process intermittency which is not sufficient to compensate for storage losses. However, this conclusion is specific to the profiles of electricity consumption and production chosen in this example. For electricity mixes with greater variations in environmental impact between time steps, non-dominated solutions will be more time-dependent and therefore storage will have a more important role.

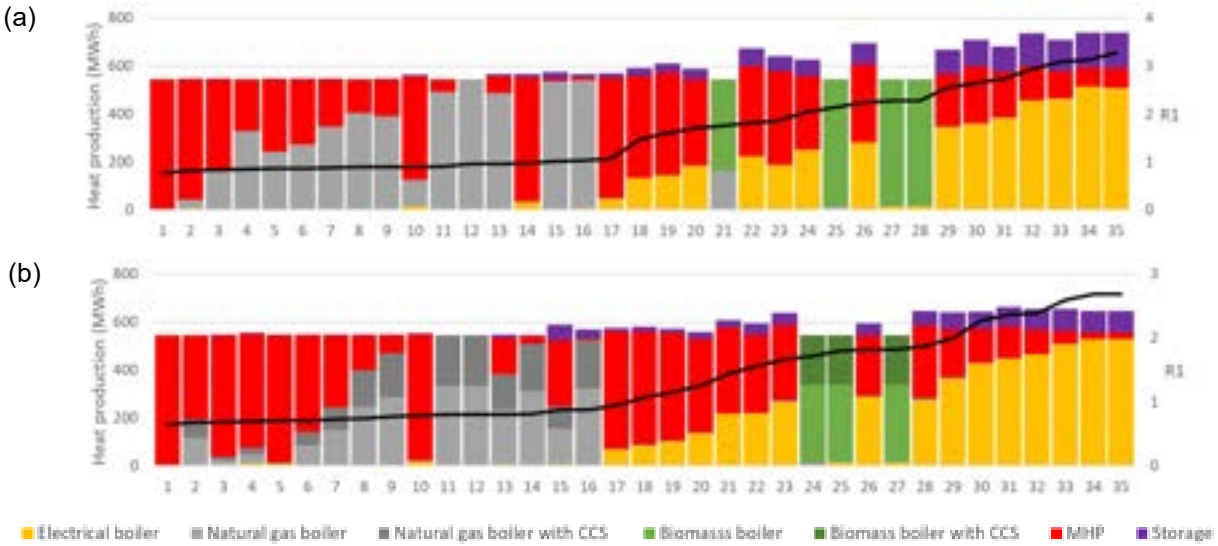


Fig. 5 – Non-dominated solutions ranked with method R1 using EF 3.0 ponderation factor for (a) years 2015-2040, (b) years 2065-2090. The score R1 is displayed with the black line.

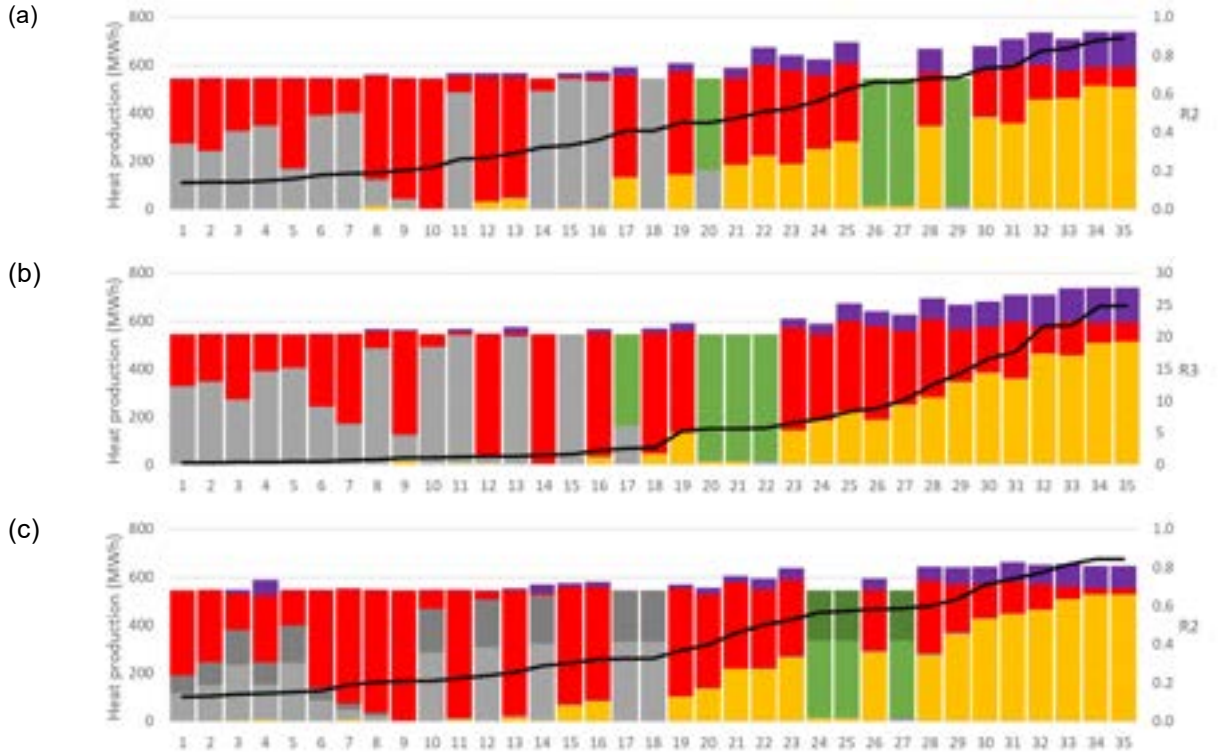
The use of the R2 and R3 ranking methods, for which the higher the threshold exceedance, the higher the penalty, leads to significant changes compared to the R1 approach as presented in Fig. 6. The greater the penalty for exceeding global limits, the greater the share of gas combined with CCS development in the optimal solutions. Indeed, gas performs well in indicators for which electricity does not, and vice versa, which results to impacts closer to sustainable levels with fewer high-performing impact categories but simultaneously fewer categories far above the thresholds. Biomass boiler also benefits from these two-ranking methods but in a more limited way. On the other hand, the more we penalise exceeding the limits, the more the best ranked solutions exceed the threshold for the climate change indicator. For the period 2015-2040, among the 10 best solutions, only 2 meet the threshold for climate change whereas there were 4 with the R1 ranking method. The presence of CCS combined with the improvement of the carbon content of electricity increases this number to 7 solutions respecting the sustainable level for climate change over the period 2065-2090 while the R1 classification method is 9.



(d)

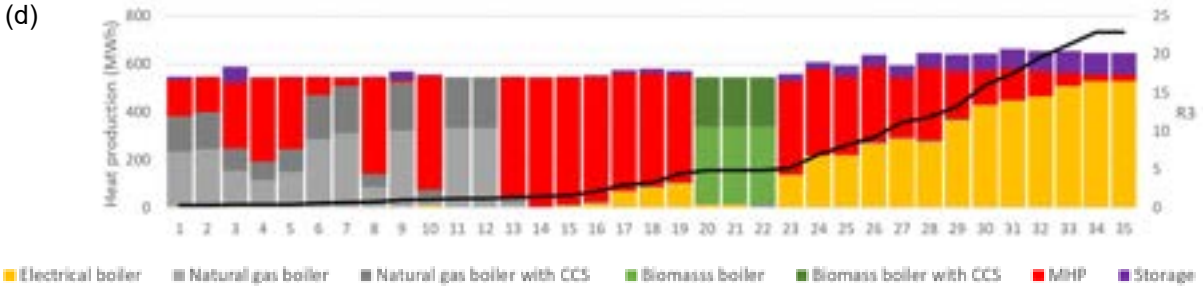


Fig. 6 – Non-dominated solutions ranked with method (a) R2 for the years 2015-2040, (b) R3 for the years 2015-2040, (c) R2 for the years 2065-2090, (d) R3 for the years 2065-2090. The score R2 and R3 are displayed with the black line.

Based on the results, it is possible to imagine two types of approaches to bring the industrial activity back to sustainable levels. The first approach requires each process to respect the global limits by defining a safe operating space for each process. This approach corresponds to the development of solutions where exceeding sustainable levels is strongly penalised, i.e. ranking method R3. The second approach requires each process to implement the best possible solution and therefore to adapt the process safe operating space for each impact category based and their ability to perform. However, this requires a comprehensive review of all human activities to ensure that the entire range of human activities is able to meet the thresholds of sustainability. The first method is simpler to implement because it is only necessary to allocate a share of the impacts to each process, whereas for the second method it is necessary to have a breakdown by impact category for each process. On the other hand, the first method will tend to ask for solutions as close as possible of the sustainable threshold (i.e. never the best but never the worst), which results in a multiplication of energy sources, and therefore in a multiplication of system for the industries to deal with, which increases the level of complexity on site.

However, if the transformation of industrial heat production means is oriented towards achieving the climate change objective, some impact categories are likely to exceed the sustainable limits. Fig. 7 shows that the best solutions with ranking method R3 are above the sustainable threshold for climate change for the period 2015-2040. The best solution for climate change indicator is ranked only 14th with the R3 method in 2015-2040 and 20th in 2065-2090, while the best solution with method R1 is also the best for the climate change indicator. However, high performing solutions on climate change exceed the sustainable levels on some other criteria, which explains their ranking with the R3 method, as can be seen in Fig. 7. Therefore, it is not possible to reach the sustainable level with the technology proposed and the safe operating space available for the process based on added value. This means that the safe operating space allocated to the process will not be sufficient to enable it to stay below the threshold. There are two ways to have sufficient safe operating space for the process:

(i) If the process needs to continue at the current level (e.g. for a vital process), other processes need to decrease in order for it to leave enough operating space.

(ii) this process must decrease

This will result in a modification of certain sectors of activity by reducing the operating space of some sectors that will be considered less essential or sufficiently efficient to leave enough safe operating space to sectors considered as essential. A reflection on this allocation is therefore essential to define the place of each sector in a sustainable world according to numerous technical parameters but also around political or sociological themes.

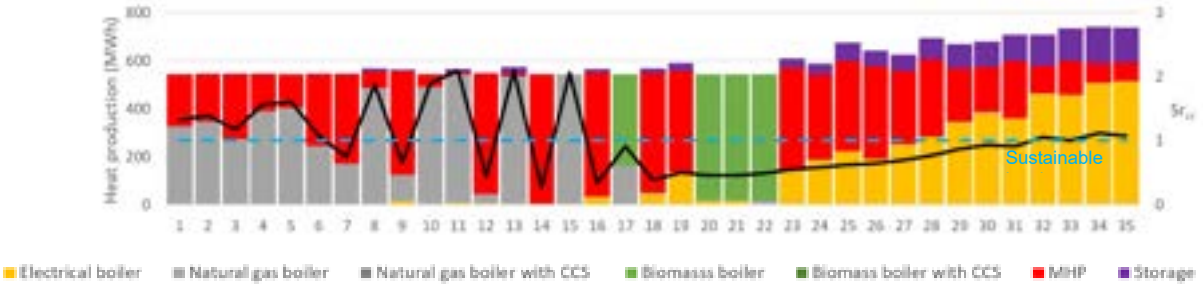

Fig. 7 – Non-dominated solutions ranked with method R3 for the years 2015-2040. The sustainable ratio for climate change is display in black and the sustainable level in blue.

4. Conclusions & Recommendations

In this paper, a method has been developed to optimize, from an energy, economic and environmental point of view, the combination of energy systems to be used to produce heat for a dynamic industrial process. The energy mix uses combinations of different possible technologies such as electric, gas and biomass boilers or heat pumps powered by waste heat or thermal storage. An optimisation model, based on LCA criteria, enables to obtain a number of non-dominated solutions. Even if some solutions enable to reduce some impact categories, no solution was found to reach sustainable levels for all impact categories. Thus, the best performing solutions on the climate change indicator also exceed the sustainable level for several other environmental impact indicators such as land use, toxicity, eutrophication or resource use fossil. By ranking the non-dominated solutions, using different weighting criteria, it can be seen that the more one penalizes the exceeding of sustainable levels for each impact category, the more mixed solutions are present and in particular the combination of MHP and gas boiler.

The results show that none of the studied solutions can reach a sustainable level regardless of the technology used and this, despite the use of resolution algorithms to highlight the best performing solution. This assessment shows that it is necessary to have a reflection on the share that each process can represent in human activities. It is possible to envisage this redistribution in two ways, (i) by requiring an identical effort from all sectors to reach the targeted level or (ii) by determining, according to the needs and potential of each sector, its maximum acceptable contribution for each impact category. The latter method requires in-depth knowledge of the potential of each sector, which could be determined using the optimization model presented in this paper but on a larger scale. For both approaches, it is essential to think holistically so that all human activities are taken into account and not to look at each sector individually to conclude about sustainability.

Comparative study of oxygen separation using cryogenic and membrane techniques for nCO2PP

Maja Kaszuba, Paweł Ziółkowski, Dariusz Mikielewicz

Gdańsk University of Technology, Faculty of Mechanical Engineering and Ship Technology, Poland,
maja.kaszuba@pg.edu.pl CA, pawel.ziolkowski1@pg.edu.pl, dariusz.mikielewicz@pg.edu.pl,

Abstract:

Due to the intense use of coal and gas while producing electricity, carbon capture and storage technologies need to be developed. One of the perspectives is oxyfuel combustion. It is the easiest method in the light of subsequent capture and storage of carbon dioxide. Due to the lack of nitrogen in the substrate, there are no nitrogen oxides in flue gases. The main drawback of that method is the very high energy consumption of the oxygen production technology. These days well-known technologies are cryogenic distillation and pressure swing adsorption. There are also novel oxygen production techniques such as chemical looping air separation and membrane processes. In the paper, a comparison between cryogenic air distillation and membrane separation is taken into consideration. Energy consumption of the cryogenic air distillation is on average 250 kWh/ ton O_2. On the other hand, there is an oxygen transport membrane but this approach requires a heat source because the process takes place at very high temperatures. Produced oxygen is required for the concept of the negative CO_2 gas power plant (nCO2PP). The power cycle uses oxygen and sewage sludge gasification gas for the combustion process. The two mentioned earlier oxygen production installations were modelled and confronted with the needs of the nCO2PP. Obtained cumulative efficiencies of the nCO2PP cycles were 21.26% and 23.48% for the power cycle integrated with a cryogenic air separation station (depending on oxygen purity), and 24.89% and 24.59% for the cycle combined with oxygen transport membrane (depending on the membrane area). The power cycle consists of a gasifier, air separation unit, compressors, turbines, wet combustion chamber, spray ejector condenser, and a CCS installation. The nCO2PP cycle is equivalent to the Bioenergy with Carbon Capture and Storage idea, because of the use of sewage sludge as fuel and CO_2 capture.

Thermodynamic analysis; Oxy-combustion; Energy penalty; CCS; cryogenic ASU; oxygen transport membrane.

1. Introduction

The oxy-fuel combustion is supposed to be one of the remedies for global warming, next to pre-combustion and post-combustion technologies [1]. The use of oxygen as an oxidizer prevents the generation of nitrogen oxides and provides only water vapor and carbon dioxide in exhaust gases. It should be highlighted, that oxy-combustion is one of the Carbon Capture and Storage (CCS) technologies and it is said to be the most promising one for the power cycles fuelled with fossil fuels [2]. The oxygen is 21% of the atmospheric air, and its amount delivered to the combustion chamber is based on the combustion stoichiometry, which is approximately 18 – 20 tons of O2/ day for 1 MW of electric installed power [3], [4]. If the biggest Polish power plant “Bełchatów” would work with oxy-combustion technology it would require as much as 92 thousand to 102 thousand tons of O2 per day depending on the power output.

The presented paper refers to oxygen production for the needs of the “Negative CO_2 emission gas power plant” (nCO2PP) [5], which is a kind of bioenergy with carbon capture and storage (BECCS) power cycle. The nCO2PP is a cycle, which utilizes sewage sludge as fuel and works with the oxy-combustion process. In this work, cryogenic air distillation and oxygen transport membrane (OTM) were taken into consideration.

Cryogenic air separation is the most popular and developed way to produce oxygen for the needs of oxyfuel combustion [6-8]. This way of oxygen production also provides other gases, like nitrogen, argon, krypton, and xenon [9]. The technology of very low temperatures is used to generate methane and helium from natural gas or in hydrogen production from coke oven gas [6]. It is based on the use of boiling points of air components to separate them. The air must be cooled first and then transported to rectification columns where is separated [10].

The second oxygen production method is the one using an oxygen transport membrane. The separation process is able to be carried out because of the electrochemical mechanisms and diffusion [11]. There are two

types of designs of oxygen production with the OTM method that can be highlighted, namely the three-end and four-end ones. The first one is about creating a vacuum on the permeate side of the membrane. The four-end is about introducing recirculated exhaust gases in counter-current on the permeate side of the membrane in case to provide the driving force [11, 12]. Oxygen transport membranes are made of two main groups of materials, that is perovskite and fluorite [13]. The third technology of oxygen production is pressure swing adsorption [14, 15], but it is not considered in this work.

The aim of this paper is to compare two technologies of oxygen production (based on air separation) for the requirements of the nCO2PP and check their impact on cycle efficiency. In this case, two models of oxygen production stations have been examined and integrated with the nCO2PP model. All analyses have been carried out using the Ebsilon software [16].

2. The power cycle

2.1. Negative emission CO_2 gas power plant

The oxy-combustion technology is said to be the best solution to capture and store carbon dioxide from power plants [17]. Over the years many power cycle installations with oxy-combustion technology have been proposed [18-20]. The negative carbon dioxide emission gas power plant means that the electricity is produced with negative carbon dioxide emission in the total balance of emissions. Emission is negative because the power plant uses sewage sludge as fuel and an oxy-fuel method to capture CO_2. If only one of the mentioned approaches was used, only a zero-emission power cycle would be an outcome. The scheme of the nCO2PP is shown in Figure. 1.

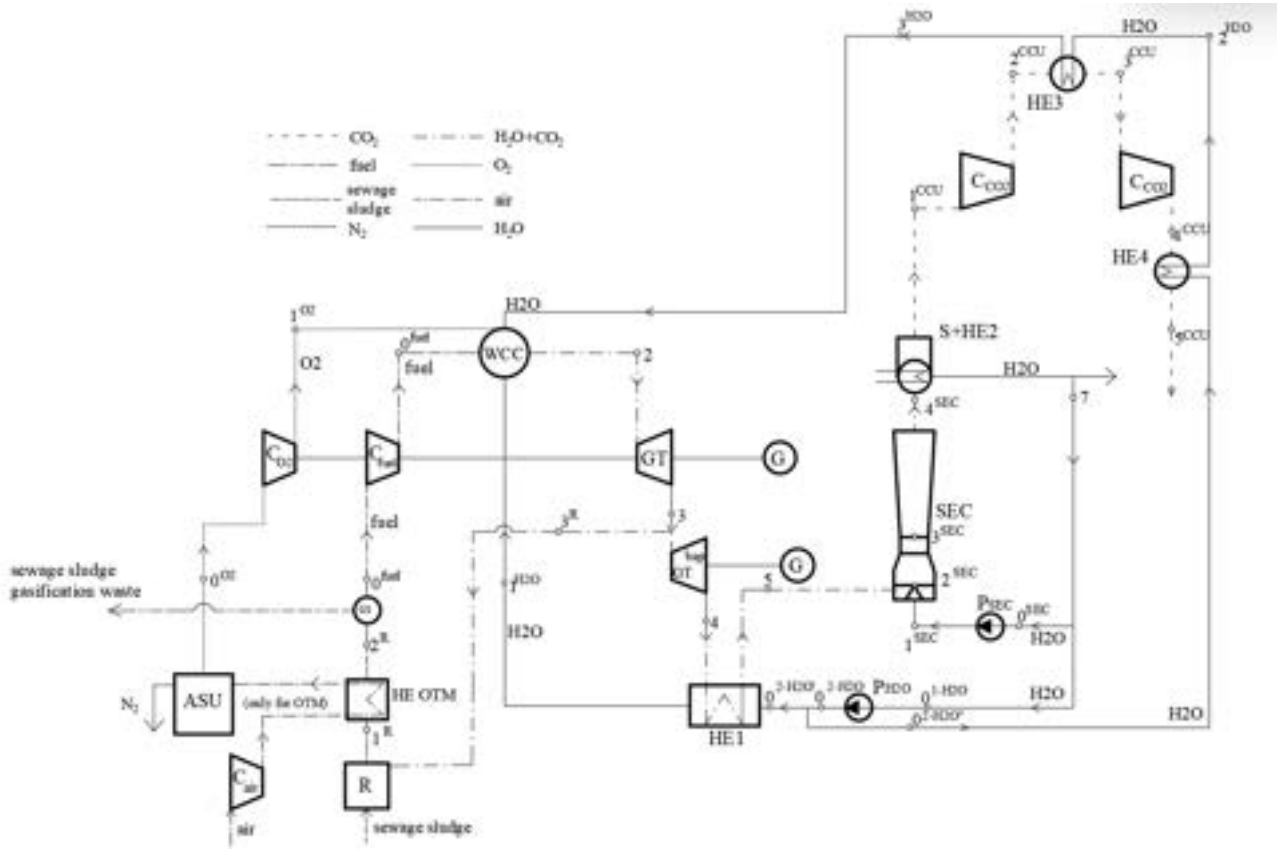

Figure. 1. The negative emission CO2 gas power plant (nCO2PP) integrated with gasification and oxygen transport membrane type of ASU, where: C_{air} – air compressor, C_{O2} – oxygen compressor, C_{fuel} – fuel compressor, WCC – wet combustion chamber, GT – gas turbine, GT^{bap} – low-pressure turbine, HE1 – heat exchanger 1, SEC – spray-ejector condenser, G – generator, P_{H2O} – water pump, P_{SEC} – SEC pump, S+HE2 – separator connected with heat exchanger 2, C_{CO2} – CO_2 compressor, HE3 – heat exchanger 3, HE4 – heat exchanger 4, HE OTM –heat exchanger for OTM separation, GS – gas scrubber, R – gasifier, ASU – air separation unit.

The nCO2PP cycle consists of an air separation unit (ASU), gasifier (R), carbon capture and storage installation (CCS), and the main part of the installation. The system is equipped with two compressors. The first one transports oxygen (C_{O2}), whereas the second one is for fuel transport (C_{fuel}). The cycle also consists of the high-pressure gas-steam turbine (GT – expansion from 10.5 bar to 1 bar), low–pressure turbine (GT^{bap} – expansion from 1 bar to 0.078 bar), wet combustion chamber (WCC – with temperature 1100℃), and generator (G). The main heat exchanger (HE1) heats the water supplied to the WCC with exhaust gases. The spray–ejector condenser (SEC) is a crucial device in the process of condensation of steam from a mixture of

CO_2+H_2O. A CCS installation consists of two compressors (C_{CO2}), two heat exchangers (HE3, HE4), and a heat exchanger connected with a water separator (S+HE2). The water pump (P_{H2O}) increases the pressure of water to a value of 10.5 bar, which is supplied to the WCC [5].

The initial nodes in the cycle can be established when fuel and oxygen compressors (C_{fuel}, C_{O2}) start transporting fluids to the combustion chamber (WCC). In WCC the combustion process takes place which creates a mixture of CO_2 and H_2O. Fuel and oxygen are necessary substrates, however, due to the high temperature of the processes there is injected water as a cooling medium to attain a temperature around 1100℃. Injection of the cooling medium is obligatory, because of the high temperature of stochiometric combustion, which can increase even to 3000 K as the effect of the oxy-combustion process. Additionally, the extra mass flow of water (nodal points 2^{H2O}, 3^{H2O}) contributes to the increase of the cycle efficiency, which is dependent on amount of regenerated heat. After the process in the WCC exhaust expands in the turbines (GT, GT^{bap}). Afterward, exhaust gases are used to heat water which is transported to the WCC in the regenerative heat exchanger (HE1). A part of the exhaust stream is directed to the gasification reactor (R) (or gasifier) and it is used in the gasification process. The spray-ejector condenser (SEC) intakes flue gases from the heat exchanger (HE1). Provided is also water, which is a motive fluid in the SEC with the pump (P_{SEC}). The presence of motive water, which breaks up into droplets and a mixture of steam and carbon dioxide enables the condensation process to take place. A mixture of water and carbon dioxide leaving the SEC goes to the separator connected with the heat exchanger (S+HE2). In the separator, water is isolated and directed to pumps (P_{SEC}, P_{H2O}). Subsequently, it is used as the motive fluid in SEC or as a coolant in the combustion chamber. The carbon dioxide is directed to the compressor (C_{CO2}), and then to the heat exchanger (HE3). It ought to be mentioned that in the air separation process with a membrane, the compressed air takes heat from fuel at the additional heat exchanger (HE OTM) downstream of the outlet of the gasifier. It is profitable because the oxygen production process with OTM needs to be carried out at a very high temperature, and fuel transported to the combustion chamber needs to be cooled before the fuel compressor (C_{fuel}).

2.2. Air separation units

As it was mentioned, two ways of oxygen production from the air were taken into consideration: cryogenic air distillation and oxygen transport membrane. Diagrams of them are shown in Figure. 2. For modelling using the Ebsilon software the cryogenic air separation unit is developed of an air compressor C_{air}, a pre-cooler PC, and two rectification columns RCI and RCII. In the separation process, the air is compressed to 5.8 bar, cooled in the pre-cooler, transported into the columns, and then separated into oxygen (O2), high-purity nitrogen (hN2), and low-purity nitrogen (lN2).

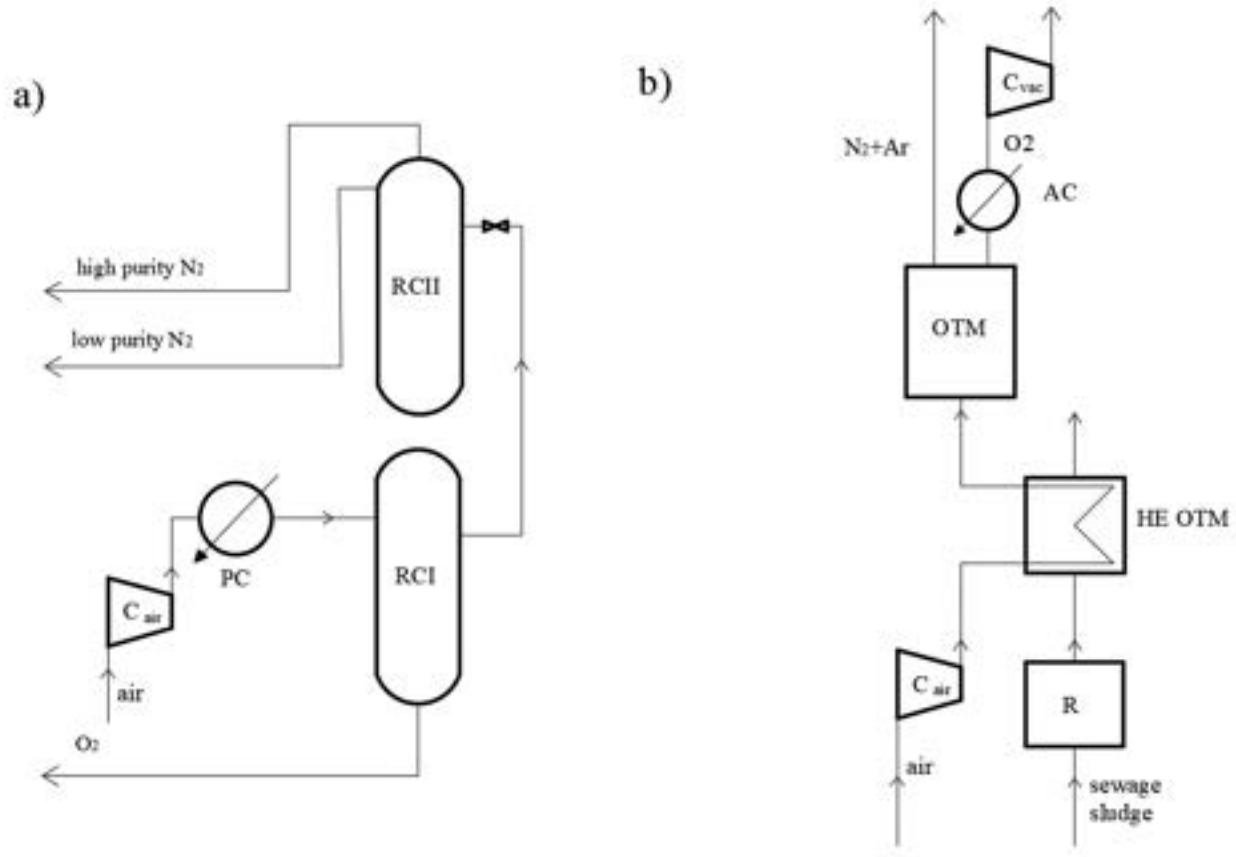

Figure. 2. Diagrams of oxygen production stations a) cryogenic b) oxygen transport membrane, where:

C_{air} – air compressor, PC – pre-cooler, RCI – column I, RCII – column II, R – gasifier, OTM – oxygen transport membrane, HE OTM – heat exchanger, AC – after-cooler, C_{vac} – vacuum pump.

The membrane separation unit consists of an air compressor C_{air}, a heat exchanger HE OTM, an after-cooler AC, a vacuum pump C_{vac}, and a membrane OTM. In this process, the proper oxygen partial pressure ratio at both sides of the membrane is set. These ratio values are 1.034 and 1.330 (depending on the membrane area), then heated to 740 ℃ in the HE OTM, separated in the membrane, and then cooled in AC before transporting to the oxygen compressor and the combustion chamber.

The main difference between the OTM method and the cryogenic ASU is that in the cryogenic separation air is cooled down in the pre-cooler after compression, whereas with the OTM, the air after compression must be heated to the correct temperature values for the electrochemical reaction to take place.

3. Methodology

The analyses have been carried out in the Ebsilon software, which uses mass and energy balance equations. Additionally, real gas correction equations such as the Peng-Robinson or the Redlich-Kwong equation can be set. The software predefined models are clearly expressed by thermodynamic tables for steam.

3.1. Efficiency calculation

The gross efficiency and the net efficiency have been calculated according to Eq. (1) and (2)

$$\eta_g = \frac{N_t}{\dot{Q}_{CC}} \tag{1}$$

where $N_t$is a combined power of turbines in kW and $\dot{Q}_{CC}$ is a chemical energy rate of combustion in kW.

$$\eta_{net} = \frac{N_t - N_{CP}}{\dot{Q}_{CC}} \tag{2}$$

Where $N_{CP}$is power needed for cycle own needs in kW and can by expressed by Eq. (3).

$$N_{CP} = N_{ASU} + N_{C_{fuel}} + N_{C_{O2}} + N_{P_{H2O}} + N_{P_{SEC}} + N_{C_{CCS}} \tag{3}$$

Where N_{ASU} is power for oxygen production, $N_{C_{fuel}}$ is power for fuel compressor, $N_{C_{O2}}$ is power for oxygen compressor, $N_{P_{H2O}}$is power for water pump, $N_{P_{SEC}}$ is power for SEC and $N_{C_{CCS}}$ is power for CCS compressors needs. All mentioned terms are expressed in kW.

Additionally, cumulative cycle efficiency which is a product of the net efficiency of the power cycle (η_{net}) and gasification process efficiency (η_{R_H}), has been calculated. The gasification process inside the gasifier was not calculated in this work but its efficiency has been taken from other work regarding nCO2PP [21]. The cumulative efficiency is presented in Eq. (4):

$$\eta_{cum} = \eta_{R_H} \cdot \eta_{net} \tag{4}$$

where gasification process efficiency (η_{R_H}) according to the literature [21] is equal to η_{R_H} =86.52% for the nCO2PP cycle.

3.2. Oxygen transport mechanism in the membrane

Oxygen permeation in the membrane is dependent on mass diffusion and electrochemical factors. Oxygen flux through the membrane can be formulated with the Wagner equation, which is presented in Eq. (5) [11]

$$j_{O2} = C_{wagner} \cdot \frac{T_m}{d_m} \cdot e^{\left(\frac{-K_{wagner}}{T_m}\right)} \cdot \ln \frac{P_{O2feed}}{P_{O2perm}} \tag{5}$$

Where j_{O2} is oxygen permeation rate in mol/(m²*s), T_m process temperature in K, d_m is membrane thickness in m, P_{O2feed} is pressure at the feed steam side in bar, P_{O2perm} is pressure at the permeate side in bar, C_{wagner} is a constant dependent on material in mol/(m*s*K), and K_{wagner} is a constant expressed in K.

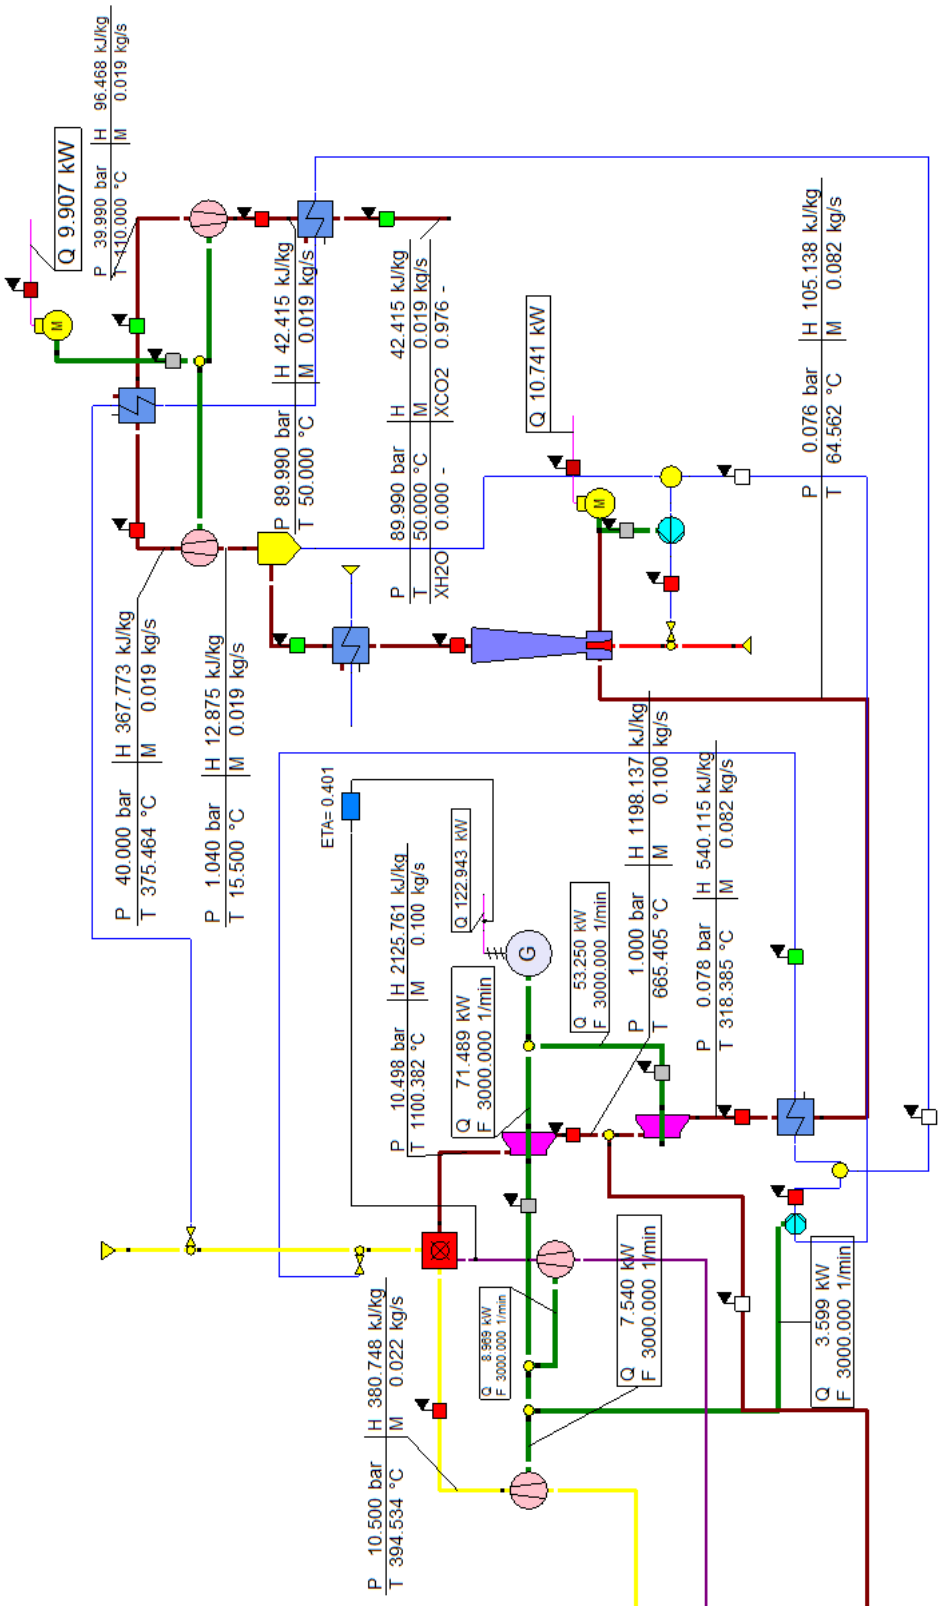

Figure. 3. The setup of the nCO2PP model in the Ebsilon software for the cryogenic case (without the ASU model) [22]

Coefficients K_{wagner} and C_{wagner} are dependent on the membrane material and they values are determined experimentally but in this case values from the literature were taken [11, 12].

The presented formula is an Arrhenius approach to Wagner equation, which assumes ionic conductivity is more important in the permeation process in the membrane than the electron based conductivity [11].

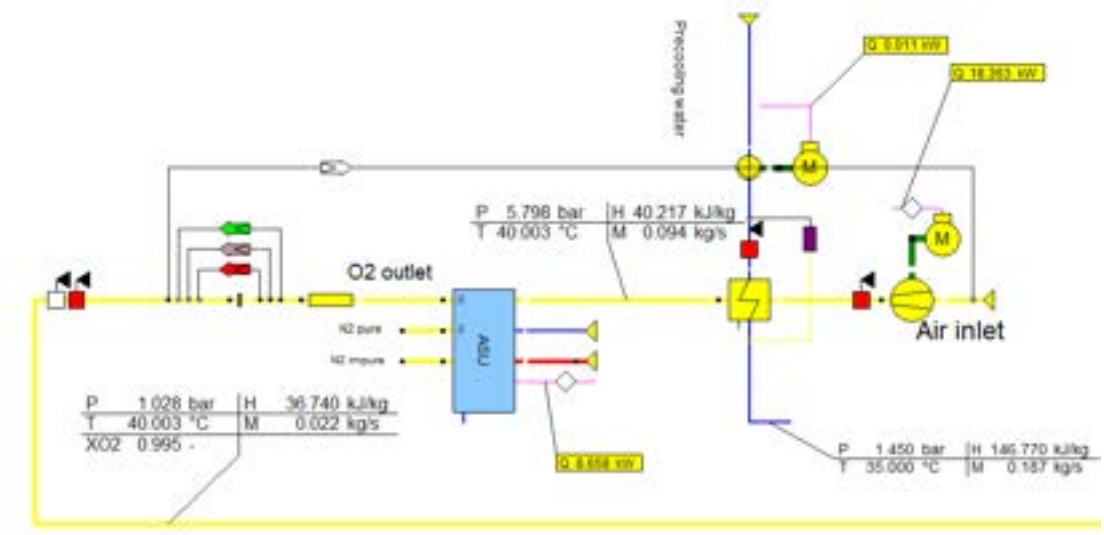

Figure. 4. The setup of the cryogenic ASU model in the Ebsilon software for 99.5% oxygen purity

3.3. Energy penalty and emissivity

For both oxygen production techniques, an important parameter is the energy penalty of oxygen production, which is expressed by the Eq. (6):

$$e_{pen} = \frac{N_{ASU}}{\dot{m}_{O2} * 3600} \tag{6}$$

where N_{ASU} is power for the needs of oxygen production expressed in kW and $\dot{m}_{O2}$ is the produced oxygen mass flow expressed in kg/s.

As the considered cycle name says, an essential factor is the emission potential (Eq. (7)) of the whole system, which can be defined with Eq. (7) [23, 24]:

$$eCO_2 = R\frac{\dot{m}_{4-CO_2}}{N_t - N_{cp}}3600 \tag{7}$$

where $\dot{m}_{4-CO2}$ is mass flow rate of carbon dioxide at the outlet of the CCS, R is a factor describing energy source as renewable energy (R for sewage sludge is 90% according to the Polish law [25]). Emission potential eCO_2 is expressed in $kgCO_2/(MWh)$.

The emission calculations should be carried out properly and carefully if the power cycle is integrated with the carbon capture and storage unit. If an energy source is only partly considered as a renewable source of energy, emissions should be multiplied by the factor that accounts for it. In this case, the relative emissions of carbon dioxide were multiplied by η_{net}. The relative emission is presented by Eq. (8).

$$\eta_{net} \cdot e_{CO_2} = \frac{N_t - N_{cp}}{LHV_{gas} \cdot \dot{m}_{0-fuel}} R\frac{\dot{m}_{4-CO2}}{N_t - N_{cp}}3600 = R\frac{\dot{m}_{4-CO2}}{\dot{Q}_{CC}}3600 \tag{8}$$

Avoided eCO_2 for the negative emission power plant is a sum of emissions without CO_2 capture and the value of negative emissions obtained because of the application of renewable energy source [24].

4. Assumptions

For the purpose of calculations, several assumptions were made. The nCO2PP cycle uses sewage sludge as feedstock for gasification and fuel production. The combustion process is carried out with oxygen as the oxidizer. On top of the mentioned earlier, the following assumptions have been made in calculations:

- mixture of fuel and oxidant is stoichiometric,
- mass flow rate of exhaust gases is constant, and its value is 0.1 kg/s,

- temperature in the combustion chamber is constant and its value is 1100 °C,
- pressure in the combustion chamber is constant and its value is 10.5 bar,
- pressure after turbines GT and GT^{bap} are respectively 1 bar and 0.078 bar.

Calculations were carried out for two oxygen production stations. For cryogenic installation, two analyses dependent on oxygen purity were made, namely one for 99.5% (extremely high with higher energy penalty) purity and the second for 96% purity (accepted value for many technical processes). The air at the inlet to the cryogenic unit was compressed to 5.8 bar. For OTM solution also two analyses were made with constant oxygen purity at the level of 99.5%. However, one for 96 cm^2 membrane area and the second for 12 cm^2. Oxygen flux through the membrane is dependent on several features. The first one is a membrane thickness, which was set as 1 mm as in the literature [26]. The process temperature was set as 740℃, because of possibility of heating up in the heat exchanger after gasification process. Values of the mentioned coefficients $\mathrm{K_{wagner}}$ and $\mathrm{C_{wagner}}$ were taken from literature respectively as 6201 K and 1.004*10^{-6} mol/(m×s×K) [11, 12]. Syngas from sewage sludge gasification has the following composition: 13.31% CO, 5.12% H_2, 11.46% CH_4, 59.29% CO_2, 8.03% C_3H_8, and its LHV is 17.44 MJ/kg.

Other assumptions are included in Table 1.

Table 1. Assumptions for the thermodynamic cycle negative CO_2 gas power plant (nCO2PP) integrated with gasification and ASU

Parameter	Symbol	Unit	Value
Initial fuel temperature	t_{fuel}	ºC	50
Initial oxygen temperature	t_{O2}	ºC	15
Syngas fuel pressure before C_{fuel} compressor	p_{0-fuel}	bar	1
Oxygen pressure before C_{O2} compressor	p_{0-O2}	bar	1
Regenerative water pressure to WCC	p_{1-H2O}	bar	254.95
Exhaust vapor quality after HE1	x_5	-	0.999
Exhaust temperature after HE1, before SEC	t_5	ºC	62.77
CO_2 pressure after compressor C_{CCU1}	p_{2-CCU}	bar	40
CO_2 pressure after compressor C_{CCU2}	p_{4-CCU}	bar	90
H_2O temperature after HE4	t_{2-H_2O}	ºC	91.67
CO_2 temperature after HE3	t_{3-CCU}	ºC	110
Water vapor from Separator in 1^{CCU} mixed with CO_2 vapor	-	%	100% humid
Pressure after GT^{bap}	p_4	bar	0.078
Temperature after SEC	t_6	ºC	18.03
Turbine GT, internal efficiency (η_i)	η_{iGT}	-	0.89
Turbine GT^{bap}, η_i	$\eta_{iGT-bap}$	-	0.89
Fuel compressor C_{fuel}, η_i	$\eta_{iC-fuel}$	-	0.89
Oxygen compressor C_{O2}, η_i	η_{iC-O2}	-	0.87
Water pump P_{H2O}, η_i	η_{iP-H2O}	-	0.43
Water pump P_{SEC}, η_i	η_{iP-SEC}	-	0.80
CO_2 compressor $C_{CO2\text{-}1}$, η_i	$\eta_{iC-CO2-1}$	-	0.85
CO_2 compressor $C_{CO2\text{-}2}$, η_i	$\eta_{iC-CO2-2}$	-	0.85
Mechanical efficiency for all devices	η_m	-	0.99
Gasification process efficiency	η_{R_H}	-	0.8652

5. Results

In the course of calculations four scenarios were considered, i.e.:

- cryogenic air separation with 99.5% oxygen purity,
- cryogenic air separation with 96% oxygen purity,
- oxygen transport membrane separation with 96 cm^2 membrane area,
- oxygen transport membrane with 12 cm^2 membrane area.

In all cases exhaust mass flow after the combustion chamber was 100 g/s, and the temperature in the combustion chamber was 1100℃. Also in all cases pressure in the combustion chamber was 10.5 bar. Start values of fluids (air at the inlet of the air compressor and fuel at the inlet to gasifier) were set as 1 bar pressure and 15℃ temperature. Between two turbines GT and GT^{bap} is a bleed stream for transporting part of the exhaust to the gasifier, and its pressure is 1 bar. All the results are shown in Table 2. In the first two columns on the left side are the results for nCO2pp with different oxygen purities produced in cryogenic air separation

unit. In the second two columns are presented results for nCO2pp with oxygen transport membrane with two different membrane areas. In Table 3 results of respective emissions are provided.

Table 2. Results of power output and efficiency of the analyses for all cases

			nCO2pp with cryogenic ASU		nCO2pp with OTM	
			oxygen purity 99.5%	oxygen purity 96%	membrane area 96 cm^2	membrane area 12 cm^2
Mass flow at the outlet of the WCC	m_2	g/s	100.00	100.00	100.00	100.00
Exhaust temperature at the outlet of the WCC	t_2	℃	1100.00	1100.00	1100.00	1100.00
Oxygen purity		%	99.50	96.00	99.50	99.5
Turbine bleed pressure		bar	1.00	1.00	1.00	1.00
Turbine power output	N_t	kW	143.05	143.68	144.54	144.61
Power for ASU/OTM needs	N_{ASU}	kW	27.03	18.97	14.00	14.81
Power for own needs	N_{CP}	kW	67.79	60.62	56.66	58.17
Fuel heat	*LHV*	kW	306.27	306.08	305.44	304.17
Gross efficiency	η_g	%	46.71	46.94	47.32	47.54
Nett efficiency	η_{net}	%	24.57	27.14	28.77	28.42
Cumulative efficiency	η_{cum}	%	21.26	23.48	24.89	24.59
Energy penalty	e_{pen}	kWh/kgO_2	0.346	0.242	0.179	0.190

Table 3. Results of emissions for all analyzed cases

			nCO2pp with cryogenic ASU		nCO2pp with OTM	
			oxygen purity 99.5%	oxygen purity 96%	membrane area 115.11 m^2	membrane area 300 m^2
Emission of CO_2	eCO_2	kgCO_2/MWh	-861.05	-741.15	-700.51	-712.20
Relative emissivity of CO_2	$\eta_{net} \cdot e_{CO_2}$	kgCO_2/MWh	-211.58	-201.12	-201.54	-202.39
Avoided CO_2 emission	Avoid CO_2	kgCO_2/MWh	1817.77	1564.65	1478.85	1503.52

6. Discussion

It was not obvious, which approach to oxygen production will be more appropriate for the negative CO_2 emission gas power plant. Both cryogenic distillation and oxygen transport membrane technologies are regarded as energy-consuming. In previous research, only cryogenic air separation was taken into consideration [22]. The nCO2pp power cycle has a characteristic gasifier that produces fuel at 967℃ [21]. This fact was a strong reason to investigate the oxygen transport membrane which needs a heat source.

Calculations indicate that net efficiencies of the nCO2PP for the cryogenic ASU for 99.5% and 96% oxygen purities are 24.57% and 27.14%. Taking into account a gasifier efficiency which was 86.52%, cumulative efficiencies values for the cycle with cryogenic ASU are 21.26% and 23.48% for higher oxygen purity and lower oxygen purity, respectively. It was similar to the cycle integrated with OTM. The nCO2PP reached higher efficiency when the OTM area was larger. For 96 cm^2 membrane area net efficiency and cumulative efficiency were 28.77% and 24.89%. For nearly six times smaller membrane area of 12 cm^2, these efficiencies were 28.42% and 24.59%. It is worth mentioning that by comparing cryogenic ASU (99.5% oxygen purity) and membranes, efficiency savings can be obtained. For 96 cm^2 of membrane area, it is 4.2%, and for 12 cm^2 is 3.85%. In [12] Portillo got 5% efficiency saving comparing these two technologies. Undeniably is the fact, that OTM ASU is thermally integrated with the nCO2PP, and the membrane does not require a heat source from the outside. All heat for air heating is taken from the gasification process, so it is internal cycle heat. It is very possible that the OTM solution would not be effective if there was a need to supply the heat source from the outside.

According to the results, the power demand for cryogenic ASU is 18.89% and 13.20% of the cycle generated power, respectively for 99.6% oxygen purity and 96% oxygen purity. According to the literature, cryogenic ASU should be responsible for 6-7% power loss for industrial solutions [27]. For lower stream rates, the energy requirement of the ASU becomes significantly higher, especially for demonstration and laboratory solutions. Therefore, this study considers a different solution, namely OTM. On the other hand, oxygen transport membrane unit power requirements are 9.69% and 10.24% of the generated power, respectively for 96 cm^2 membrane area and 12 cm^2 membrane area. It is very visible that power requirements for OTM are strongly dependent on the membrane area. It is similar to membrane thickness, air temperature, and membrane material [11, 12, 26].

An important thing is also the power needed to produce oxygen unit. To ensure a stoichiometric combustion process, to the combustion chamber 0.0217 kg/s oxygen mass flow was transported in all four cases. Obtained power consumption values for cryogenic ASU are 0.346 kWh/kgO_2 and 0.242 kWh/kgO_2 for 99.5% oxygen purity and 96% oxygen purity. It can be said those values are possible, especially in the light of the statement by Aneke [28] who says that for 99.9% oxygen purity the power consumption is 0.357 kWh/kgO_2, Tafone in [29] for 99.5% in his research assumes 0.370 kWh/kgO_2, and Fu C. in [4] says that for 95% purity the power consumption is 0.229 kWh/kgO_2. For OTM oxygen production 0.179 kWh/kgO_2 and 0.190 kWh/kgO_2 power consumption for 96 cm^2 and 12 cm^2 membrane area were obtained. Perhaps in this work, the membrane area doesn't occur to be a significant factor but if a bigger power cycle were considered, it would might be a very important thing for examination. According to every special case, it might be more effective to buy a smaller membrane but use more power during operation, or to buy a bigger membrane but use less power. Nevertheless, some researches show [30] that an infinite increase of the membrane area has rather a small effect on power saving.

Emissivity results are interesting. According to the results, cases with theoretically lower efficiency (cryogenic ASU with 99.5% oxygen purity and OTM with 12 cm^2 membrane area) reached a larger value of negative CO_2 emission. These two scenarios also obtained higher values of avoided CO_2 emission. It is because these two solutions have higher values of power for their own needs, which is important according to Eq. (7). Negative emission occurs due to the use of renewable energy source as fuel and using CCS installation. If there was only one of these two solutions, the power plant would be zero emissive.

7. Conclusions

The main novelty of the present work was the thermodynamic analysis of the nCO2PP cycle integrated with gasification and an OTM-type oxygen separation station. As the objective of the paper was to find an appropriate way of oxygen production technology for the negative CO_2 emission gas power plant (nCO2PP) it proved to be an uneasy task. Firstly, cryogenic air distillation was regarded to be a superior technology as it is recommended in most of the literature. However, the efficiency reductions obtained indicate that for such low flows of oxygen produced (as assumed in calculations), it makes more sense to buy it from industrial producers.

According to the obtained results, the oxygen transport membrane has better perspectives for the nCO2PP, especially because of a large amount of heat from the sewage sludge gasification process. To be sure of that, more factors such as membrane material, area, process temperature, and pressure difference at both sides of the membrane should be widely considered by CFD calculation. However, this is beyond the scope of this paper.

Acknowledgments

The research leading to these results has received funding from the Norway Grants 2014-2021 via the National Centre for Research and Development. This research has been prepared within the frame of the project: "Negative CO2 emission gas power plant" - NOR/POLNORCCS/NEGATIVE-CO2-PP/0009/2019-00 which is co-financed by programme "Applied research" under the Norwegian Financial Mechanisms 2014-2021 POLNOR CCS 2019 - Development of CO2 capture solutions integrated in power and industry processes.

Presented research regarding oxygen transport membrane is a result of a project and it was financed from RADIUM LERANING THROUGH RESEARCH PROGRAMS.

Abstract:

Cities have great potential to implement innovative solutions and improve energy efficiency and the use of non-conventional energy sources, laying the foundations for a new, more sustainable urban model. With this vision and the aim of finding solutions to this challenge, Madrid Subterra emerges. This work is within the project of this association created with the aim of promoting the exploration and exploitation of the potential of clean and renewable energy of the urban subsoil of Madrid. This study analyses the energy use of the Seville Metro station for the thermal supply of the Building of the Ministry of Environment of the Community of Madrid. The main goal is to extract the waste heat generated in the metro tunnels due to the traction and braking of machines, auxiliary facilities, or transit of people on the platforms and use it to produce domestic hot water (DHW) using a heat pump to supply the referred building. This concept could reduce the temperature in Metro facilities and save energy. From the tunnel the ventilation flow and temperatures data, the performance of the system has been estimated using the CoolPack program. The results obtained show that this system could supply domestic hot water for 7640 people per month with a COP of 2.663 and SCOP of 1.975.

1. Introduction

Cities today and focusing on the specific case of the city of Madrid, has a great potential for waste heat that is generated in tunnels and platforms. This waste heat could be studied, extracted and implemented innovative solutions for improving energy efficiency and using non-conventional energy sources. This potential can be boosted to further reduce CO_2 emissions and make cities more sustainable. For all the above, the Madrid Subterra Association arises, created with the aim of promoting the exploration and exploitation of the clean and renewable energy potential of Madrid's urban land, allowing to transform the current vicious circle of waste, and overheating into a virtuous circle of energy efficiency.

Heat pumps are considered one of the most efficient heating and cooling systems and, according to Directive 28/2009/EC, the aerothermal, geothermal or hydrothermal energy captured by these appliances is considered energy from renewable sources. For these reasons, they will play a key role in reducing greenhouse gas emissions [1].

Aerothermal energy encompasses all the systems that allow energy to be extracted from the air. The most used technology for the use of aerothermal energy is the air-water heat pump that is developed in this work and that allows heating or cooling the water of a building, Figure 1.

Heat pumps consume up to 70% less energy than a traditional heating system. The consumption will depend on the type of heat pump we have, in the case of the aerothermal heat pump, the consumption would be 1 kW electric and would allow to deliver up to 4 kW of heating.
The International Energy Agency, in its 2016 report on Energy Efficiency, considered the heat pump as the Best Available Technology (BAT) for space heating. In addition, Greenpeace in 2011 chose the heat pump as the best heating system when it comes to energy efficiency.
The objective of this work is to take advantage of clean and renewable energy from the subsoil in Metro de Madrid's infrastructures. It is intended to extract the waste heat generated in the metro tunnels due to the traction and braking of machines, auxiliary facilities, or transit of people on the platforms and use it to produce domestic heat water (DHW) of a building in the Community of Madrid, thus assuming savings in kWh.

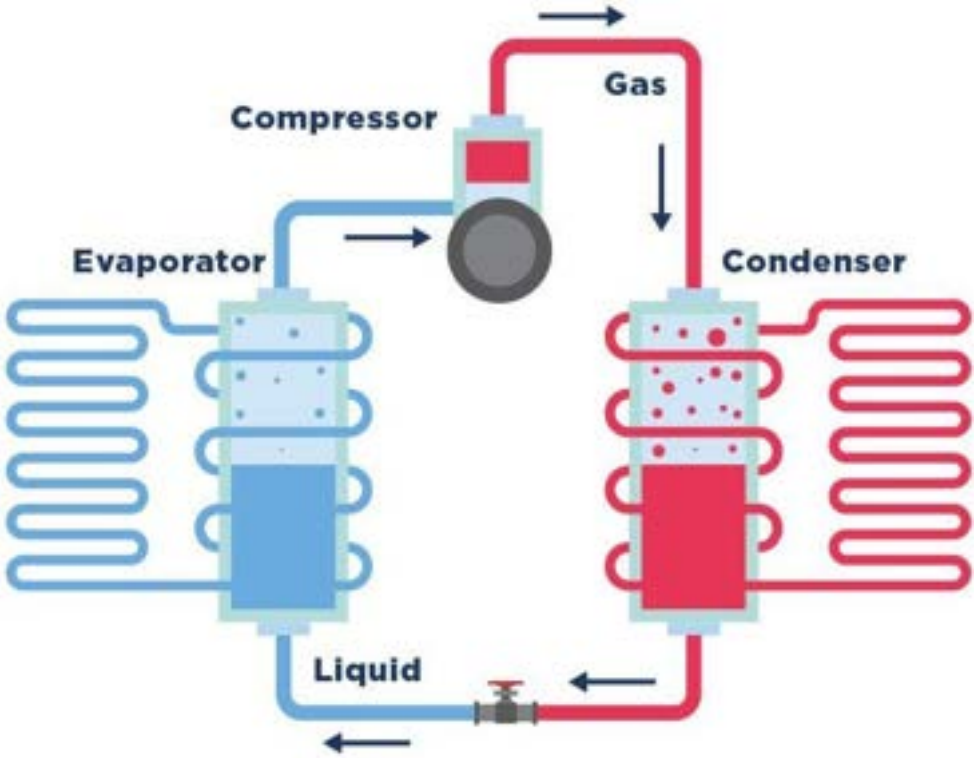

Figure 1. Heat Pump. Source https://www.bordgaisenergy.ie/home/heat-pump-guide

The study of the thermal use of air will be carried, out in the Seville metro station and in the Building of the Ministry of Environment of the Community of Madrid, Figure 2.

Figure 2. Location of Metro Sevilla and the building of the Ministry of Environment

Sevilla Metro station is a station on line 2 of the Madrid Metro located under Calle Alcala, at the junction with Calle de Sevilla, which gives its name to the station. It is a very small station of approximately 1000 m^2, with "light" trains of 4 cars, with platforms of 60 m and with low influx according to the data provided with Metro Madrid.

The objective of the work is, therefore, to have an estimate of the liters of domestic heat water that could be obtained from the flow of air extracted by means of the fans of the extraction well. In addition, the number of people inside the Building of the Ministry of Environment that could be supplied with that volume of water will be estimated.

2. Methodology

The methodology followed in this study consists of three steps:

- **Step 1:** The simulations provided by Metro de Madrid corresponding to the Seville station allow us to know and analyze the air temperatures and the ventilation flows of the tunnel and determine the design conditions.
- **Step 2:** The aerothermal heat pump is designed and sized. The result of this step is the fundamental parameters of the heat pump.
- **Step 3:** The installation performance is estimated using the CoolPack program [2] from the results obtained in the previous steps.

The centralized DHW installation object of this study has been designed according to the Technical Guide of Central Sanitary Hot Water of the IDEA [3]. This document establishes certain design criteria, especially highlighting the importance of control over Legionella. The hygienic-sanitary measures that must be adopted in those facilities in which Legionella is capable of proliferating and spreading are described on the Royal Decree 487/2022, of June 21 [4].

2.1. Analysis of the data provided by Metro Madrid.

For the calculation of the use of heat from the Seville Metro station, the simulations provided by Metro Madrid have been analyzed. In them, there is on the one hand the thermal evolution in a winter, half-time and summer day for four fundamental domains: station (platform level), vestibules and the two adjacent tunnel sections. On the other hand, there is the flow of air, which is massively directed to the shafts of the tunnels, and especially to the tunnel of Banco de España, (Tunnel 1) since it has forced ventilation. The place chosen to put the pump and carry out the study is Tunnel 1 due to its greater air extraction flow, Figure 3.

The following points have been considered for the study and diagnosis:

- It has been decided to work according to the key variables of the problem: the ventilation flow and temperatures. An average temperature will be taken for winter, halftime and summer, Table 1.
- Operating hours of the fans, in winter they would work 10 hours a day, in halftime 13 and in summer they would be on for 15 hours extracting the air flow, according to the data provided by Metro Madrid.

Table 1. Average data of the selected temperature Metro Madrid.

Parameters	Values
Average winter temperature	12.9 ^oC
Average halftime temperature	17.6 ^oC
Average summer temperature	20.9 ^oC

With these data, we proceed to define the design of the components of the heat pump that would be installed in Tunnel 1 and the selection of the parameters of the simple thermodynamic cycle with which it would work.

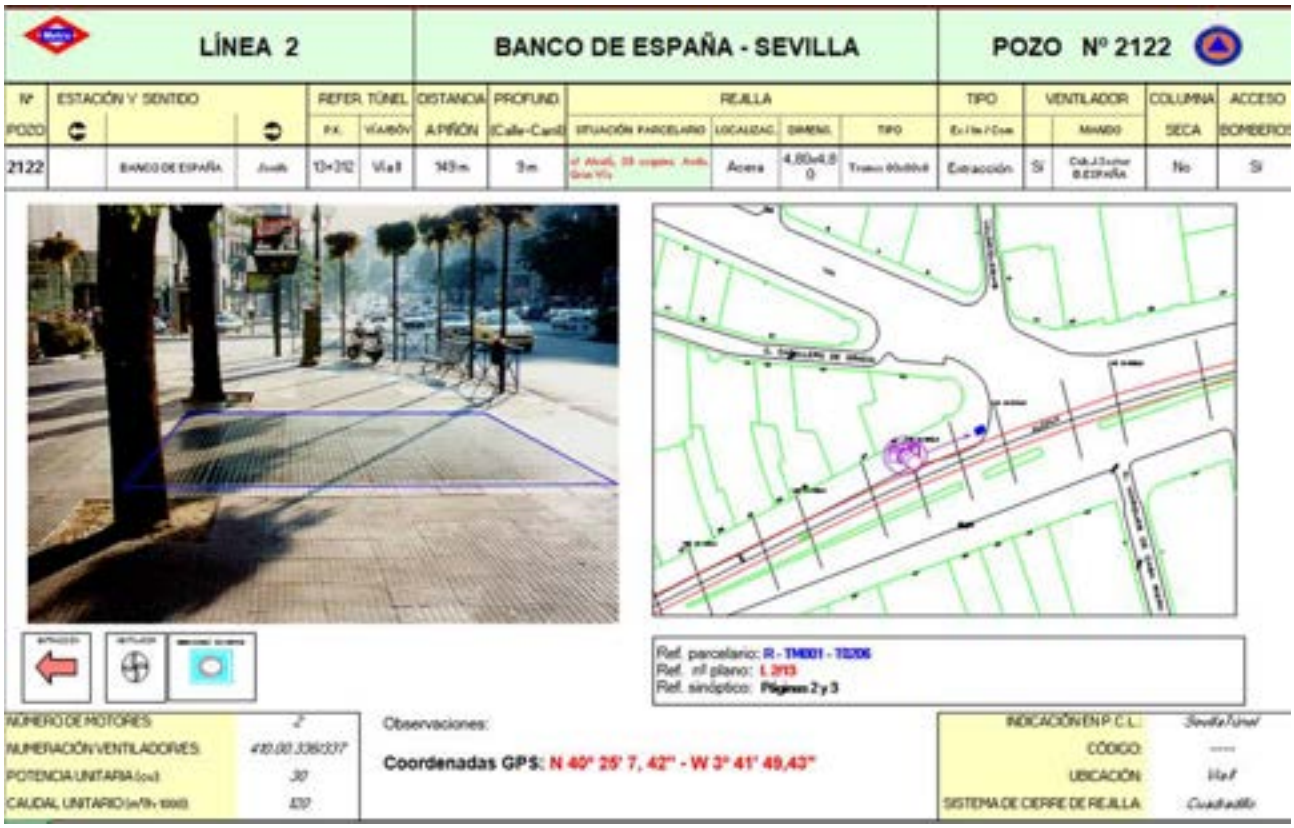

Figure 3. Photo of the place where the Heat Pump will be located.

2.2. Design and size of the aerothermal heat pump.

The proposed installation will comprise a simple heat pump system that consists of four primary components: a compressor, two heat exchangers (condenser and evaporator), and an expansion valve, as depicted in Figure 1. The initial calculation parameters selected for the analysis are specified in Table 2.

Table 2. Parameters for calculating.

Parameters	Data
Domestic hot water temperature	55ºC [3]
Condensation temperature	60ºC
Subcooling temperature	10K
Useful superheat temperature	7K
Exhaust air flow	30 m^3/s (Tunnel 1)
Seasonal temperature data	Table 1

2.2.1. Evaporator.

The evaporator serves as a heat exchanger, facilitating the phase change of the refrigerant from liquid to vapor while absorbing heat. In order to determine the power associated with the evaporator, Eq. (1) is employed, considering the parameters outlined in Table 3 in order to evaluate the energy balance between evaporator refrigerant and air to subtract heat.

$$Q(kW) = \dot{v}_{air}\left(\frac{m^3}{s}\right) \cdot \rho\left(\frac{kg}{m^3}\right) \cdot C_p\left(\frac{kJ}{kgK}\right) \cdot \Delta T = \dot{m}_{\text{refrigerant}} \cdot \Delta \text{h} \quad (1)$$

Table 3. Parameters for calculating the power of the evaporator.

Parameters	Data
Air flow ($\dot{v}_{air}$)	30 m^3/s
Air density (ρ)	1.2 kg/m^3
Specific heat of air (C_p)	1.007 kJ/kg K
Temperature difference at evaporator inlet and outlet (ΔT)	Variable in the study

Upon analysis of the evaporator power results presented in Table 4, it was observed that the extracted power remained independent of variations in the air inlet temperature. It should be noted that the calculation of efficiency is contingent upon the time of year for which it is being computed.

Table 4. Evaporator powers (Q_{evap}), according to thermal jump.

ΔT (K)	Q_{evap}(kW)
2	72.5
4	145.0
6	217.5
8	**290.0**

In order to determine the efficiency of the evaporator, the NTU (Number of Transfer Units) Effectiveness Method [5] is employed, Eq. (2). Number of Transfer Units (NTU) is a dimensionless parameter used in heat exchanger analysis to determine the efficiency of heat transfer. It is defined as the product of the overall heat transfer coefficient and the effective heat exchanger length, divided by the heat capacity rate.

$$\in = 1 - e^{NTU} \tag{2}$$

The analysis entails experimentation with varied evaporator temperatures (T_{evap}) during three seasonal periods, namely winter, mid-season, and summer. Ultimately, the case with the highest evaporator power Table 4 is chosen. The results, including T_{ms} (the temperature at the outlet of the evaporator), LMTD (logarithmic mean temperature difference), and UA (heat transfer coefficient per unit area) are documented in Table 5 and referred in [5] and [6].

Table 5. Data selected for the highest evaporator power in each seasonal period.

Period seasonal	T_{evap} (ºC)	ΔT (K)	T_{ms} (ºC)	Q_{evap} (kW)	LMTD	UA (kW/K)	NTU	**Efficiency**
Winter	4	8	4.9	290.0	3.4	83.1	2.3	89.9
Mid-season	4	8	9.6	290.0	10.2	28.4	0.8	54.3
Summer	4	8	12.9	290.0	12.4	23.3	0.6	47.4

2.2.2. Condenser.

The next point is to set the condensation temperature. As previously defined, the purpose of the work is to be able to supply DHW, therefore the temperature is 60 ºC which will be the same as the condenser temperature ($T_{cond.}$), the domestic heat water temperatures T_s = 55 ºC [3], the cold-water temperature (T_{water}), whose average values are detailed in Table 6 and the Eq. (3) and Eq. (4), we are defined the analysis of the condenser at each time of the year Table 7.

Table 6. Temperature of the cold-water network of Madrid.

Seasonal period	Cold water temperature of the Madrid network (ºC)
Winter	7
Halftime	13
Summer	10.8

$$Qcond = UA \cdot LMTD \tag{3}$$

$$LMTD = \frac{T_s - T_{water}}{ln\left(\frac{T_{cond} - T_{water}}{T_{cond} - T_s}\right)} \tag{4}$$

Table 7. Analysis of the condenser according to the seasonal period.

Seasonal period	T_s (º C)	T_{water} (º C)	T_{cond} (º C)	LMTD	UA (kW/K)	Q_{cond} (kW)
Winter	55	7	60	20.1	83.1	1667.2
Halftime	55	13	60	18.7	23.2	435.7
Summer	55	10.8	60	19.3	28.4	548.0

2.2.3. Compressor.

Its function is to increase the pressure (and temperature) of the refrigerant. The refrigerant must be entirely in a gaseous state, if there was refrigerant in a liquid state, it would lead to serious damage to the compressor. Gas compression losses and charge losses in refrigerant circulation shall be considered. Will be used for the calculation of the thermodynamic cycle performance the CoolPack Software [2]. This program uses by default an isentropic yield of 0.7 and a loss factor of 10%.

2.2.4. Expansion Valve.

The coolant passes through expansion valve, decreasing its pressure and increasing its volume abruptly at the outlet. Some of the liquid coolant evaporates with the pressure reduction. The amount of refrigerant gas produced shall be kept to a minimum to increase the performance of the evaporator.

2.3. Study of the system efficiency.

Determination of fundamental parameters of this type of systems to realistically study how efficient the aerothermal system is:

- ✓ **COP** (electricity consumption required to meet heat demand)
- ✓ **sCOP** (Seasonal Coefficient of Performance).

2.3.1. Determination of the COPs

This parameter is essential when analyzing the operation of a heat pump. To improve the COP of the pumps, it is important that the condensation temperature is as low as possible, and that the evaporation temperature is as high as possible.

The **operating or performance coefficient (COP)** is an expression of the efficiency of a heat pump. In this case, it is a relationship between the heat transferred and the electrical energy consumed mainly by the compressor, Eq. (5).

$$COP = \frac{Q}{W_{comp}} \tag{5}$$

The study of the electricity consumption required to meet the heat demand is carried out with the CoolPack program that allows you to enter the parameters with which you are going to work:

- evaporation temperature, condensation temperature, subcooling, useful reheating, compressor performance, air flow and type of refrigerant. The values of these parameters are reflected in the Table 8.

Table 8. Heat pump cycle parameters.

Parameters	Values
Evaporation temperature	4 ºC
Condensation temperature	60 ºC
Compressor efficiency	0.7
Evaporation capacity	290.016 kW
Subcooling	10 K
Useful reheating	7 K
Useless overheating	1 K
Refrigerant (the program defaults)	R290

This analysis is fundamental since this value supposes a first filter for the viability of the supposed heat pump. For proper efficiency and functionality, a heat pump must reach a COP of between 2 and 6, depending on the difference between the temperatures of both sources (indoor or outdoor). In this work, a value of **COP= 2.663** is obtained, Figure 4.

In addition, with the COP you can make a comparison between the price of fuel (natural heat source) and the electricity price (cost of operation with heat pump) that we see below:

- COP < 2.5 the variable thermal cost with boilers is lower than with heat pump.
- COP=2.5 the thermal variable cost is identical in both cases.
- COP > 2.5 the variable thermal cost with boilers is higher than with heat pumps.

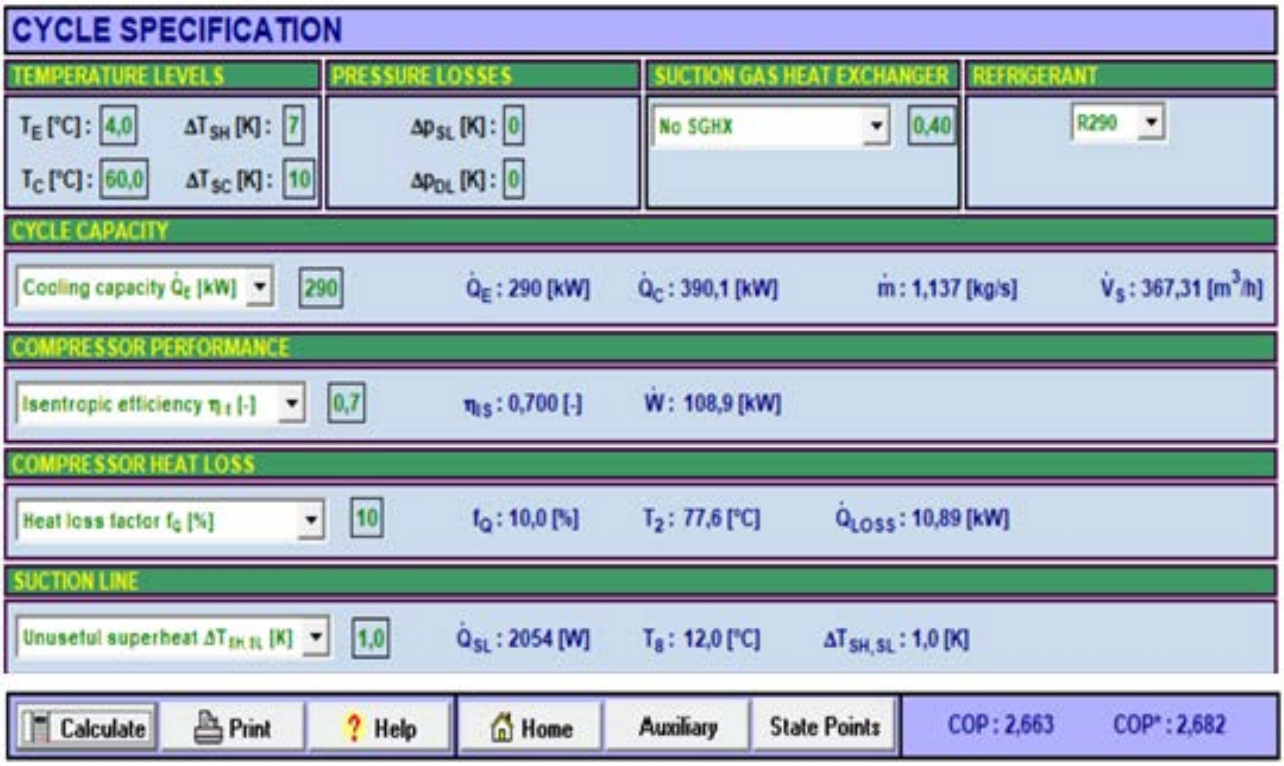

Figure 4. Obtaining COP with the CoolPack program.

There is a very important point in heat pumps, and it is the issue of the refrigerant used. In the previous analysis, the R290 is used, which defaults to the CoolPack program. To get an idea of how important the refrigerant is, is represented in the following, how the COP change depending on the refrigerant used, Figure 5.

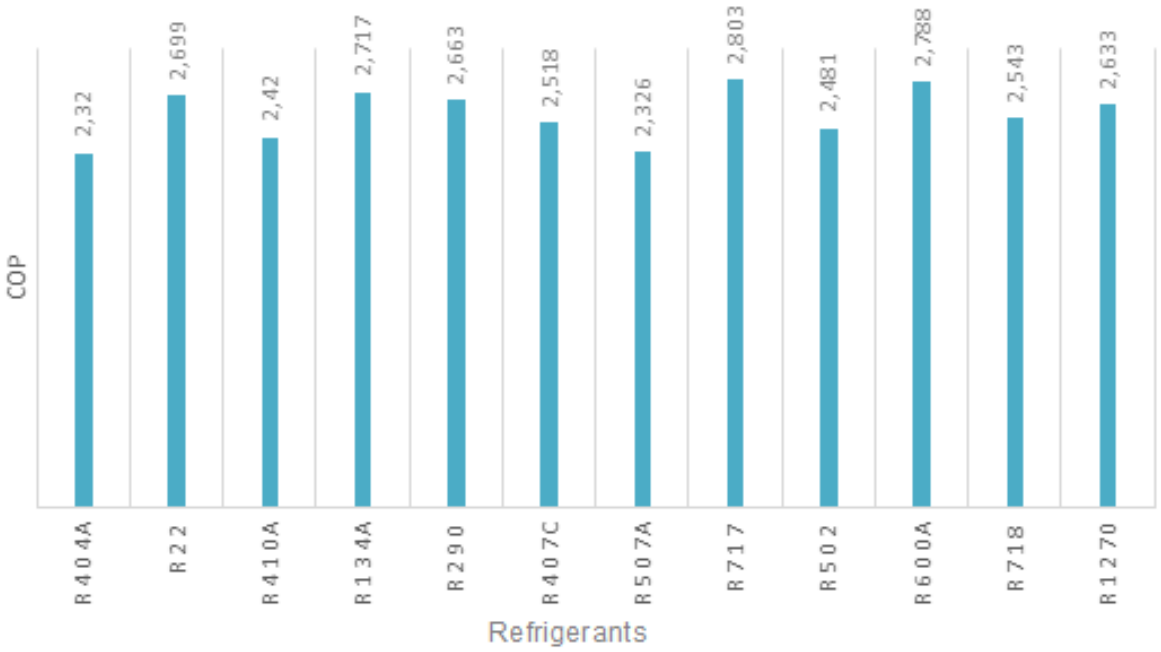

Figure 5. COP results with different refrigerants.

Based on this analysis we could conclude that the best refrigerant would be R717, but differences are quite small with R600A, R134a, R22, R1270, model uncertainties can group these refrigerants with the same possibilities to be the better one. However, other factors must be considered when choosing the refrigerant, such as safety, environment, corrosion resistance and at the same time good thermodynamic properties [7].

2.3.2. Determination of sCOP

After obtaining the potential COP values for a heat pump, an additional parameter that holds greater significance is introduced when evaluating the installation's performance. This parameter is known as the Seasonal Coefficient of Performance (sCOP). The main difference between the COP and the sCOP is that the latter refers to the seasonal term, i.e. a certain period of time, while the former refers to a specific operation conditions.

For the estimation of sCOP values, the procedure explained in the IDEA [8] document "Average seasonal performance of heat pumps" is followed.

The average seasonal performance of an equipment or system (SPF) shall be calculated by multiplying its rated performance (COP) by a factor called the representative weighting factor (FP), Table 9, and by a correction factor (FC), Table 10, for the different technologies and applications of electrically driven heat pumps. The weighting factor considers the different climatic zones of Spain marked by the CTE [9] and has been calculated using an exclusively technical methodology, using objective values and existing recognized documents. The correction factor considers the difference between the distribution or use temperature and the temperature for which the COP have been obtained in the test.

Table 9. Weighting factor (FP) [8]

Heat pump energy source	A	B	C	D	E
Aerothermal energy. Centralized teams	0.87	0.80	0.80	0.75	0.75
Aerothermal energy. Individual teams type Split.	0.66	0.68	0.68	0.64	0.64
Hydrothermal Energy	0.99	0.96	0.92	0.86	0.80
Closed-loop geothermal energy. Horizontal heat exchangers	1.05	1.01	0.97	0.90	0.85
Closed-loop geothermal energy. Vertical heat exchangers	1.24	1.23	1.18	1.11	1.03
Open Circuit Geothermal Energy	1.31	1.30	1.23	1.17	1.09

Madrid is a zone of climatic severity D as can be seen in Figure 6. The type of heat pump used throughout the document is aerothermal, therefore, the weighting factor (FP) that corresponds to it is FP **= 0.75.**

Figure 6. Climate zones in Spain

For the choice of the correction factor (FC) the one that agrees with the COP at 60ºC is chosen, this being the ideal condensation temperature to supply domestic hot water to the building of the Ministry of the Environment. According to Table 10 we are left with the correction factor being **FC=1.**

Table 10. FC correction factor

Condensation temperature (ºC)	FC (COP a 35 ºC)	FC (COP a 40 ºC)	FC (COP a 45 ºC)	FC (COP a 50 ºC)	FC (COP a 55 ºC)	FC (COP a 60 ºC)
35	1.00	------	------	-------	------	------
40	0.87	1.00	------	------	------	------
45	0.77	0.89	1.00	------	------	------
50	0.68	0.78	0.88	1.00	------	------
55	0.61	0.70	0.79	0.90	1.00	------
60	0.55	0.63	0.71	0.81	0.90	1.00

With the data explained above and the Eq. (6) a **sCOP = 1.975** is obtained.

$$\boldsymbol{sCOP} = COP\,nominal \cdot FP \cdot FC \tag{6}$$

The use of standard methodology to evaluate sCOP is clear, and it is quite useful. In this case, common methodology is not correct at all, because temperature in tunnels suffer different variations that in the environment air, so these coefficients are underestimating the real value of sCOP considering the comparison between air tunnels temperature variation and environmental air temperature variation. Further analysis with implemented temporal series will include this calculation of sCOP.

3. Amount of domestic heat water produced

With the data provided by Metro Madrid and the results calculated to compose the heat pump, the hot water flow is determined with the following Eq. (7),

$$Qcond = \dot{m}_{water}\left(\frac{kg}{s}\right) \cdot C_p\left(\frac{kJ}{kg*K}\right) \cdot (T_s - T_e) \tag{7}$$

The power of the condenser (Q_{cond}) estimated to calculate the production of domestic hot water is considered since the heating of the water occurs in this component. The formula uses a C_{pwater} = 4.196 kJ / kg K, the density of water ρ_{water} = 999.91 kg / m^3, the outlet temperature of domestic heat water T_s = 60ºC and the inlet temperature that coincides with that of the cold water of the Madrid network that will depend on the time of year collected in Table 6. Thus, the flow of domestic heat water produced during the months of the year would be represented in the following graph, Figure 7.

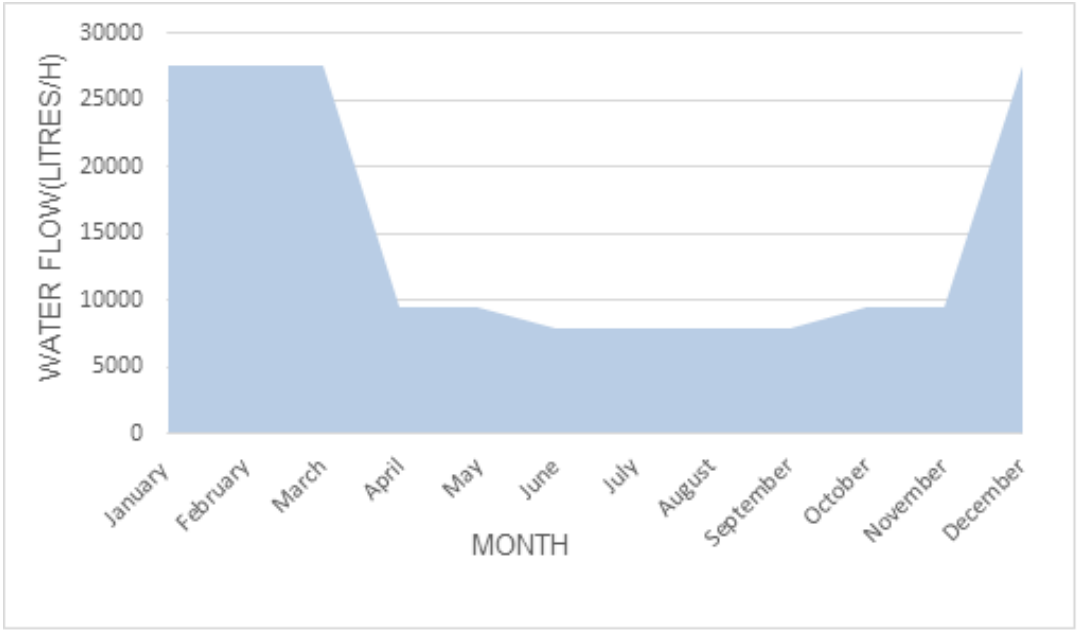

Figure 7. DHW flow during the year per operating hour

Upon analysis of the current air extraction rate from Tunnel 1 (108000 m^3/h), it was determined that an average flow rate of 15007 liters/hour of fan operation can be produced. It should be noted that higher flows will be obtained during the winter season due to the greater power in the condenser resulting from much lower average air intake temperatures. Additionally, the hours of fan operation coincide with those of the heat pump to be installed in Tunnel 1. As such, the monthly amount of domestic hot water that can be obtained is also presented in Figure 8.

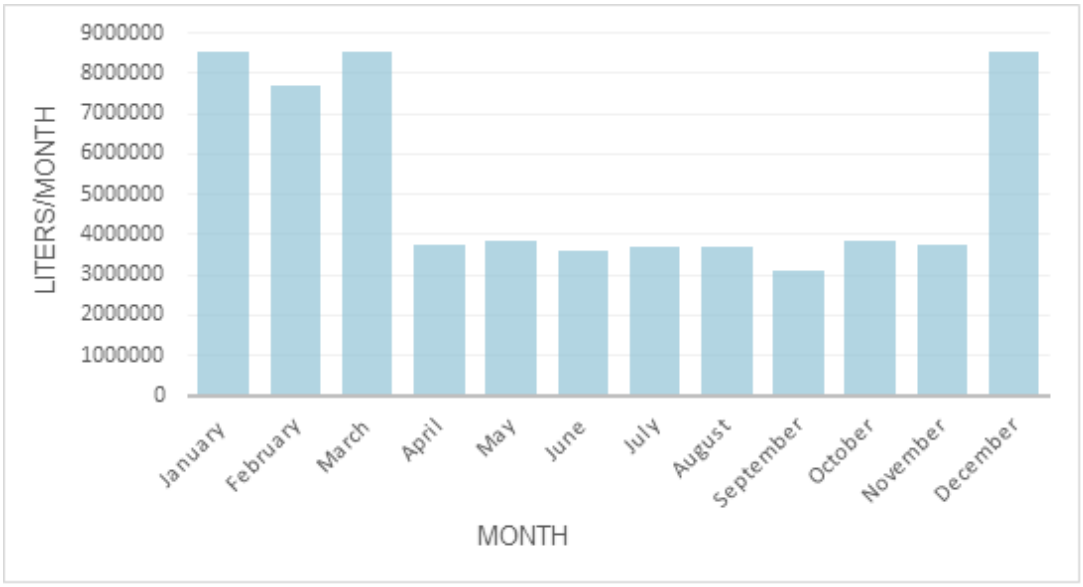

Figure 8. Flow rate in liters of DHW per month

Finally, if it is considered that in a public building such as the Building of the Ministry of Environment a person can consume 22.5 liters per day [9], an estimate can be made of the number of people that could cover the demand for DHW per month, Table 11.

Table 11. People who can be supplied with DHW from the extracted air flow.

Month	Q_{cond} (KW)	T_e (ºC)	$\dot{v}_{water}$(m³/s)	$\dot{v}_{water}$(l/h)	Hours of operation	l/day	People
January	1667	8	0.00764	27510	310	275096	12227
February	1667	8	0.00764	27510	280	275096	12227
March	1667	8	0.00764	27510	310	275096	12227
April	548	11	0.00265	9557	390	124243	5522
May	548	11	0.00265	9557	403	124243	5522
June	436	13	0.00221	7955	450	119325	5303
July	436	13	0.00221	7955	465	119325	5303
August	436	13	0.00221	7955	465	119325	5303
September	436	13	0.00221	7955	390	103415	4596
October	548	11	0.00265	9557	403	128384	5706
November	548	11	0.00265	9557	390	124243	5522
December	1667	8	0.00764	27510	310	275096	12227

4. Conclusions and future works

Once the methodology for the study of the use of waste heat from the Bank of Spain Tunnel of the Seville Metro station has been established, it can be concluded that the

1. Heat pump would produce an average flow of 15007 liters / hour during the hours in which they are operating throughout the day. In addition, the extraction of the air flow from Tunnel 1 could supply an average of 7640 people per month.
2. With respect to the heat pump placed at the outlet of the air extraction well, it is obtained that using the refrigerant R290, an evaporation temperature of 4ºC and a condensation temperature according to that required for DHW (60ºC) a COP = 2.663 is reached, a positive value (> 2.5) when measuring the viability of the system for correct efficiency and functionality that would mean savings in euros compared to gas, but which remains below the minimum COP necessary (6.08 for DHW at 60ºC) to be considered renewable.
3. The results of the Seasonal Coefficient of Performance are less encouraging since a value of 1.975 will be obtained, which is below the minimum 2.5 to be considered renewable according to the IDAE report. Anyway, IDAE sCOP methodology calculation procedure underestimate real value, as working conditions for Metro are better than the ones expected for the common use of this systems.[8]
4. This concept helps to reduce the temperature in Metro facilities, that is a problem for the infrastructure as an all-year net heat source.

However, the main essence of this project is the dissemination and awareness of the possibility of installing aerothermal systems capable of taking advantage of the residual heat of the subsoil of Madrid to achieve an energy use since a virtuous circle of heat recovery that would otherwise be wasted in the environment will be implemented regardless of whether it is renewable.

The methodology developed will allow, using more precise data and details on the installation of the Building of the Ministry of the Environment, the dimensioning of the installation necessary to take advantage of the heat of the metro or numerous other equally unknown infrastructures with enormous potential to exploit.
In conclusion, the results show that heat pumps are presented as indispensable allies of the energy efficiency of buildings in cities as it is the only proven and available system capable of producing great savings and reducing CO_2 emissions in indoor air conditioning.

Future works include the more precision evaluation of the annual production with temporal series of temperature and comparison with the alternative of a common aerothermal facility working with environmental air, as in summer the overground higher temperature gives better performance to the production of hot water.

Abstract

Solid wastes management constitutes an unavoidable issue in modern overconsuming societies, but apart from that, it is also an energy source. Combustion of waste, like other carbonaceous fuels, emits carbon dioxide, which needs to be mitigated in order to achieve the Paris Agreement targets, concerning the limitation of carbon dioxide emissions in the atmosphere. The CCS implementation at waste to energy (WtE) plants is an attractive strategy to achieve this. Chemical Looping Combustion (CLC) is considered as a very promising combustion for power plants to produce efficiently thermal energy, given that it includes an inherent CO_2 capture, avoiding in this way the cost or energy penalties that accompany other existing CO_2 capture technologies. In this study, the integrated model of a CLC unit fuelled with waste derived fuel for power production with the simultaneous CO_2 capture in an effective way is presented. Several aspects that affect the overall plant efficiency such as the heat recovery configuration, the steam pressure level and the fuel type are assessed. Moreover, the CLC is benchmarked with other two competitive CO_2 capture technologies, amine scrubbing and calcium looping.

Keywords: Chemical looping combustion; waste to energy plants; CO_2 capture; process modelling; Calcium looping; amine scrubbing

Introduction

Chemical Looping Combustion (CLC) is an emerging technology for waste incineration, with an inherent CO_2 capture. It is characterized by low energy penalty and high CO_2 capture efficiency. The basic idea behind the Chemical Looping Combustion technology lies in the recirculation of an oxygen-carrier material between two interconnected fluidized bed reactors, reacting with atmospheric air in the one reactor (Air Reactor) and with the feedstock in the other (Fuel Reactor). The oxygen-carrier material, usually in the form of a metal-oxide [1], has the ability to transfer oxygen from the atmospheric air to the fuel, therefore avoiding the formation of nitrogen oxides (NO_x) and leading to the production of almost pure CO_2 and H_2O in the Fuel Reactor. After condensation of the Fuel Reactor flue gas, vapour is removed and hence CO_2 can be captured and transported or further utilised. The Air Reactor flue gas consists mostly of N_2 and O_2 that did not react with the oxygen-carrier. What is more, apart from the fuel, a gas stream enters the Fuel Reactor needed for its fluidization, which is usually either steam or recirculated CO_2. Chemical Looping Combustion is a rather new and up-and-coming technology, so there is not so much experience yet with using waste as fuel. However, since waste incineration has been conducted already in fluidized beds in Waste-to-Energy plants, the transition to CLC is not expected to pose such a big challenge. The process flowsheet diagram of a simplified CLC system is depicted in Figure 1.

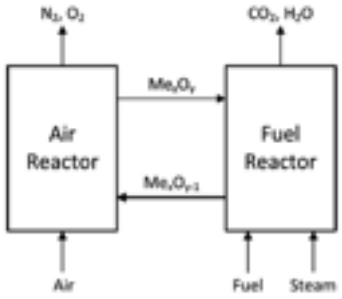

Figure 1: Schematic diagram of the Chemical Looping Combustion process (source: [2])

Regarding the post-combustion techniques for CO_2 capture, chemical absorption in an aqueous MEA solution is widely considered as the most mature available technology. In this process, CO_2 reacts with the solvent in an absorber column, forming chemical dissolved compounds. Subsequently, the solvent is regenerated in a stripper column due to the reversal of the chemical reactions at higher temperatures [3]. The necessary heat duty for the MEA regeneration is delivered by steam extraction of the initial power plant's Rankine cycle.

Calcium looping (CaL) is a promising post-combustion technology. This process relies on two reversible chemical reactions: carbonation and calcination. The first one occurs in a carbonator reactor, where CO_2 is captured by reacting with solid lime (CaO) and limestone ($CaCO_3$) is formed. Afterwards, the sorbent is regenerated in the calciner and CO_2 is released and purified in a PCU [4]. As the calcination is an endothermic reaction, fuel (RDF) combustion is necessary to maintain a constant temperature whereas pure O_2 is used as oxidizing agent in order to achieve high CO_2 concentrations in the calciner flue gas.

Several studies and projects can be found in the literature that are dedicated in the implementation of CO2 capture technologies in Waste-to-Energy plants. In [5], Fortum Oslo Varme AS used Shell's proprietary amine-based solvent DC-103 (previously untested in WtE flue gases) as a CO_2 capture technology in a WtE plant in Oslo and achieved high carbon-capture efficiency (around 90-95%) while also diminishing its amine emissions (fewer than 0.4ppm) and operating successfully for over 5000 hours. In Saga city, Japan, Toshiba has constructed a CCU facility, using an alkaline aqueous amine to capture CO_2 from a WtE plant situated nearby, accomplishing capturing up to 10 tons of CO_2 every day and further utilising it to cultivate crops and algae [6], [7]. Martin Haaf et al. in [8] presented the results of a $1MW_{th}$ CaL pilot plant, using SRF as fuel in the calciner, which captured carbon dioxide from the flue gases, provided by the combustion of pulverized coal or natural gas. In [9], the implementation of a CaL unit with a WtE plant was studied, with SRF, natural gas, and coal being tried out as the additional fuel. Their study showed that the use of SRF achieved the lowest net electrical efficiency out of them all. In [10], a process simulation was carried out for a $60MW_{th}$ CLC plant, fired by SRF, which achieved a very high carbon capture efficiency of 97% and had an oxygen demand of 17%, in order for the flue gas to be fully converted in the post-oxidation chamber. What is more, Yaqub et al., in [11] conducted experiments with plastic and paper waste in a batch fluidized-bed reactor, which showed that the paper waste had a higher fractional conversion of CO to CO_2, due to its augmented volatile content.

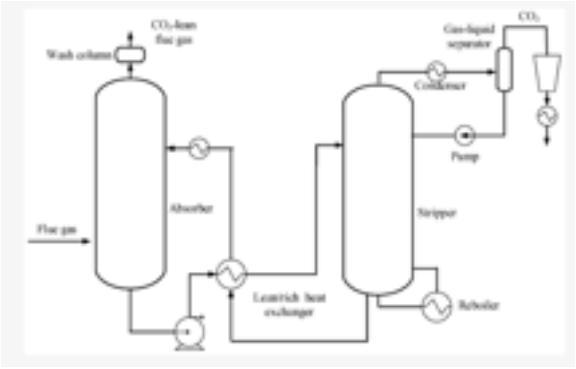

Figure 2: Amine Scrubbing process

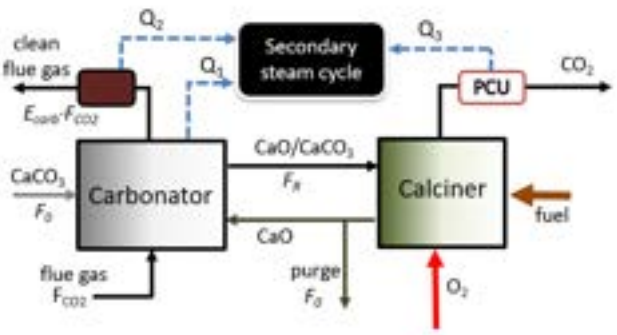

Figure 3: Calcium Looping process

This study analyses the implementation of the CLC technology with waste-derived fuels. The main purpose of this paper is to indicate which of the three abovementioned carbon capture technologies is more energy effective, taking into account in each case the net electricity production derived from the RDF combustion.

2. Model description

2.1 Chemical Looping Combustion

The process simulations for all technologies are performed with ASPENPlus^{TM}. The properties of the RDF fuel used in all cases are summarized in Table 1.

Table 1. Fuel properties

C (% d.b.)	H (% d.b.)	O (% d.b.)	N (% d.b.)	S (% d.b.)	Cl (% d.b.)	Ash (% d.b.)	Moisture (w/w %)	*LHV* (kJ/kg w/w)
40.03	4.1	24.9	0.47	0.19	0.51	29.8	27.8	9598.9

In CLC with solid waste, after the feedstock enters the Fuel Reactor, devolatilization and gasification of char take place, the products of which react with the oxygen-carrier. The reduced particles of the oxygen carrier (here ilmenite) are then transported to the Air Reactor to be oxidised, carrying some unconverted char particles with them. That char, if it reaches the Air Reactor, is oxidised by the air and transformed into CO_2, which will later on be emitted in the atmosphere. Both reactors are modelled as an RSTOIC in the ASPEN flowsheet. The reactions taking place in the AR are the (R1) and (R2), while the reactions (R3) until (R8) are the ones occurring in the FR:

$$C + O_2 \rightarrow CO_2 \quad \text{(R1)}$$

$$4FeTiO_3 + O_2 \rightarrow 2Fe_2O_3 + 4TiO_2 \quad \text{(R2)}$$

$$Char\ (mainly\ C) + H_2O \rightarrow CO + H_2 \quad \text{(R3)}$$

$$Char\ (mainly\ C) + CO_2 \rightarrow 2CO \quad \text{(R4)}$$

$$CO + H_2O \rightarrow CO_2 + H_2 \quad \text{(R5)}$$

$$CH_4 + Fe_2O_3 + 2TiO_2 \rightarrow CO + 2H_2 + 2FeTiO_3 \quad \text{(R6)}$$

$$CO + Fe_2O_3 + 2TiO_2 \rightarrow CO_2 + 2FeTiO_3 \quad \text{(R7)}$$

$$H_2 + Fe_2O_3 + 2TiO_2 \rightarrow H_2O + 2FeTiO_3 \quad \text{(R8)}$$

The rates of the reactions taking place in the FR were defined through ‘Design Specs’, so that the final composition of the FR exhaust gases would be in accordance with the composition of the

corresponding gases from an application of a CLC plant with biomass (see Table 2). Given that there aren't many literature sources regarding CLC operation with SRF, and that SRF has a large biogenic fraction, the admission was made that these two fuels should have a similar performance. Regarding the impurities such as SO_2, NO and HCl that form in CLC applications with SRF, these were produced in a separate RSTOIC in the ASPEN flowsheet, preceding the FR, the reaction rates of which were based on data from different literatures sources. It should be stated that in reality, all these reactions take place in one reactor (the FR). In the AR, both the char and the oxygen-carrier were considered to convert fully to their products in the reactions (R1) and (R2) respectively.

In order to reduce the amount of these CO_2 emissions, a Carbon Stripper is used, separating the char particles from the oxygen-carrier and returning them back to the Fuel Reactor to be gasified. Unconverted gases in the FR flue gas can be fully oxidised to CO_2 and H_2O in a Post-Oxidation Chamber (POC), using a pure stream of O_2. The thermal energy of the flue gases exiting the two reactors is used for the production of electricity in an adjoining Rankine Cycle and the preheating of air and steam needed in the AR and the FR respectively. For the superheating of steam, the heat of the AR flue gas is used, given that it is a stream clean from impurities, hence overcoming the problem of possible corrosion faced in most Waste-to-Energy plants, which limits the superheated steam temperature to 400°C. Therefore, the steam in this model was able to be superheated to a temperature of around 520°C and expanded in 3 stages in steam turbines [1]. The FR flue gas, being rich in CO_2, after being cooled down to just before its dew point in the Rankine Cycle, is purified and gradually compressed and condensed to reach the appropriate conditions for CO_2 capture and delivery [12]. On the other hand, the AR flue gas, after being cooled down to around 80°C, consisting mainly of N_2, O_2 and CO_2, is released in the atmosphere, therefore constituting the only CO_2 emissions of the CLC system.

Regarding the CO_2 emissions of the plant, the carbon capture efficiency was introduced, calculated as the amount of carbonaceous gases (measured in kmol/s) in the off-gas that is captured to the amount of the total carbonaceous gases both captured and emitted to the atmosphere.

$$\eta_{CC} = \frac{(F_{CO2} + F_{CO} + F_{CH4})_{FR\ flue\ gas}}{(F_{CO2} + F_{CO} + F_{CH4})_{FR\ flue\ gas} + (F_{CO2})_{AR\ flue\ gas}} \quad (1)$$

Table 2: Main characteristics of the CLC case

Temperature in FR / AR (°C)	950 / 1000
Feedstock mass flow (kg/sec)	5.21
Oxygen-carrier mass flow (kg/sec)	250
FR flue gas mass flow (kg/sec)	8.29
AR flue gas mass flow (kg/sec)	11.22
Supercritical steam conditions (°C / bar)	520 / 80
Total feedwater mass flow (kg/sec)	12.17
O_2 needed in POC (kg/sec)	1.22
AR outlet flue gas composition (%vol)	97% N_2, 2% CO_2, 1% O_2
FR outlet flue gas composition (%vol)	28% CO_2, 4% CO, 56% H_2O, 8% H_2, 3% CH_4, 1% impurities (SO_2, NO, HCl, N_2)
FR outlet flue gas composition range requirements (%vol d.b.) [13]	65-70% CO_2, 10-12% CO, 11-18% H_2, 5-8% CH_4

2.2 Reference Case

As for the reference case, a typical Waste-to-Energy plant is considered. This plant consists of a typical WtE supercritical boiler that produces steam at 400 °C in order to avoid corrosion problems [9], two reheaters and three steam turbines at escalated pressures. The feedwater preheating is performed using part of the thermal content of the flue gas. The main characteristics for the reference plant are summarized in Table {3}:

Table 3: Main characteristics of the reference case

Boiler efficiency (%)	93.6	HP/IP/LP Turbine isentropic efficiency (%)	92/94/88
Turbine inlet HP/IP/LP pressure (bar)	40/17.5/6.3	Superheated steam temperature/pressure (°C/bar)	400/40
Condenser pressure (bar)	0.077	Feedwater temperature (°C)	143.6
Flue gas outlet temperature (°C)	330		

2.3 Chemical Absorption with MEA

In MEA scrubbing, flue gas is in countercurrent flow with an aqueous MEA solution in an equilibrium absorption column that operates in atmospheric pressure. CO_2 separation from the flue gas is conducted via the following exothermic reactions [3]:

$$MEAH^+ + H_2O \leftrightarrow MEA + H_30^+ \quad (R9)$$

$$HCO_3^- + H_2O \leftrightarrow CO_3^{2-} + H_30^+ \quad (R10)$$

$$CO_2 + 2H_2O \leftrightarrow HCO_3^- + H_30^+ \quad (R11)$$

$$MEACOO^- + H_2O \leftrightarrow MEA + HCO_3^- \quad (R12)$$

$$2H_2O \leftrightarrow OH^- + H_3O^+ \quad (R13)$$

Subsequently, the abovementioned reactions are reversed and the solvent is regenerated in a stripper column. The necessary heat for solvent regeneration is given from low pressure steam (3.09 bar), which is extracted from the second turbine of the reference plant. The whole process is simulated and ELECNRTL is being used as property method. Variables like reboiler temperature (has to be lower than 120 °C in order to avoid thermal degradation), amine loading, etc. are presented in Table 4:

Table 4: MEA scrubbing key parameters

MEA scrubbing	
Lean solvent w/w	30 %
Lean solvent temperature	40 °C
Lean solvent loading	0.2
Rich solvent loading	0.49
L/G ratio	3.11 kg/kg
Specific heat duty	3.74 MJ_{th}/kg_{CO2}
Absorption capacity	349.3 g_{CO2}/kg_{MEA}
Auxiliary power demand	0.37 MJe/ kg_{CO2}
Reboiler temperature	118 °C
Steam temperature/pressure	133.5 °C/ 3.09 bar

2.4 Calcium Looping

In this study, chemical equilibrium between the inlet CO_2 (F_{CO2}) and the average fraction of the available CaO is assumed in order to form $CaCO_3$ ($X_{max} \cdot F_R$). This assumption is valid and widely found at literature [14], as the high operating temperature and fluidization phenomena of both carbonator and calciner lead to equilibrium conditions. Therefore, Gibbs free energy minimization is applied for the simulation of carbonator and calciner. As for the X_{max} parameter, it practically represents the fraction of the sorbent that is available to react and is a function of the make up limestone stream (F_0) and the solid recirculation ratio (F_R). It can be estimated by the following semi-empirical correlation [15]:

$$X_{ave} = \frac{f_m(1-f_w)F_0}{F_o + F_R(1-f_m)} + f_w \quad (2)$$

where f_m, f_w are constants based on each sorbent characteristics. The carbon capture efficiency in the carbonator is calculated via the following equation:

$$E_{carb} = \frac{F_{CO2,carb,in} - F_{CO2,carb,out}}{F_{CO2,carb,in}} \quad (3)$$

where $F_{CO2,carb,in}$ is the inlet CO_2 flow in carbonator and $F_{CO2,carb,out}$ the outlet CO_2 flow of the carbonator. Regarding the CO_2 capture efficiency of the whole Calcium Looping process, the following equation is applied:

$$E_{tot} = \frac{F_{CO2,calc,out}}{F_{CO2,carb,in} + F_0 + F_{CO2,RDF}} \quad (4)$$

where $F_{CO2,carb,in}$ is the inlet CO_2 flow in the carbonator and $F_{CO2,RDF}$ is the CO_2 flow due to the RDF combustion in the calciner.

The hot streams released from the carbonator and calciner can be further exploited in a secondary Rankine steam cycle for steam production, whereas the heat released from the exothermic reactions of the carbonator is being used for water evaporation. Apart from sorbent regeneration, RDF combustion takes place inside the calciner. Therefore, desulfurization and dechlorination of the RDF's combustion flue gas have been taken into account via the formation of $CaSO_4$ and $CaCl_2$. Concerning the secondary steam cycle, the efficiency is calculated with the following equation:

$$eff = \frac{Net\ power\ output}{mcp\Delta T_{flue\ gases} + Q_{carb}} \quad (5)$$

Table 5: Calcium Looping key parameters

F_R/F_{CO2}	7.5
X_{max}	0.25
T_{carb}	650 °C
T_{calc}	900 °C
E_{carb}	89.77 %
Raw supplementary fuel consumption	39.76 % of total fuel
$O_2/CO_{2\ cap}$	0.436 kg/kg
ASU specific power consumption	220 kWh/tn O_2
Air to fuel ratio	1.2
Secondary steam cycle's efficiency	32.89 %

3. Methodology

The fuel input was set as such, so that the total thermal input of the feedstock would be 50MW on an LHV basis. The net electric efficiency of the whole plant was calculated according to the following definition:

$$\eta_{net} = \frac{P_{gross\ electric} - P_{consumptions}}{Q_{thermal\ fuel}} \quad (6)$$

,where the consumptions mostly refer to the work of pumps or compressors needed and the gross electric is the power produced by the steam turbines.

In addition to the aforementioned efficiencies, the CO_2 emissions intensity was also calculated as the amount of carbon dioxide released in the atmosphere (measured in kg) divided by the amount of net total electricity produced by the plant:

$$CO_2\ intensity = \frac{m_{CO2,emitted}}{P_{net\ total}} \left(\frac{kg_{CO2}}{KWh_{el,net}}\right) \quad (7)$$

Furthermore, the specific fuel consumption was determined as the total amount of the input fuel to the net total electricity output of the whole plant:

$$\frac{m_{fuel}}{P_{net\ total}} \left(\frac{kg_{fuel}}{KWh_{el,net}}\right) \quad (8)$$

Lastly, for the cases of MEA scrubbing and CaL, where a reference plant already exists, SPECCA (Specific Energy Consumption for CO_2 Avoided) coefficient is introduced and expresses the additional fuel that is required to be consumed in order to avoid the emission of 1kg of CO_2:

$$SPECCA = 3600 * \frac{\frac{1}{n} - \frac{1}{n_{ref}}}{E_{ref} - E} \left(\frac{MJ}{kg_{CO2emitted}}\right) \quad (9)$$

4. Results and Discussion

Simulations of the reference Waste-to-Energy plant have shown that a net electrical efficiency can be achieved of around 27% on a LHV basis. Figures 4, 5, 6 depict the energy flow through a Sankey diagram in each scenario for amine scrubbing, Calcium Looping and Chemical Looping Combustion respectively.

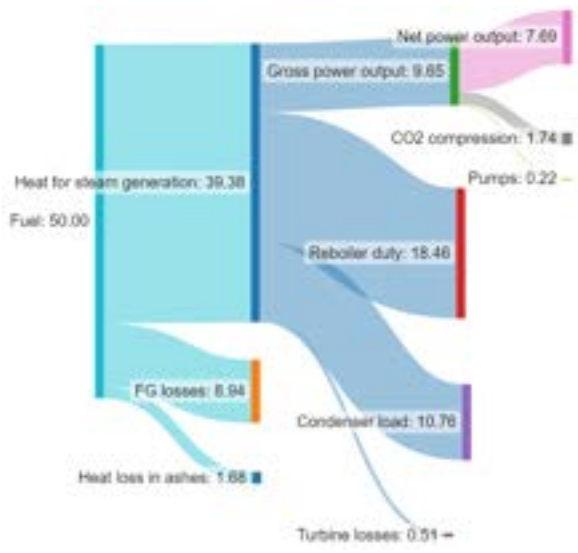

Figure 4: Sankey diagram for MEA scrubbing

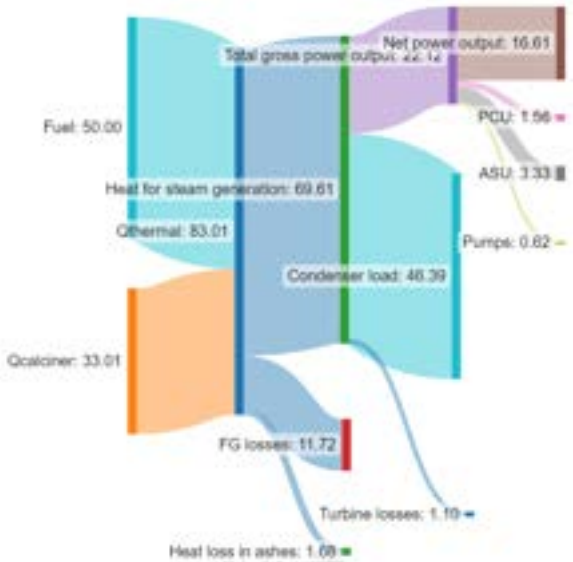

Figure 5: Sankey diagram for CaL

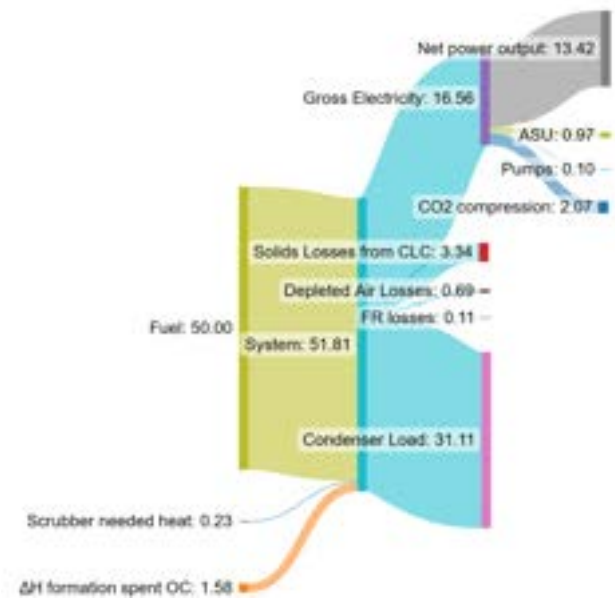

Figure 6: Sankey diagram of CLC plant

In the CLC case, around 51.5MW_{th} is inserted in the system, of which 50MW_{th} derive from the fuel thermal input, 220kW_{th} is needed for the Scrubber's operation and 1.6MW_{th} come from the difference of the enthalpy flows between the make-up material and the spent oxygen carrier. 31MW_{th} of that input is lost as waste heat in the condensers, 16.5MW_e of electricity is produced through the steam turbines and 4MW_{th} are heat losses in the atmosphere (in the form of the hot depleted air exiting the AR, the ash and spent OC exiting the FR and FR heat losses). Out of the 16.5MW_e of electricity produced, 2MW_e of electricity is consumed for the gradual compression of the CO2 stream, 100kW_e is consumed for the pumps operation and considering the use of an ASU for the oxygen production needed in the POC (requires 220kWh/tn_{O2}) [16], which consumes about 970kW_e, the remaining 13.4MW_e penetrate the grid. The overall net electric efficiency of the plant ended up being 26.84%.

Regarding the MEA scrubbing case, 50 MW_{th} of fuel is consumed. From this thermal input 39.38 MW_{th} is used for steam generation, while the rest thermal energy is considered to be waste heat. The gross electrical output of the initial plant steam cycle is approximately 9.65MW_e, but taking into account the electric consumption of pumps and the CO_2 compression unit, the net electrical output of turbines is estimated at 7.7MW_e. Hence, the net electrical efficiency of the whole process is about 15.4%. The rest of the useful heat to the Rankine cycle is used for solvent regeneration (18.46MW_{th}), as condenser load (10.76MW_{th}) and about 0.51MW_{th} are turbine losses.

As for the Calcium Looping process, the total thermal input is 83.01MW_{th}, of which 50MW_{th} is used as heat source for the steam cycle of the reference plant and 33.01MW_{th} in the calciner for the Ca sorbents regeneration. The useful heat for steam generation in both steam cycles (Rankine cycle of initial plant and secondary Rankine cycle of CaL process) is estimated at 69.61MW_{th}, while heat losses is 13.4MW_{th}. The gross electrical output of the whole process is 22.12MW_e. However, the electrical consumptions in PCU and ASU lead to a net power output of 16.61MW_e and a net electrical efficiency equal to 20%. The rest of the useful heat is consumed in the condensers of the two cycles (46.39MW_{th}) and turbine losses (1.10MW_{th}).

Table 6: Comparison of main indexes

	Reference WtE plant (no CO_2 capture)	**MEA scrubbing**	**Calcium Looping**	**Chemical Looping Combustion**
Capture efficiency (%)	-	90	93.41	94.64
Net electric efficiency (%)	27.13	15.38	20.00	26.84

Specific fuel consumption (kg_{fuel}/MWh_{el})	1382	2438	1874	1397
CO_2 emission intensity ($kg_{CO2emitted}/MWh_{el\_net}$)	1449.63	254.76	151.45	79.31
Energy penalty (%)	-	-11.75	-7.13	-0.29
SPECCA ($MJ/kg_{CO2emitted}$)	-	8.48	2.63	Not defined

Based on the data shown on Table 6, CLC technology can achieve a higher net electric efficiency than the other two methods, slightly lower than that of the reference plant. All three methods perform at a high capture efficiency, with no significant difference between them. Regarding the specific fuel consumption and the CO_2 emission intensity, MEA scrubbing has the lowest net efficiency of the three technologies, with CaL coming in second and CLC achieving the best performance. The energy penalty was calculated as the difference between the efficiency of each CO_2 capture technology and the efficiency of the reference plant. The SPECCA index cannot be defined for the Chemical Looping Combustion technology, given that it is not an equipment that can be implemented on an existing Waste-to-Energy plant. However, out of the two other methods, CaL achieved the lowest SPECCA index.

5. Conclusions

This study presented the comparison of three different CO_2 capture technologies implemented on Waste-to-Energy plants. In the case of MEA scrubbing, the net electric efficiency was calculated to be around 15%, mainly due to the significant amount of steam that is extracted from the power plant in order to regenerate the aqueous MEA solvent. Calcium Looping achieved a better efficiency, around 20%, with a rather low SPECCA of only 2.63MJ/ $kg_{CO2emitted}$ and seems to be less energy consuming than MEA scrubbing. Chemical Looping Combustion achieved the highest net electric efficiency out of the three technologies, while also being the least intense in terms of CO_2 emissions to the atmosphere. In CLC's case, a significant amount of heat was lost due to the thermal losses of the solids exiting the Fuel Reactor. Overall, all three technologies managed to reduce severely the CO_2 emission intensity of the reference plant, raising however the specific fuel consumption and decreasing, depending on the technology, the net efficiency. In conclusion, Chemical Looping Combustion is the least energy consuming and most effective technology and therefore is highly suggested as a CO_2 capture technology in case of a new power plant construction.

Abstract:
Anthropogenic carbon dioxide (CO_2) emissions have raised the global average temperature in 1.0 °C with respect to pre-industrial levels and this increase is likely to reach 1.5 °C before 2050, according to Intergovernmental Panel on Climate Change (IPCC, 2021).
To limit the temperature rise, most envisioned policies regarding CO_2 emissions rely on carbon capture, use and storage (CCUS), being essential to keep its concentration in the atmosphere below 450 ppm by 2100. IPCC forecasts 12 Gt/y of CO_2 removal in 2050 but the current capacity is 40 Mt/y. CCUS play a vital role in decarbonization, and it may be impossible to get emissions to net-zero fast enough without them.
For the marine industry, CCUS facilitate both CO_2 capture and transport. Ships fitted with this technology can capture carbon from burning fossil fuels. Among the newbuilding ships in 2021, 88% of them were fuelled with fossil fuels and according to ABS, in 2050 still 40% of them will be in this situation. Therefore, CO_2 capture onboard is necessary. Ships can also transport captured CO_2 to facilities for its use and/or storage.

This article investigates the value of ships as CO_2 carriers, focusing on the transport conditions of CO_2. An energy and techno-economic analysis is performed, considering several combinations of pressure and temperature. From an exclusive transport perspective, results show that lower pressures of CO_2 are likely to be more economic. From the pre-processing point of view, results suggest that higher pressures of CO_2 will imply energy savings and potentially cost savings. From the whole logistic chain perspective, the trade-off pressure is still unknown. More research is advised.

1. Introduction

Carbon dioxide (CO_2) is an essential gas for the presence of life on our planet. It is also the main "greenhouse gas" (GHG). These gases absorb and emit infrared radiation that reaches Earth from the Sun, heating the planet's surface as well as the lower layers of the atmosphere.

It is present in the Earth's atmosphere naturally, historically, in concentrations of approximately 300 parts per million (ppm) or 0.03%. During the ice ages, the levels were around 200 ppm and during the interglacial periods, slightly less than 300 ppm. the concentration of other GHGs has increased very significantly in the Earth's atmosphere in recent decades. Scientists attribute most of this increase in CO_2 concentration to human sources.

Human activities are estimated to have caused approximately 1.0°C of global warming above pre-industrial levels, with a likely range of 0.8°C to 1.2°C. Global warming is likely to reach 1.5°C between 2030 and 2052 if it continues to increase at the current rate, according to the Intergovernmental Panel on Climate Change (IPCC).

Most of net CO_2 emission models developed by the IPCC [1] require significant use of CCUS. According to the IPCC, carbon capture, utilization and storage (CCUS) is essential to maintain the concentration of CO_2 in the atmosphere below 450 ppm in the year 2100.

According to the International Energy Agency (IEA) [2], currently CCUS facilities around the world have the capacity to annually capture more than 40 $MtCO_2$. However, the mean of IPCC global net CO_2 emissions scenarios predicts 12 $GtCO_2$/yr sequestration from the energy sector in 2050. Therefore, CCUS technologies

play a vital role in decarbonization and it may be impossible to reduce net emissions down to zero fast enough without them.

It shall be noted that CO_2 is a commodity but still without a market. Moreover, according to IEA [3], CO_2 utilisation is a complement but it is not an alternative to CO_2 storage. Mac Dowell et al. [4] estimated that the contribution of carbon capture and utilisation (CCU) to the global CO_2 emissions reduction would be negligible (0.2 $GtCO_2$/year in 2050) and it could not compete with carbon capture and storage (CCS) as it has a much higher CO_2 capture potential, which was estimated at 7.8 Gt CO_2/year in 2050 [5]. In the IEA Net Zero Scenario [6], over 85% of BECC (Bio-energy with Carbon capture) and DAC (Direct Air Capture) CO_2 is permanently stored, and under 15% is used as feedstock.

Roussanaly et al. [7] stated that CO_2 shipping can be expected to play an important role in early CCS development, for "small" capacities, and/or long distance transport. According to the Global Global CCS Institute [8], CCUS technology facilitates both CO_2 capture and transport for the marine industry. First, ships fitted with carbon capture technologies can catch carbon emissions released from burning fossil fuels onboard. This is done via the use of scrubbers, which already clean emissions from exhaust gas and can be adapted to capture CO_2. This would enable shipowners to remove significant quantities of CO_2 from the exhaust. Second, ships can transport captured CO_2 to its drop-off point or offshore. Technology providers have developed safe solutions for storing CO_2 during transport at the right temperature and pressure, similar to those for ammonia and liquid petroleum gas (LPG). As stated by Xing et al. [9], shipowners can choose among materials for CO_2 storage tanks and optimize onboard space with either a single large tank or several smaller tanks. CCS technologies in maritime applications are still at an early stage, and their future prospects depend on reasonable technological innovation in combination with policy support.

Transport is that stage of carbon value chain that links sources and storage sites. Alongside pipelines, CO_2 shipping can enable flexible and scalable CCS infrastructure that can adapt to future capture projects and storage sites. Ships are also preferable for small or short lifetime CO_2 sources that cannot justify a dedicated pipeline.

Gas transported at pressure close to atmospheric ones occupies such a large volume that very large facilities are needed. Gas occupies less volume if it is compressed, and compressed gas is transported by pipeline. Volume can be further reduced by liquefaction, solidification or hydration [10].

At atmospheric pressure, CO_2 is as gas phase or as solid phase depending on the temperature. Lowering the temperature at atmospheric pressure cannot by itself liquefy CO_2, only make so-called 'dry-ice'. Liquid CO_2 can only exist at a combination of low temperature and pressure well above atmospheric [11].

CO_2 can be liquified at various pressures between the triple point (5.18 bar, −56.6°C) and critical point (83.8 bar, 31.1°C). When pressured above its critical temperature and pressure, the CO_2 can be compressed to reach supercritical form that has a higher density and can avoid two-phase flow [12].

Currently there are three ways of transporting CO_2 to onshore reception facilities and or offshore underground storages [6]:

- Gaseous transportation: CO_2 is compressed up to 35 bar and transported by pipeline, with intermediate boosters.
- Liquid transportation: CO_2 is compressed and transported by ship or pipeline.
- Supercritical transportation: CO_2 is compressed up to 250 bar and transported by pipeline.

CO_2 transport by ships is based on the shipping experience in the food and beverage industries and it a mature technology (TRL 9) as it has been practised for over 30 years at small-scale, with only 3 Mt CO_2/year. According to Hong [5], CO_2 shipping is now considered for large-scale transport of CO_2 because it may be more economical when CO_2 needs to be transported on a large-scale over large distances or overseas than constructing new long-distance pipelines or repurposing gas pipelines at existing loading facilities and unloading platform.

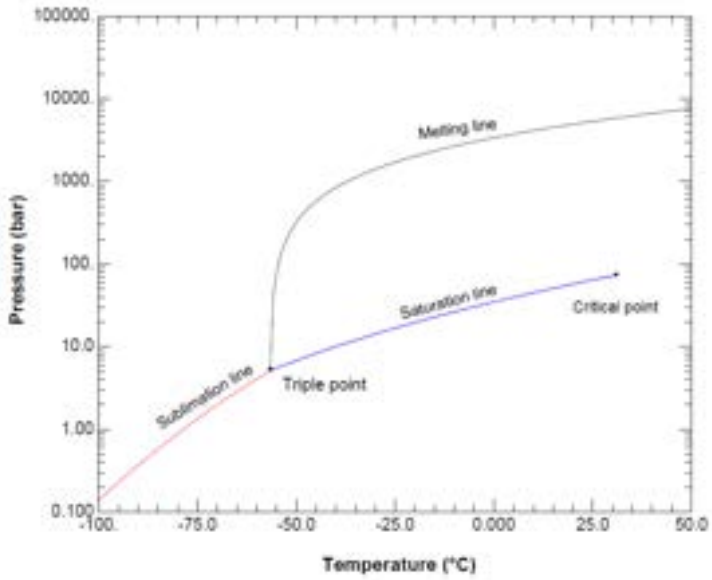

Figure. 1. CO_2 pressure-temperature diagram [13].

Liquefied CO_2 is the most obvious choice for ship transport, but even ships carrying compressed, gas phase CO_2 have been suggested. Transporting compressed CO_2 can be compared to transport of CO_2 in pipelines. Transport conditions will therefore be similar to that of pipelines, but with more flexibility and ease of inspection than pipelines. The temperature should be about 25°C and the pressure above 75 bar. The concept of compressed CO_2 on ships has been developed by ship companies, but remains untested and no international regulations exist for such transport of CO_2 [14].

Most literature recommends conditions near the triple point for shipping of liquefied CO_2, for the benefit of lower storage costs and enhanced density. However, other research suggests a higher liquefaction pressure for higher energy efficiency. Thus, there is no set optimal liquefaction pressure for all conditions; it should instead be determined from individual needs and the wider chain and project variables [12].

The code which applies to new gas carriers (built after 1986) is the International Code for the Construction and Equipment of Ships Carrying Liquefied Gases in Bulk. In brief, this Code is known as the IGC Code. The IGC Code, under amendments to Safety of Life at Sea Convention (SOLAS), is mandatory for all new ships since 1986 [15]. Kokubun et al. [16] stated that the physical properties of CO_2, specifically the vapor liquid equilibrium properties of CO_2, are such that the design of a storage tank for the containment of liquid carbon dioxide is very similar to existing designs for intermediate pressure liquefied petroleum gas (LPG) containment systems. The design methodology for LPG cargo tanks is well understood and is regulated by international standards (specifically the IGC code) and those of Classification Societies, such as Det Norske Veritas (DNV), Bureau Veritas (BV) and Lloyd's Register (LR).

As mentioned above, there is not enough number of CO_2 carriers for a realistic comparison. For this reason, it is assumed that similar ships can be a good starting point for energy and techno-economic comparison. The most similar ship to CO_2 carriers are LPG ships (pressurized or semi-pressurized) for liquid transportation and compressed natural gas (CNG) ships for gas transportation. However, there is only one existing CNG ship in the world fleet and compressed CO_2 transportation has not been developed yet as a practical solution.

The object of this article is to perform a comparison of transport conditions of liquid CO_2 by ship, considering several pressures of CO_2 (defined in Table 2), a common ship model and two different cargo tanks configuration, as defined in Section 2. The following CO_2 conditions have been considered:

Table 1. Thermophysical properties of CO_2 for pressures from 6 to 45 bar [17].

Case No.	Pressure, bar	Temperature, ºC	Density, kg/m^3
#1	6	-53.12	1166.00
#2	10	-40.12	1116.90
#3	15	-28.52	1069.50
#4	20	-19.50	1029.40
#5	25	-12.01	993.20
#6	30	-55.52	959.25
#7	35	0.16	926.47
#8	40	5.30	894.05
#9	45	9.98	861.27

2. Methods

Focusing on the maritime transport part of the CCUS chain, and in order to investigate the value of ships as CO_2 carriers, some Key Performance Indicators (KPI) are presented and discussed, considering a specific ship as a comparison element.

2.1 Ship definition

First of all, a ship has been identified and chosen as a model to compare transport cases defined in Section 1. Based on the information provided yearly by the Royal Institution of Naval Architects (RINA) in its publication "Significant Ships" [18], a LPG carried named "Alkaid" (named "Sibur Voronezh" until 2022) has been selected as a reference ship to compare the different transport conditions of CO_2 from a common base.

This ship was designed to carry liquefied gases such as propane, butylene, propylene, anhydrous ammonia, butadiene and vinyl chloride monomer (VCM). The cargo space is divided into four cargo holds to accommodate four independent self-supporting cargo tanks built to International Maritime Organization (IMO) type C standard of bi-lobe shape with a centre longitudinal bulkhead; along with one cylindrical type deck tank. The vapour pressure range of the cargoes carried is up to 5.3 bar, the minimum cargo temperature is -40 ºC and the maximum specific gravity 0.972. The main technical particulars and ship drawings are presented in Table 2 and Fig 2.

Table 2. Technical particulars and characteristics of LPG carrier "Alkaid" [18], [19].

IMO number	9655509
Length (overall) (m)	159.97
Length (between perpendiculars) (m)	152.20
Breadth (moulded) (m)	25.60
Depth (moulded) (m)	16.40
Draught (scantling) (m)	10.90
Deadweight (design) (t)	13 650
Deadweight (scantling) (t)	22 700
Cargo capacity (m^3)	20 800
EEDI [$gCO_2/(t \cdot nm)$]	10.7

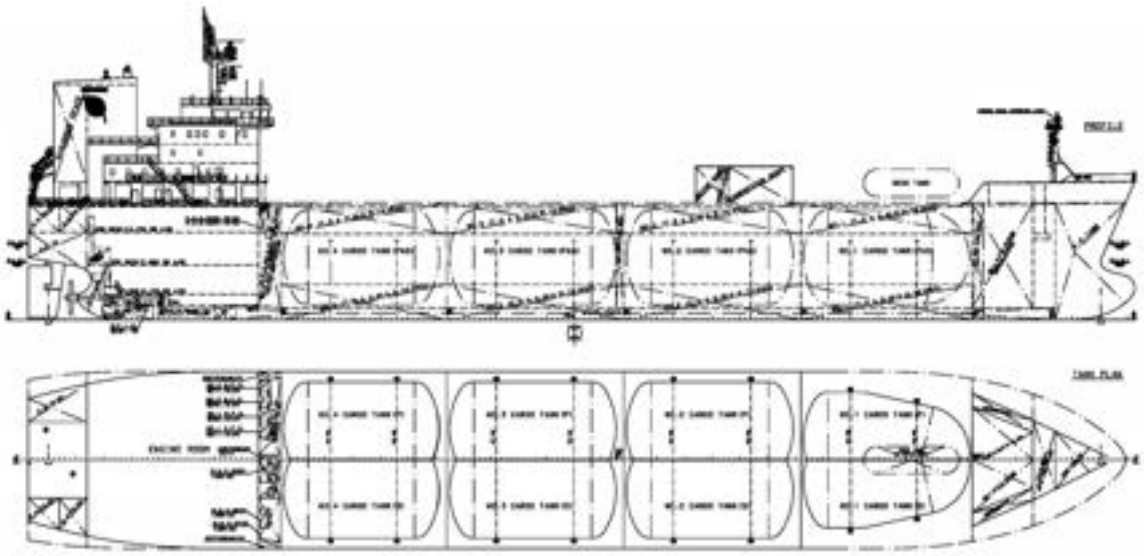

Figure. 2. "Alkaid" side and top views [18].

The dimensions of the cargo holds and LPG tanks (No.2-4) are shown in Fig 3. For calculation purposes, it is assumed that the fore tank (No. 1) has the same shape and volume as cargo tanks 2-4.

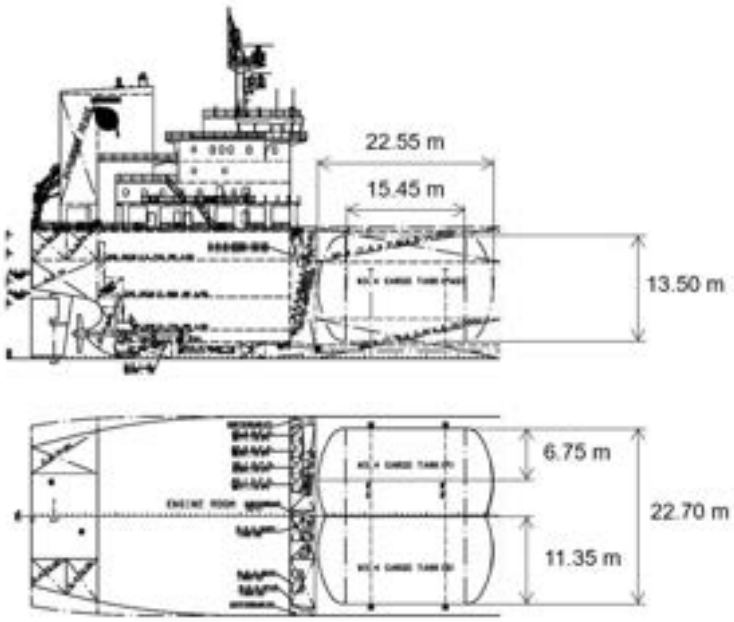

Figure. 3. Cargo hold and bi-lobe tank main dimensions [18].

As a general constraint for the different proposed arrangements, the following control volume has been defined, considering the maximum dimensions of the bi-lobe tank, as shown in Fig 3 and detailed in Table 3. In order to establish a common basis for comparison, the new redesigned tanks can occupy the complete control volume, despite its shape (bi-lobe, cylindrical) or its position (vertical, horizontal), thickness included.

Table 3. Dimensions of cargo hold control volume.

Dimension	Value
Length (m)	22.5
Breadth (m)	22.7
Height (m)	13.5

Redesigned bi-lobular tanks are arranged as in the existing ship. As the design pressures considered are higher than the LPG storage pressure (5.3 bar), the thickness growth will reduce the net volume of the cargo. The key parameter of the new configuration of the bi-lobular tanks for CO_2 storage is summarized in Table 4.

Table 4. Configuration and dimensions of bi-lobular tanks.

Characteristic	Value
Number of tanks per cargo hold	1
Total number of tanks	4
Length (thickness included) (m)	22.5
Breadth (thickness included) (m)	22.7
Height (thickness included) (m)	13.5
Main axis direction	Horizontal

Another proposed configuration is to store CO_2 in cylindrical tanks of smaller diameter, within the same control volume. New calculated cylindrical tanks can be transported vertically or horizontally. There are several variables (diameter, number of tanks per cargo hold, etc.) so the different potential configurations shall be considered carefully. Considering the boiloff management, and free-surface area to prevent sloshing and stability issues, a vertical arrangement seems preferable. In addition, a minimum clearance between cylindrical tanks must be considered for isolation, supporting structures, etc. Table 5 displays the key assumptions of the vertical cylinders. A 6x6 tank grid per hold has been deemed a good tradeoff considering a small free-surface area, while keeping the number of the ancillary components (pumps, valves, manifolds etc.) of all the tanks within reasonable levels.

Table 5. Configuration and dimensions of vertical cylindrical vessels.

Characteristic	Value
Number of vessels per cargo hold	36 (6x6)
Total number of tanks	144
Length (m)	13.5
Diameter (thickness included) (m)	3.5
Main axis direction	Vertical

Both CO_2 type of tanks proposed are based on ships in operation or projects under development, such as Samsung Heavy Industries (bi-lobular tanks) or KNCC (cylindrical tanks), both Approved in Principle by DNV in 2022 [20], [21].
According to American Bureau of Shipping (ABS) [22], both bi-lobe and cylindrical tanks are "pressure vessels", which are designed and built to meet the requirements of recognized pressure vessel standards such as the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code (BPVC), as well as additional classification society requirements and statutory regulations.
The nominal body and head wall thicknesses are calculated based on ASME VIII Div. 1 UG-27 (Thickness of shell under internal pressure) and UG-32 (Formed heads and Sections, pressure on concave side). The main inputs and assumptions are listed below:

- For thickness calculations, the bi-lobe tank thickness has been calculated considering a cylinder with a radius of 6.75 m, in order to avoid complex strength calculations.
- The welded joint efficiency factor to be used is 0.875.
- The allowance for corrosion is 1 mm.
- The material selected for both types of tanks is American Society for Testing and Materials (ASTM) A537 Class 2 (quenched and tempered), a higher yield and tensile strength carbon steel used in the fabrication of pressurised vessels and steel boilers and a lowest usual service temperature −60 ºC.

Table 6. Mechanical properties of carbon steel ASTM A537 class 2 [23].

Material	Thickness, mm	Yield strength, MPa	Tensile strength, MPa
ASTM A537 class 2	< 65	415	550
	> 65 < 100	380	515
	> 100	315	485

2.2. Key Performance Indicators (KPI) definition

The following Key Performance Indicators (KPI) are analysed and discussed, considering the transport pressures described in Section 1.

- Preconditioning of CO_2 (liquefaction):
  - Thermomechanical Exergy
- Transport of CO_2:
  - Mass of CO_2
  - Ratio mass of CO_2 vs. tank structure
  - Ratio volume of cargo vs. cargo hold
  - Energy Efficiency Design Index

The first KPI is the *thermomechanical exergy* of the preconditioning phase of the CO_2. In this case it represents the minimum work required to change a substance from the restricted dead state to a particular state using the ambient as the only heat source [24]. This KPI is defined by Eq. 1, where U is internal energy, V volume and S entropy of a closed system that is in nonequilibrium with the environment, T_0 is the reference temperature of the surroundings environment (so called "restricted dead state"), and index 0 refers to the values of the parameters when the system is in thermomechanical equilibrium with the environment. The restricted dead state conditions are described in Table 7.

$$Ex = (E - U_0) + p_0(V - V_0) - T_0(S - S_0) \quad (1)$$

Table 7. Restricted dead state conditions.

Property	Value
Pressure (kPa)	100
Temperature (K)	288.15

The mass of CO_2 transported is calculated considering the two tank types defined in Section 2. The thickness of shell and head are calculated and the gross and net volume and mass of the CO_2 and tank are obtained, considering the size limitations. Mass and volume ratios are then calculated based on this. It is assumed that the balance of mass of LPG cargo and tanks of "Alkaid" shall remain invariant. Hence, if the mass of CO_2 and tanks is bigger than "Alkaid" cargo mass (to be called "Maximum CO_2"), the exceeding mass is considered as a cargo loss and will be deducted from the CO_2 mass.

$$Mass\ LPG + Mass\ LPG\ tanks = Mass\ CO_2 + Mass\ CO_2\ tanks \quad (2)$$

The last KPI considered is the Energy Efficiency Design Index (EEDI). It provides a specific figure for an individual ship design, expressed in grams of CO_2 per ship's capacity-mile and is calculated by a formula based on the technical design parameters for a given ship. EEDI was made mandatory by the IMO [25] for new ships and the Ship Energy Efficiency Management Plan (SEEMP) for all ships at Marine Environment Protection Committee No. 62 with the adoption of amendments to International Convention for the Prevention of Pollution from Ships (MARPOL) Annex VI.

The EEDI is calculated based on a complex formula, taking the ship's emissions, capacity, and speed into account. The lower a ship's EEDI, the more energy-efficient it is and the lower its negative impact on the environment. IMO regulations stipulate that ships must meet a minimum energy efficiency requirement, so their EEDI must not exceed a given limit.

$$EEDI = \frac{grams\ of\ emmited\ CO_2}{tonne\ of\ cargo \cdot nautical\ mile} = \frac{Power \times Fuel\ consumption \times CO_2\ emission\ factor}{Capacity \times Ship\ speed} \quad (3)$$

Aiming to compare EEDI of "Alkaid" with the calculated CO_2 cases, it is assumed that all factors of the equation remain equal except the cargo mass (capacity) so the following relation applies:

$$(EEDI \times Capacity)_{ALKAID} = (EEDI \times Capacity)_{CASE} \quad (4)$$

$$EEDI_{CASE} = \frac{EEDI_{ALKAID} \times Capacity_{ALKAID}}{Capacity_{CASE}} \quad (5)$$

According to the IMO, the EEDI reference line for gas carriers is calculated as follows [26]:

$$EEDI = 1120 \times DWT^{-0.456} \quad (6)$$

For gas carriers with 10000 DWT (deadweight) and above, the reduction factors are 20% in phase 2 (January 2020 to December 2024) and 30% in phase 3 (starting January 2025).

3. Results & Discussion

Figures 4 to 9 show the results of the analysis, giving the overview, and the results in detail.

In Fig 4 it is shown the specific exergy (kJ/kg) for the different cases studied, despite its packing conditions. Considering the dead state defined in Section 2, it is observed that the exergy is greater for low temperatures and low pressures than for higher temperatures and pressures. This means that the higher the pressure, the less energy is expected to be required to drive CO_2 from a restricted dead state to the saturated liquid state corresponding to the pressure. For example, the exergy of case #9 (45 bar, 10ºC) is 6.4% lower than case #1 (6 bar, -53ºC). Only from the exergetic point of view, liquefaction up to the highest range of pressures considered in this study is more convenient than low pressures close to the triple point. This metric reflects that the processes required to produce liquid CO_2 at 45 bar will foreseeably require less energy than the lower pressure alternatives. Energy savings at this stage are key considering they will have an associated cost that will impact for the whole lifetime of the logistic chain, which could easily span for 30 years.

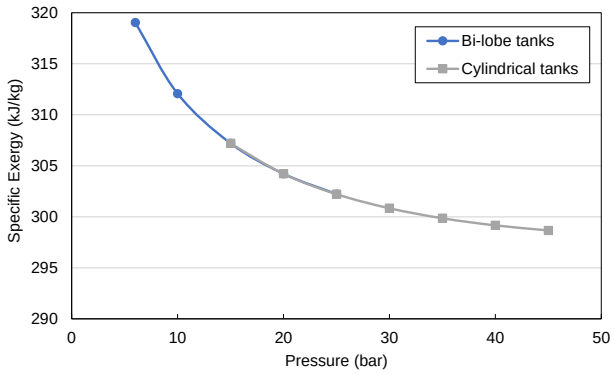

Figure. 4. Specific Exergy of CO_2 as a function of CO_2 pressure.

Regarding mass of cargo and tank structure, its different values are shown in Fig 5 for bi-lobe tanks (CO_2 cargo, tank structure and excess of CO_2) and Fig 6 for cylindrical tanks (CO_2 cargo, tank structure and lost mass/excess of CO_2). The maximum amount of CO_2 that can be stored in a bi-lobe and cylindrical tanks is shown in dark blue colour, called "maximum CO_2". However, as introduced in Section 2 and in order to do a consistent comparison, the balance of mass shall remain invariant with respect to the reference LPG ship. Therefore, the excess of mass compared with the LPG ship is identified and discounted, presented in blue colour, so called simply "CO_2".

	6 bar	10 bar	15 bar	20 bar	25 bar
Maximum CO2 (t)	25512	24164	22867	21664	20572
CO2 (t)	21318	19848	18241	16234	14040
Excess of CO2 (t)	4194	4316	4626	5429	6532
Steel (t)	2639	4109	5716	7723	9917

Figure. 5. Mass of CO_2, tank structure and excess of CO_2 for bi-lobe tanks.

Opposite to the situation with bi-lobe tanks and due to the lower storage volume utilization, additional ballast must be supplied to the vertical cylinder arrangement at pressures under 35 bar to keep the balance of mass invariant. The additional ballast coincides with the loss of of CO_2 mass in Fig. 6.

	15 bar	20 bar	25 bar	30 bar	35 bar	40 bar	45 bar
Maximum CO2 (t)	18656	17829	16955	16206	15545	14897	14175
CO2 (t)	18656	17829	16955	16206	15545	14559	13489
Loss/Excess of CO2 (t)	-1691	-1485	-1031	-642	-154	338	686
Steel (t)	3610	4643	5971	7109	8258	9397	10468

Figure. 6. Mass of CO_2, tank structure and lost mass or excess of CO_2 for cylindrical tanks.

With regard to the mass of transported CO_2 the best solution is to transport CO_2 at 6 bar in bi-lobe tanks as they are able to transport 21318 t while complying with the balance of mass constraint.

As shown in Fig 7, exclusively considering the amount of CO_2 transported, from pressures of 10-15 bar it is better to use cylindrical tanks as the CO_2 stored decreases rapidly from that operating pressure in bi-lobe tanks. It shall be noted that an optimized calculation of the bi-lobe tank structural strength may end up with a higher transition pressure, closer to the 15-20 bar range. Considering only the storage pressure, low pressures are more interesting, as the amount of CO_2 is higher. For example, the difference between transporting CO_2 at 10 and 45 bar is 47.1% and 70.5% (maximum CO_2).

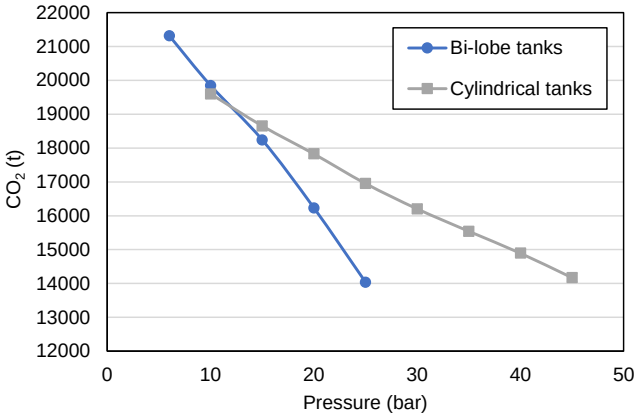

Figure. 7. Mass of CO_2.

Two ratios have been calculated: mass of CO_2 versus tank structure and volume of tank versus cargo hold, both shown in Fig 8. Both KPI serve as a measure of efficiency in the mass and volume dimensions. In both cases, the higher the ratio, the better. A low mass ratio implies that more mass of steel of the structure is being transported with respect with the CO_2. Analogously, a low volume ratio, implies that there is more empty space with regard to used space. As expected, the volume of cylindrical tanks makes much less use of available cargo hold space than bi-lobe tanks. However, bi-lobe tanks only take advantage of this for low pressures, as the mass of the structure increases rapidly. Note that for a storage pressure of 25 bar, the mass ratio of the bi-lobe tank considered is only 1.42. Under this KPIs, transporting CO_2 at low pressures, will probably result in a lower ship acquisition cost per unit mass of transported CO_2, as the mass of steel has a great influence on the final cost of a ship. The low ratios that this method yield, very likely imply that the base LPG ship main dimensions are not optimal for the transport of CO_2, thus a change of geometry in actual CO_2 could be expected Fig 2 and Fig 3 if an Ad hoc bulk CO_2 carrier was designed.

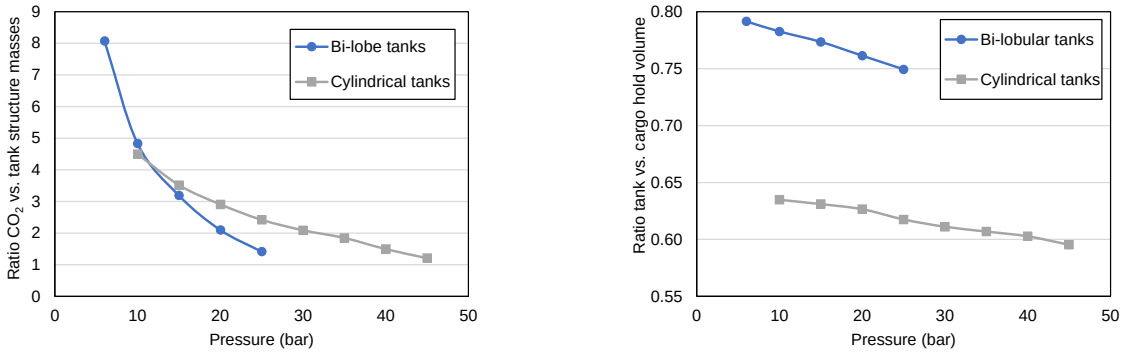

Figure. 8. Ratio of CO_2 vs. tank structure mass (left) and ratio of tank vs. cargo hold volume (right).

The last KPI is EEDI, presented in Fig 9, considering the mass of CO_2 for both type of tanks and the assumptions described in Section 2. As the storage pressure increases, so does EEDI value. In this case, the lower the value, the more efficient will be the ship. This KPI suggests that the ship with 6 bar and bi-lobe configuration will use less fuel per unit distance and unit mass of transported CO_2, probably meaning that the Voyage Cost of the low-pressure ship will be lower.

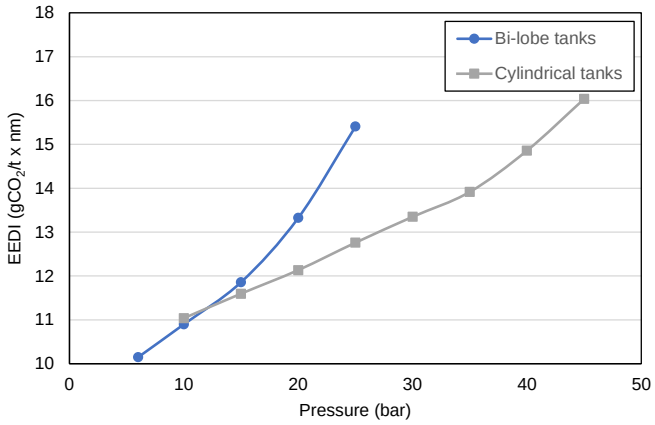

Figure. 9. EEDI of the ships proposed.

4. Conclusions

The results obtained in the different analyzes carried out establish unaligned conclusions. On one hand, from the exergetic point of view, liquefying the CO_2 to the highest range of pressures considered in this study is more efficient than lower pressures, closer to the triple point. Nevertheless, once thermoeconomy is included in the analysis, results could be different. On the other hand, lower CO_2 pressures allow more mass to be transported, and will probably result in reduced voyage costs, and the reduced steel mass in the ship's construction will probably mean cheaper acquisition costs. Considering that the whole logistic chain of CO_2 include the preprocessing costs, transport costs and post processing costs, it is not clear what the optimal transport pressure will be. Varying the pressure of the CO_2 cargo will have opposed effects in different elements of the logistic chain. Therefore, more research will have to be conducted to unveil the trade-off pressure, and the parameters that define it, considering the whole CCUS chain.

Attention should be paid to the tank design, as there is a transition pressure where bi-lobe tanks are no longer a smart option due to its mass and cylindrical tanks would be better even considering its worse volumetric efficiency. Attention should be paid to transporting CO_2 at low pressures close to the triple point, as in that region there is a higher risk of undesired CO_2 solidification, which can potentially clog pipes or damage pumps.

Dynamic Life Cycle Sustainability Assessment of Mini-grids: A Proof-of-Concept

Abstract:

As per the 'World Energy Outlook 2022' projections, 660 million people worldwide (mostly from rural areas) would be without electricity access in 2030. There are three main approaches to rural electrification - centralised grid extension, mini-grids, and solar home systems (SHS) including pico-solar. Mini-grids are considered a promising solution in rural areas with higher reliability (as compared to the central grid) and higher capacity to meet demand (as compared to the SHS). However, there have been failures of several mini-grid projects worldwide. There are various challenges faced by mini-grids – technical, social, economic, and strategic. The past efforts to assess mini-grid sustainability have used static approaches. Consideration of dynamic variations in the mini-grids over the life cycle for sustainability assessment is an emerging research area and is being explored in this paper. An attempt has been made to show how the dynamics and the interdependency of different aspects related to the mini-grids can be considered for life cycle sustainability assessment. Complex environments, local operations, many interacting variables, and feedback processes characterise mini-grids. 'System dynamics' is a systems method suitable to describe behaviours of such systems and tackle relevant problems. A system dynamics approach has been used in assessing an Indian mini-grid for a systemic understanding of its life cycle. The analysis reveals the impact of different variables on the mini-grid's life cycle. Developed stock-flow (SF) diagram is useful for analysing different scenarios (e.g. arrival of centralised grid) and policies (e.g. tariff variations). This proof-of-concept (PoC) may help to develop a comprehensive framework for the dynamic life cycle sustainability assessment (D-LCSA) of mini-grids.

1. Introduction

1.1. Global electricity access

Electricity access has been a requisite part of any global development process. In the Sustainable development goals (SDGs) set by United Nations [1], SDG 7 is — Ensure access to affordable, reliable, sustainable, and modern energy for all. Particularly, SDG 7.1 aims at 'universal access to modern energy'. Modern energy access also includes other types of energy carriers like cooking fuels and transportation fuels. But due to its strong linkage with the development, 'electricity access' is an area of interest for researchers, policymakers, and executors.

In India, on 30th April 1945, Mahatma Gandhiji wrote a letter to Cambridge return economist Shri.Amiya Nath Bose and expressed his concern about the electricity access to every home in India. He asked "Have you worked out the problem of electricity for every home? What is the cost?" [2]. In later years, various schemes for the extension of the electricity network in India, as well as at the global level improved electricity access but the challenges like network expansion, and poor financial returns on investment, remain for remote areas. Due to rapid urbanisation, more focus was on urban electrification and a majority of the rural population remained without any electricity access during the development stages.

As per the 'World Energy Outlook 2022' [3] projections, 660 million people worldwide would be without electricity access in 2030. The report [4] published to track the progress of SDG 7 mentions that rural electricity access is more deficient than in urban areas. In 2020, out of the world's population without electricity access, 80% of people lived in rural areas. Also at the current pace, the 2030 target for rural electrification will fall short. Figure 1 highlights the need for more focus on rural electrification in the next few years.

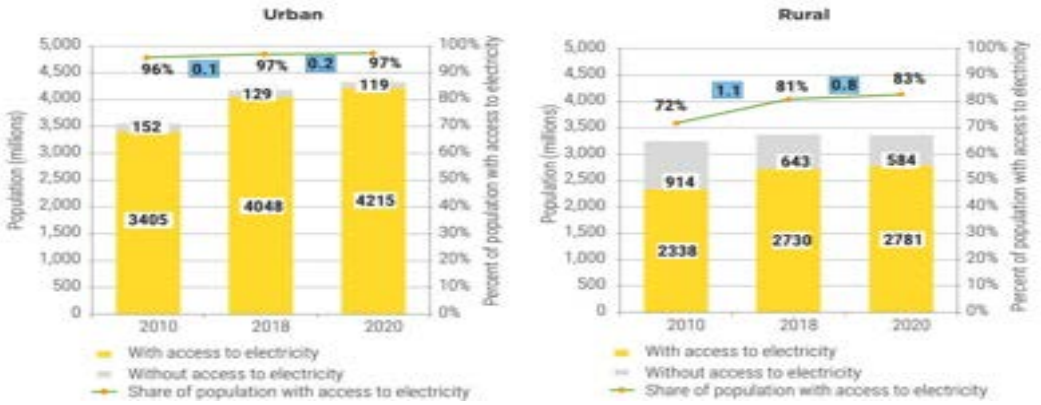

Figure. 1. Electricity access in urban and rural regions at the global level [4].

1.2. Approaches to rural electrification

Electricity access can be provided through three possible schemes/modes: - centralised electricity grid, mini-grids (or micro-grids), and solar home systems (SHS) including pico-solar. Off-grid electricity can be generated with more resources like diesel and biogas, but their share compared to solar electricity generation is much less. Moreover, the government schemes are more tilted towards “solar” due to the ease of installation, operation, and maintenance.

Centralised electricity supply is the conventional type of electricity supply scheme. This supply type is also called grid extension. The electricity is generated using various resources, such as fossil fuels (coal or NG-based plants), nuclear energy, and renewables e.g. water (hydropower plants), wind, or solar energy in centralised power plants. The same is transferred through the transmission and distribution network monitored by the national and state-level utilities. This is called the vertical structure of electricity supply. Until the technological advances started taking place in the renewable energy sector with the choice of decentralized electricity generation, the centralised supply scheme was the only option for providing electricity access.

The monopoly of the centralised supply scheme ended due to various reasons like increased competition in the electricity industry, entry of private players, technology development in renewable electricity generation, etc. There are various environmental, economic, technical, political, and social reasons for developing small-scale generation near the loads. This small-scale generation is called a decentralised electricity supply scheme. The systems can run in isolation (off-grid mode) or connected to the grid (grid-connected/online mode). The generation technology is either renewable (e.g. solar, wind) or non-renewable (diesel generator), or a combination of multiple technologies (hybrid mini-grids).

As discussed in [5], an SHS is usually defined as a solar PV-based generator rated 11 Wp to more than 100 Wp with suitable battery storage. The maximum PV module rating in an SHS kit is expected not to exceed 350 Wp as per the current standards. Products with rated PV power lesser than 11Wp are pico-solar.

Due to the various challenges like cost recovery and supply reliability for the central grid extension and the limitations of SHS and pico-solar ratings to fulfill the electricity demands, the rural areas find mini-grids as a promising solution. ‘Ease of electrification vs. Power level’ of various electrification modes is shown in Figure 2.

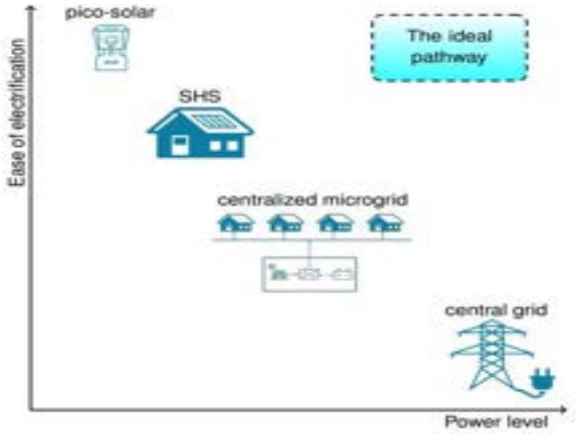

Figure. 2. Modes of electrification and comparison of ease of electrification vs. power level [5].

Delivery of electricity connections under the IEA Net Zero Emissions by 2050 Scenario, by technology, is shown in Figure 3.

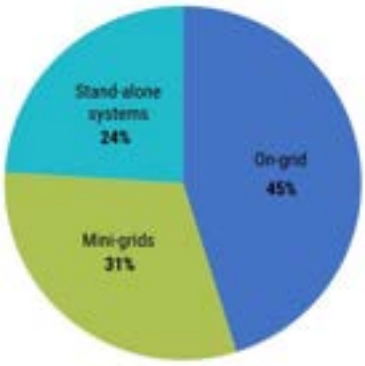

Figure. 3. Delivery of electricity connections by 2050 Scenario, by technology [4].

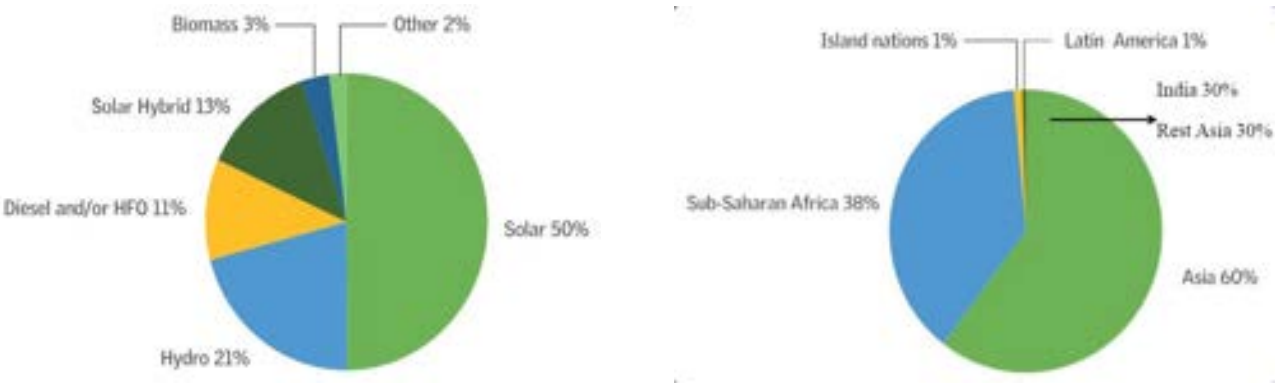
1.3. Mini-grids

1.3.1. Introduction

Mini-grids are off-grid systems but have provisions to connect with the grid and operate in parallel. They are local electric power networks with distributed generators, loads, and energy storage technologies. The term “mini-grid" is merged with “microgrid" in the literature though they have different generating capacities and a mini-grid has a higher capacity than a microgrid. A renewable energy-based mini-grid is defined in [6] as a system that uses a renewable energy-based generator (with a capacity of 10 kW or more) to supply electricity to a specific set of consumers (e.g. households and/or commercial, industrial, and/or institutional organizations) through a power distribution network. In this paper, the term “mini-grid" is used for off-grid AC electrical systems with solar PV as a source. Solar PV technology is more focused because of the maximum share as a mini-grid source as shown in Figure 4. A typical mini-grid consists of energy generation technology, battery energy storage, a power electronics converter, a power distribution system, and an energy management system (for metering and control purposes).

1.3.2. Global status and mini-grid scenarios

Plethora of literature discussing the technical aspects of mini-grids, their importance, and the challenges in mini-grids have been published. Their status in the global south and India are discussed in the reports [6,7] recently published by The Centre for Science and Environment (CSE). The status of the ten countries having best practices in mini-grid installations and the barriers to mini-grid installations and sustainable operations in India are explained in detail. There are 5,544 mini-grids deployed worldwide out of which 60 percent are present in Asia and 39 percent in Sub-Saharan Africa. India has 1,792 mini-grid installations, the highest in Asia. The status of mini-grid installations at the global level by technology and region is shown in Figure 4.



(a) (b)

Figure. 4. The global status of mini-grid installations: a) technology-wise, b) region-wise [6].

Mini-grid case studies discussed in [6] may be classified as off-grid (e.g. Raimongol Kumirmari Island and Madavchandra Satjelia Island in Sundarbans, West Bengal), mini-grids with grid extension but poor grid services (Jargatoli and Basua Gumla, Jharkhand and Chanpatia in West Champaran of Bihar), mini-grid not operational due to grid arrival (Darewadi, Maharashtra and Dharnai, Bihar), grid-connected mini-grid (Odanthurai, Tamilnadu) and mini-grids with SHS (Chopan, Maharashtra).

1.3.3. Need for sustainability assessment of mini-grids

Life cycle sustainability assessment (LCSA) is a combination of three approaches of sustainability assessment- environmental life cycle assessment (E-LCA), life cycle costing (LCC), and social life cycle assessment (S-LCA). This is also called the triple bottom approach. Some more dimensions such as 'technical' or 'institutional' are also considered in the LCSA. A sustainability assessment of mini-grids is needed for various reasons. The literature having the notion of mini-grid sustainability is evolving since 2009. Mini-grids play a vital role in rural electricity access and their unsustainability will impact the sustainable development goal achievement.

Turkson et al. [8] infer that several global and national level policies and practices are envisioned to ensure sustainable energy generation. Boche et al. [9] discuss various barriers like lack of business consideration, the gap in strategic planning approach, and the neglect of social issues. It is also mentioned that overall microgrid sustainability consideration is still deficient at the global level.

The need for sustainability assessment is also understood from the field experiences of mini-grid projects. A mini-grid case study at a village called Darewadi from Khed Taluka (District Pune, Maharashtra, India) is discussed in [6]. This mini-grid was in operation since 2012. In 2019, the battery replacement was carried out. The centralised grid reached the village in 2021 but reliability and quality of supply are poor. Mini-grid could have been used in grid-connected mode but tariff regulations for the interconnection were absent. This case study highlights the failure of mini-grid projects after certain years of operation. The Dharnai mini-grid in Bihar state and the Barapitha mini-grid in Odissa state faced similar issues.

The rest of the paper is organised as follows. Section 2 describes the review of the sustainability assessment of mini-grids and highlights the research gaps. Section 3 introduces dynamics and systemic approaches in mini-grids. In section 4, the conceptual framework and proof-of-concept model are discussed. Section 5 simulates the model with the mini-grid case study in Maharashtra state. The results of the simulations are discussed in section 6.

2. Sustainability assessments of mini-grids

The literature was reviewed for "energy sustainability" and "electricity sustainability". The literature for "mini grid sustainability" was shortlisted from the above two sub-areas. A literature database platform "Scopus" was used for the literature review. The use of suitable keywords and the operators like "AND" and "OR" helped to review the literature systematically. Research gaps in the area of mini-grid sustainability are summarised in Table 1.

Table 1. Literature and research gaps.

Author/s	Research Gap
Turkson et al. [8]---------	Sustainability as a systems problem, Practical implications of the different sustainability dimensions, Systems thinking for explaining dynamic interactions and the long-term effects of different dimensions in detail. "Dynamic life cycle sustainability assessment" as the state-of-the-art method supports static analysis.
Boche et al. [9]----------	Analysis of interdependence issues, Development of sustainability diagnosis tools, and systemic modeling of microgrids with short, medium, and long-term dynamics for causal linkages amongst various issues
Haase et al. [10]----------	Inclusions of more social indicators, the derivation of indicators, the consideration of methodical and input data uncertainties
Khatami ---------- and Goharian [11]	An all-inclusive approach toward energy sustainability and a better framework for defining sustainability giving equal weightage to all dimensions and spatial considerations
Brent and Roger [12]---	An understanding related to the complexity of the socio-institutional systems
Ilskog [13]----------	An interdisciplinary approach to sustainability evaluation.
Lassio et al. [14]----------	More emphasis on the social dimension of sustainability is recommended.
Viegas et al.[15] ---------	Project and location-specific sustainability assessment methods for integrative and at the same time customized assessment

Author/s	Research Gap
Corona and San Miguel [16] ---------	The use of a dynamic approach for sustainability assessment temporal and spatial variation in the criteria (indicators).
Poudel et al. [17]---------	Internal and external factors influencing the sustainability of mini-grids, and linkages between the project attributes and sustainability dimensions
Katre et al. [18]----------	Time-based sustainability studies capturing temporal variations.
Chatterjee et al. [19] ----	Microgrid definition, typology identification, standards revision, electrification planning, energy utilisation and planning, resiliency, system dynamics, and technology adoption and policy recommendations.

'Use of system thinking and system dynamics in sustainability assessment of mini-grids' is research gap as inferred by many authors. This paper explores the consideration of dynamics in the mini-grid life cycle for sustainability assessment. The next section discusses how the concept of dynamics is linked to mini-grids.

3. Dynamics in mini-grids

3.1. System thinking approach in mini-grids

Hartvigsson in his Ph.D. dissertation [20] discusses the systems thinking approach and its linkages with mini-grids. System thinking is a method for understanding interaction amongst variables and the resulting behaviour of the system. This is useful when systems are complex and influence the users at different levels. Systemic studies help to change the system structures which are the cause of certain behaviours. System thinking is divided into "soft" and "hard" system thinking. The "hard" approach is used in well-defined problems while the "soft" approach is useful when problems are "fuzzy", "messy" or "ill-defined". Mini-grids being complex and messy systems, the system thinking approach is useful for analysing mini-grids' behaviour. Some mini-grid problems can be engineered while others being societal are difficult to define. Thus mini-grids can be analysed with both "soft" and "hard" system thinking.

System dynamics (SD) is a dynamic thinking tool for qualitative (soft) and quantitative (hard) analysis which helps to understand the behaviour of the system over time. SD analysis consists of plotting behaviour over time (BOT) graph, development of causal loop diagram (CLD), and stock-flow (SF) analysis. Another characteristic of SD applicability is many feedback processes and interdependency among variables. The important literature in the area of SD applications to mini-grids is discussed in the next subsection.

3.2. System dynamics and mini-grids

SD conceptual modeling to tackle complexity in mini-grids is proposed in [21]. Variables and causal relations are either assumed or identified from literature and field visits. The paper develops CLDs for mini-grids but there is no discussion on part how they can be further used for the sustainability assessment of the mini-grids. Also, conceptual models like CLDs are often vague and ambiguous. Re-evaluation is needed by building SF diagrams. SF diagrams are useful for quantitative analysis and consideration of various scenarios. Riva et al. [22] develop CLDs for analysis of the impact of electricity access on rural-socio-economic development. Electricity- demand nexus with income generating activities (IGAs), local market production, households' economic availability, local health and population, education, habits, and social network is developed. This is a conceptual model development similar to the work published in [21]. Hence SF diagrams (simulation models) are required to validate the model. The authors also raise the need for reliable data collection from the field. Gonzalez et al. [23] construct CLDs using driving factors of social acceptance of renewable energy systems (RES). CLDs help to understand the multiple interactions of RES projects with rural communities. The sustainable livelihoods framework, created by the British Department for International Development (DFID) is used with system thinking qualitatively to understand RES acceptance. Though barriers to RES acceptance are discussed, their sensitivity to the project is not analysed through the SF diagram quantitatively.

Mini-grids behavior may be understood when their life cycle sustainability is analysed with system dynamics using simulations. To the best of the authors' knowledge, the research area is not much explored. The main contribution of this paper is proposing a PoC model for the "dynamic life cycle sustainability assessment (D-LCSA) of mini-grids".

4. Materials and methods

In section 4.1, a conceptual framework depicting the system boundaries and various sustainability dimensions is discussed and a visual summary is provided in Figure 5. Then, section 4.2 illustrates a PoC model built according to the conceptual framework and focuses on system dynamic analysis. The PoC model is implemented in section 5 as a case study. The PoC addresses dynamics in mini-grids by connecting LCSA, mini-grids, and SD.

4.1. Conceptual framework for D-LCSA of mini-grids

Decision-making in sustainability assessment has the least or no influence on background processes while foreground processes are under the control of the decision-makers. In this paper, the sustainability assessment of operating mini-grids is considered. Hence the phases considered in the foreground system are the “use phase” and the “end of life phase”. This is called as “Gate to Grave” approach in LCSA. The mini-grid system has physical exchanges (vertical arrows) for all phases in the form of input and output flows. These exchanges may be “elementary flows” (e.g. raw resources, emissions of pollutants and other materials into the environment, waste generated during the maintenance or at the end of the life cycle). The functional unit for LCSA is considered as 1 Unit (1 kWh) of electricity generated. A conceptual framework is shown in Figure 5.

For life cycle impact assessment, the conceptual framework considers the following two groups of variables: (i) variables in the mini-grid system (e.g. electricity generated, expenditure on maintenance, distribution losses) (ii) influencing variables in the socio-economic system (e.g. population, per capita income). These variables can be realised by different indicators like technical, economic, social, environmental, and institutional.

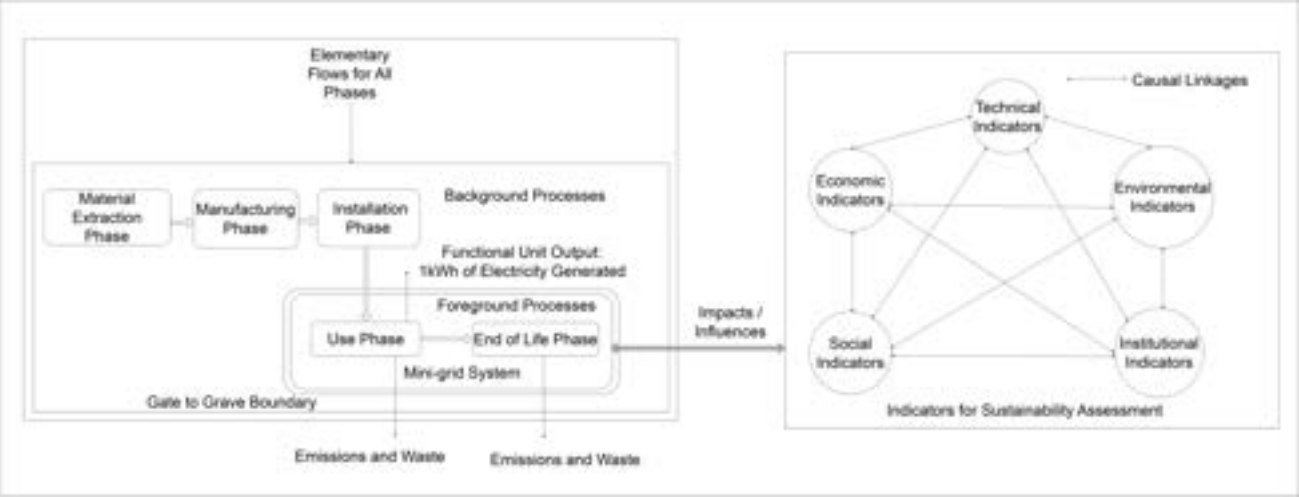


Figure. 5. Conceptual framework.

4.2. Proof-of- concept model for D-LCSA of mini-grids

Proof-of-concept model is developed to simulate “the dynamic impact assessment of mini-grid systems on livelihood and vice versa.” Figure 6 represents the steps and all the elements considered in the model. Indicators used for LCSA of mini-grids are finalised by literature review and field visits for systemic understanding. The indicators are classified as technical, economic, social, environmental, and institutional. Cause-effect relationships amongst the indicators can be represented by CLD. Once the indicators are finalised, the next important step in the model is to develop the SF diagram. SF diagram requires two inputs: i) mathematical relationships amongst variables and ii) variables' values and changes with time. For the second input, a detailed questionnaire and interactions with the stakeholders are required. This activity will help with the local characterisation of mini-grid sustainability. Consideration of mini-grid location-specific data helps to model the local impacts and their consequences on the mini-grid system.

SF diagrams can be used to simulate the behavior of mini-grids. To compare the results from the analysis, it is required to decide the criteria for mini-grid sustainability. Literature review and initial fieldwork may help in deciding criteria. These criteria may be different for different stakeholders and thus need multi-criteria analysis. Inference on mini-grid sustainability can be drawn by comparing the simulation results with defined criteria. Scenario and policy analysis may help to minimize the sustainability gap. The next section discusses the development of the CLD and SF diagram for an Indian mini-grid case study.

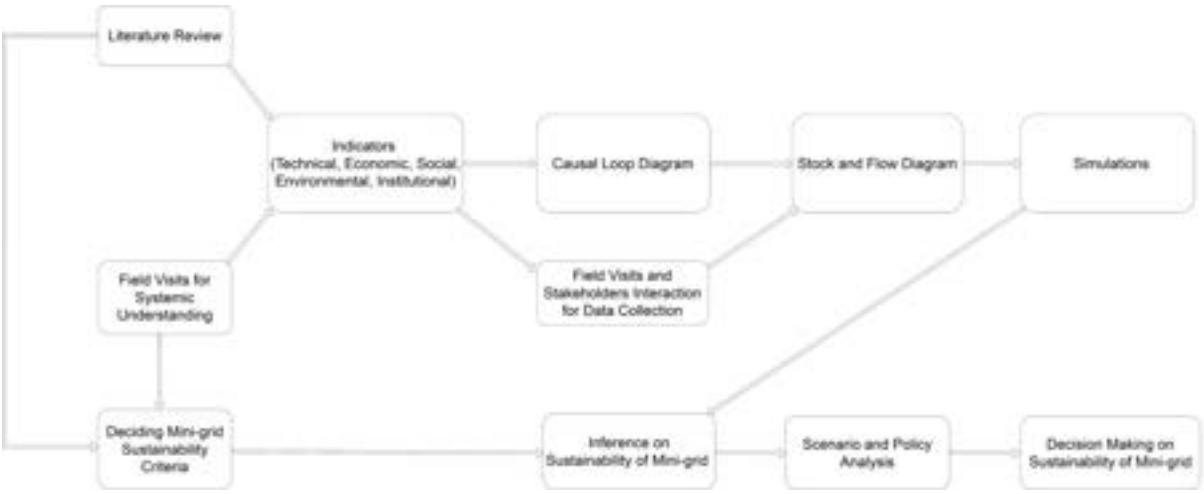

Figure. 6. Proof-of-concept model.

5. Case study

This section aims to develop CLD and SF diagram to assess mini-grid sustainability. The application of the PoC model is currently limited by the data availability for all the variables (indicators). In this paper, the development of CLDs and simulations of the behavior of a few indicators with SF diagrams are explored. Simulations show the variations in the mini-grid behavior with changes in the indicator values (assumed or collected during the field visit for systemic understanding). Comprehensive D-LCSA using all steps in the PoC model is envisaged after the survey questionnaire preparation and data collection from the field. CLD for a case study of a mini-grid at a place called "Makhla" is developed referring to [20-23] and modified as per interactions with stakeholders conducted for systemic understanding.

Makhla (Tembhurni Dhana) is a village in Chikhaldara taluka, Amravati district of Maharashtra state. The village is 104 km away from the district head quarter and is located in the Melghat tiger reserve forest. Electricity was not available in the village till October 2021 and the nearest centralised grid is 10 km away (Semadoh). 154 predominantly tribal families are residing in the village. Maharashtra Energy Development Agency (MEDA), a Government of Maharashtra institution has installed 37.8 kWp off-grid mini-grid in the village. Mini-grid was commissioned on 22nd October 2021. The basic energy requirement of the village is estimated at 200kWh/day. Energy storage of 110 kWh is supplied by 'amperehour solar technology Pvt. Ltd - energy storage solutions Company in Pune, Maharashtra, India. CLD for the Makhla mini-grid is shown in Figure 7.

In the developed CLD, the variables not bounded in any shape are referred from the literature. The variables in the solid box are the authors' contributions and in highlighted box are outcome of field interactions. In CLD, '+' sign represents the change in the variable in the same direction as the first. '-'sign represents the opposite change. Loops classified as reinforcing loops (R) and balancing loops (B) are marked in the CLD and listed in Table 2. Reinforcing loops create exponential growth while balancing loops create stability.

Table 2. Different loops in Makhla CLD.

Loop No.	Loop	Type
1	Mini-grid Income--Timely Repair and Maintenance--Battery Energy Storage Rating--Reliability of Electricity--Electricity Usage--Mini-grid Income	Reinforcing (R1)
2	Mini-grid Income--Timely Repair and Maintenance--Battery Energy Storage Rating--Reliability of Electricity--Social and cultural events--Conflicts between community and VEC--Mini-grid Income	Reinforcing (R2)
3	Mini-grid Income--Timely Repair and Maintenance--Battery Energy Storage Rating--Reliability of Electricity--Social and cultural events--Electricity Usage--Mini-grid Income	Reinforcing (R3)
4	Mini-grid Income--Timely Repair and Maintenance--Battery Energy Storage Rating--Reliability of Electricity--Electricity Usage--Cooking time--Health improvements--Satisfaction--Conflicts between community and VEC--Mini-grid Income	Reinforcing (R4)

Loop No.	Loop	Type
5	Mini-grid Income--Timely Repair and Maintenance--Battery Energy Storage Rating--Reliability of Electricity—Electricity Usage--Safety from wild animals--Health improvements--Satisfaction--Conflicts between community and VEC--Mini-grid Income	Reinforcing (R5)
6	Electricity Usage--Working hours--Number of IGAs--Business Income--Investment in IGAs--Local economic opportunities--Local Employment--Per capita income-- New Appliances Purchase--Demand for electricity--Battery Energy Storage Rating--Reliability of Electricity--Electricity Usage	Reinforcing (R6)
7	Electricity Usage--Study time for students, Education level--Per capita income-- New Appliances Purchase--Demand for electricity--Battery Energy Storage Rating--Reliability of Electricity--Electricity Usage	Reinforcing (R7)
8	Battery Energy Storage Rating--Reliability of Electricity--Repairs and Maintenance Needed--Repair and Maintenance--Battery Energy Storage Rating	Balancing (B1)

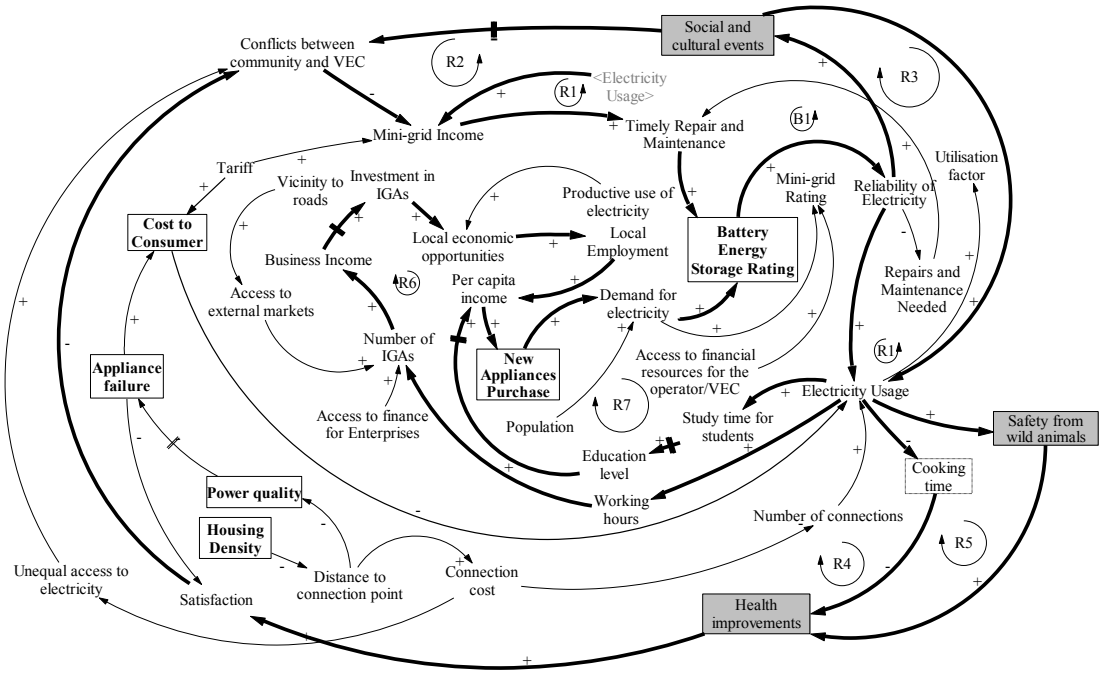

Figure. 7. CLD for Makhla mini-grid.

Mini-grid dynamics can be simulated using SF diagrams where stocks represent the accumulations in the system while flows represent the dynamics by defining how the stocks change with time. For SF analysis of the mini-grids, the identified stocks are mini-grid net income, battery capacity, electricity demand, electricity usage, and population. SF diagram for the Makhla mini-grid is shown in Figure 8. All variables from CLD, specifically qualitative ones are not included in the SF diagram as the aim is to show how quantitative analysis can be realised. Quantifying the qualitative variables is one of the challenges in the D-LCSA.

6. Results and discussions

In this section reinforcing loop R1 in Table 2 is simulated using Vensim software and results are explained in detail. Loop R1 consists of the variables: - “Mini-grid Income”, “Timely Repair and Maintenance”, “Battery Capacity”(Battery Energy Storage Rating), “Reliability of Electricity”, and “Electricity Usage”. “Mini-grid Income” is linked to “Timely Repair and Maintenance” by expressing later as the average delay in the process through a look-up table. The repair and maintenance are delayed due to lesser income which impacts the battery capacity. The relevant degrading factor is assumed. To calculate the “Reliability of Electricity”, it is necessary to understand the shortage of both battery energy and the power rating of the mini-grid system. For simplicity, faults or equipment failures are not considered. The “Reliability of Electricity” is linked to “Electricity Usage” through the sensitivity factor. Electricity usage will impact the mini-grid income and hence the loop is completed. The simulation results are shown in Figure 9 to Figure 12.

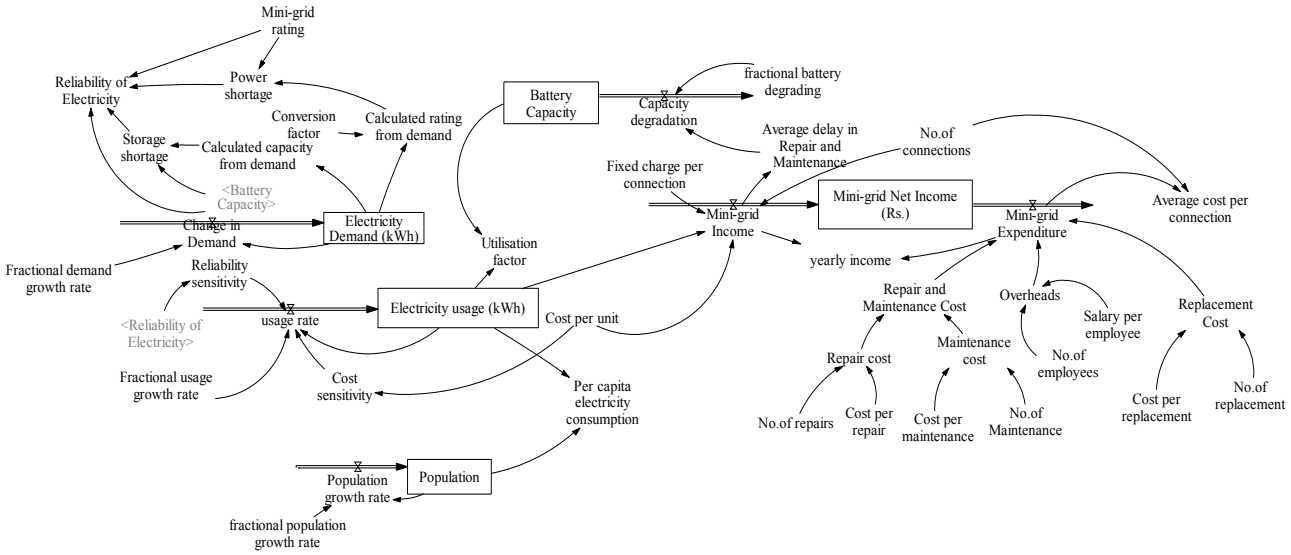

Figure. 8. SF diagram for Makhla mini-grid.

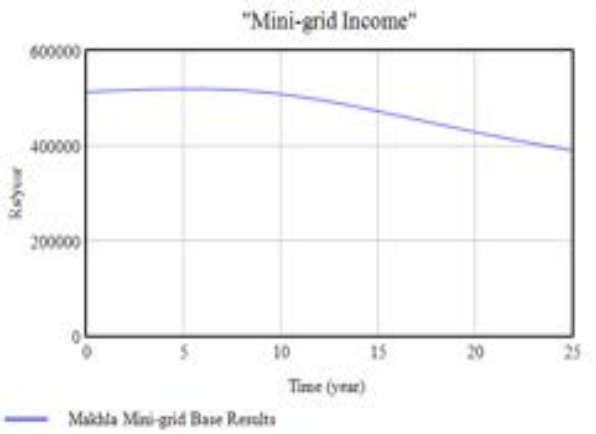

Figure. 9. Mini-grid Income.

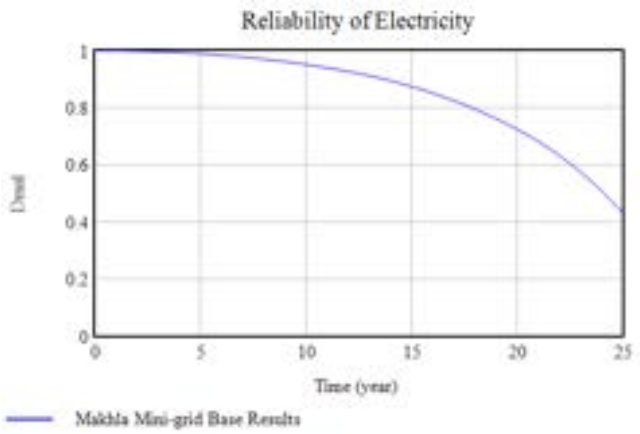

Figure. 10. Reliability of Electricity.

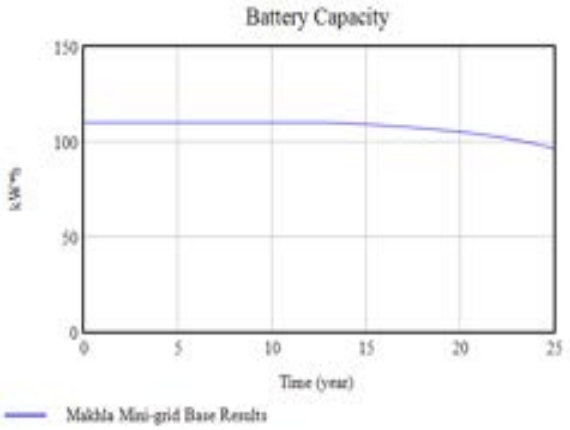

Figure. 11. Battery Capacity.

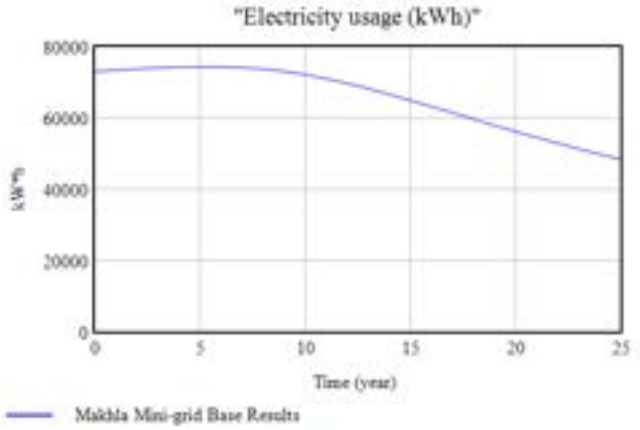

Figure. 12. Electricity Usage.

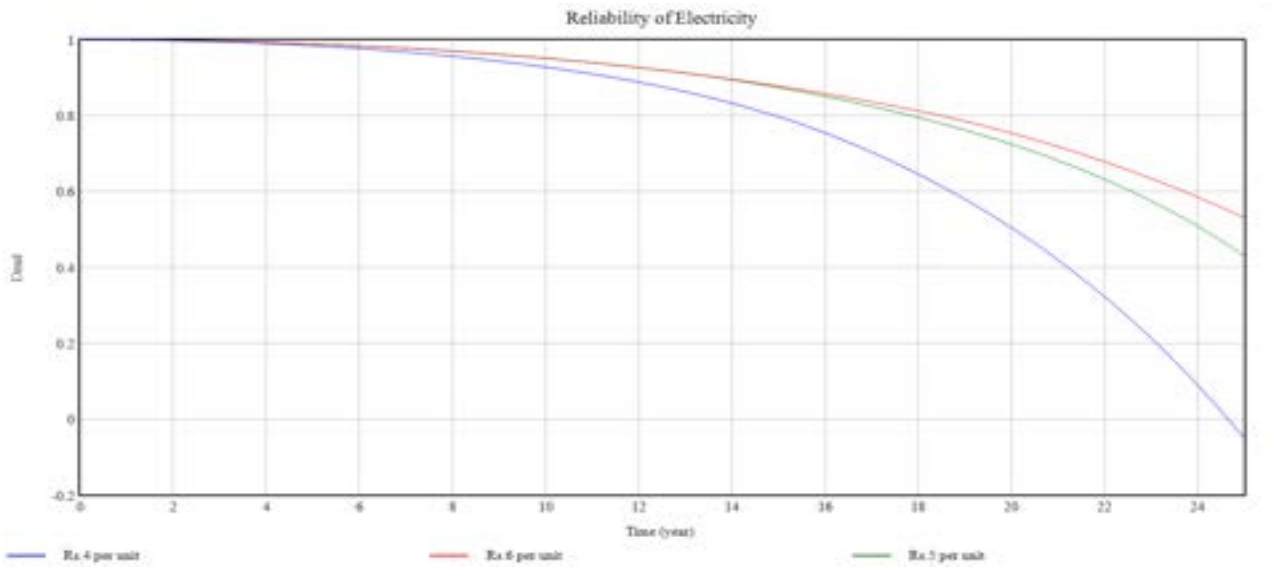

Figure. 13. Variations of Reliability of Electricity with Cost per Unit.

SF diagrams can be used for scenario analysis. The variation in the cost per unit (tariff) and its impact on reliability is shown in Figure 13. The existing tariff of Rs.5 per unit is first increased to Rs.6 per unit and then decreased to Rs.4 per unit for scenario analysis. Lower tariff results in higher usage decreasing reliability. Higher tariff reduces electricity usage and hence the reliability is higher. Similarly, the policies can also be analysed with the help of the SF diagram.

The inference for mini-grid sustainability can be drawn by comparing the simulation results with defined mini-grid sustainability criteria. The changes in the values of related variables may reduce or increase the gap in expected sustainability results. These analyses can be used as levers in decision-making related to mini-grid operations as shown in Figure 6. During the field visits, mini-grid systems are observed to follow some common patterns and face some common challenges irrespective of the location. These patterns may be modelled to generalise the performance of the mini-grid systems having similarities.

Conclusions

The framework presented in this paper attempts to conceptually identify limitations or scope of improvement in the LCSA of mini-grids. A proof-of-concept model was developed linking to dynamic causal relationships between technical, social, economic, environmental, and institutional variables to address life cycle changes in mini-grids. The important steps in models like the development of CLD, SF diagram, and simulation of the same are illustrated with a case study of a mini-grid in India. The results highlight the advantages of adding SD analysis into LCSA. The proposed model expands state-of-the-art impact assessment by incorporating dynamics. The results represent the behavior of the mini-grid systems by considering the complexity and non-linearity in the modeling. Developing the case study has highlighted the need for data monitoring for mini-grid systems. The accuracy of output depends on the availability of localised data. Future work could build on the research by use of the proposed model for comprehensive D-LCSA and developing a digital dashboard useful for all the stakeholders. Further applications of the D-LCSA model to case studies of various mini-grid scenarios may validate the proposed PoC model. “Defining mini-grid sustainability” is necessary to set the benchmark useful for sustainability analysis. The common and recurring patterns in the scenarios that shape the mini-grid behavior may be identified. Participatory SD not considered in the PoC can be explored for the formation of CLDs and quantify the feedback between different variables.

Acknowledgments

The authors would like to thank the officials of MEDA, Amravati Division of Maharashtra state (India) for the introduction to the installed mini-grids, the support extended during the field visits, and the participation in the stakeholders’ interactions.
